Nevertheless, a simple pre/post design has an important limitation: *any change* that affects the average value of the outcome between period 0 and period 1 is attributed to the intervention. In many situations, the mean value of an outcome changes over time for reasons that have nothing to do with the intervention or change in policy under study. One way to check whether such factors are present is to construct average differences in the outcome for earlier periods and verify that these are all very close to zero. For example, equation (13) implies that the *lagged difference* in outcomes $\Delta Y_i^{(-1)}$ is determined by

$$\Delta Y_i^{(-1)} = Y_{i0} - Y_{i(-1)} = \varepsilon_{i0} - \varepsilon_{i(-1)}. \quad (20)$$

The same arguments that support the contention that the error term $\varepsilon_{i1} - \varepsilon_{i0}$ in equation (16) has a mean value of 0, so that $Mean(\Delta Y_i)$ provides a good estimate of β_1 , imply that the error term in equation (20) also has a mean value of 0. Thus, $Mean(\Delta Y_i^{(-1)})$ should be very close to 0. Indeed, the mean values of the changes in the outcome for all periods where there was no change in policy should be close to 0. In the absence of evidence that this is true, a simple pre/post design is not very credible.

Difference in Differences

A natural way to address the presence of unmeasured factors that are changing over time and confounding the interpretation of a simple pre/post design is to compare the change in the outcome for units where the new program was adopted to the change in the outcome over the same period for units that did not adopt the program. This is the difference-in-differences approach.

To spell this out, call the treatment group the set of units where the program is adopted between period 0 and period 1; call the other set of units the comparison group, and let T_i be an indicator variable that is equal to 1 for units in the treatment group. Suppose that data are only observed in periods 0 and 1. Then, the difference-in-differences model can be written as a multiple linear regression model of the form

$$Y_{it} = \beta_0 + \beta_1 T_i \times Post_t + \beta_2 T_i + \beta_3 Post_t + \varepsilon_{it} \quad (21)$$

The key coefficient in this model is β_1 , the coefficient on the interaction between the indicator for the treatment group and the indicator for period 1 (the post period).

To understand this equation, notice that for units with $T_i = 0$, it implies

$$Y_{it} = \beta_0 + \beta_3 Post_t + \varepsilon_{it} \quad (22)$$

Thus, the change in outcomes for units in the comparison group is

$$\Delta Y_i = Y_{i1} - Y_{i0} = \beta_3 + \varepsilon_{i1} - \varepsilon_{i0} \quad (23)$$

The inclusion of the term $\beta_3 Post_t$ in equation (22) captures the possibility that even in the comparison group, unobserved factors can change between period 0 and period 1. Assuming the mean value of $\varepsilon_{i1} - \varepsilon_{i0}$ is 0 for comparison units, the expected average change in the outcome in the comparison group will be β_3 .¹⁵⁰ For units in the treatment group, equation (21) implies

$$Y_{it} = (\beta_0 + \beta_2) + (\beta_1 + \beta_3)Post_t + \varepsilon_{it} \quad (24)$$

Thus, the change in outcomes for units in the treatment group is

$$\Delta Y_i = (\beta_1 + \beta_3) + \varepsilon_{i1} - \varepsilon_{i0} \quad (25)$$

Assuming that the mean value of $\varepsilon_{i1} - \varepsilon_{i0}$ is 0 for units in the treatment group, the expected average change in the outcome in the treatment group will be $\beta_1 + \beta_3$, which is a combination of the change experienced by the comparison group, β_3 , and the effect of the program, β_1 . In fact, the OLS estimate of β_1 in the difference-in-differences model (21) is exactly

$$\hat{\beta}_1 = Mean(\Delta Y_i | T_i = 1) - Mean(\Delta Y_i | T_i = 0) \quad (26)$$

where $Mean(\Delta Y_i | T_i = 1)$ denotes the mean in the subsample with $T_i = 1$ (i.e., among the treatment group), and $Mean(\Delta Y_i | T_i = 0)$ denotes the mean in the subsample with $T_i = 0$ (i.e., among the comparison group).

The critical assumption in a difference-in-differences design is that in the absence of the program, the mean change in outcomes for the treatment group and comparison groups would have been the same. Under that assumption, the mean change for the comparison group forms a counterfactual for the change that would have occurred in the treatment group in the absence of the program. As noted previously, this assumption is sometimes referred to as a parallel trends assumption. With only two periods of data, it cannot be directly evaluated. If there are additional periods of data, however, parallel trends can be assessed by forming differences in differences for other periods that do not overlap with the start of the program. These should all be close to zero. Visually, a graph of the mean outcomes for the treatment group over a sequence of periods (for example, $t = -2, -1, 0, 1, 2$) should show that the the gap between the treatment means and

150. To be precise, the “expected average change” means the mathematical expectation of the sample average change in the outcome.

comparison means is stable prior to the program date, then shifts discretely between period 0 and 1, reflecting the treatment effect, then stabilizes again.

Another way of thinking about the validity of a difference-in-differences specification is to ask whether the choice of the pre-treatment period matters. For example, consider an evaluation of a state law that liberalizes state divorce law. A difference-in-differences approach to measuring the effect of the law would be to compare the change in divorce rates from some year prior to the law to the year after the law changed in the “treatment” state (the state that passed the new law) relative to the change in divorce rates in a “comparison” state. If the assumptions of a difference-in-differences specification are correct, then the relative change in divorce rates in the treated state relative to the comparison state should not depend on the particular year that is selected as the benchmark prior to the law change. Under those assumptions, the difference in divorce rates in the treated and comparison states can be expected to be similar in all the years prior to the new law. As a result, choosing one particular year as a benchmark versus another will not matter. Graphically, this requires that the year-to-year changes in divorce rates in the treated state and the comparison state are the same, and a plot of the divorce rates prior to the law change would appear as two parallel lines. This is the origin of the term *parallel trends*.

A common scenario where the parallel trends assumption may fail is one in which the timing of the program is correlated with the trend in recent outcomes for the treatment group. For example, Ashenfelter (1978) noted that people who entered government retraining programs had *temporarily depressed* earnings in the period before entry, driven by recent job losses or other problems—the Ashenfelter dip.¹⁵¹ Building on equation (18), this suggests that program participants may be particularly likely to have large negative values of ν_{i0} (the period-specific part of their earnings residual in the period just prior to the program). In that case, the mean value of the error term $\varepsilon_{i1} - \varepsilon_{i0} = \nu_{i1} - \nu_{i0}$ in equation (25) will be positive, implying that

$$Mean(\Delta Y_i | T_i = 1) = \beta_1 + \beta_3 + Mean(\varepsilon_{i1} - \varepsilon_{i0} | T_i = 1) > \beta_1 + \beta_3 \quad (27)$$

causing a difference-in-differences estimator to overstate the effect of the program. The possibility of such pre-trends can be evaluated empirically by examining the mean outcomes of the treatment and comparison groups in the periods before the start of the program and making sure that the parallel trends assumption is valid.

151. Ashenfelter, *supra* note 94.

Instrumental Variables

An alternative method that is widely used to address omitted variables problems in regression models is instrumental variables (IV). Consider the case where an expert has posited a model relating an outcome Y to an observed explanatory variable:

$$Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i \quad (28)$$

For clarity, subscripts indicate the different units (indexed by i) in the sample. The expert wants to give a causal interpretation of the coefficient β_1 . Specifically, in the expert's model, β_1 represents the effect of a unit change in X on the average or expected value of the outcome, holding constant all other unmeasured/unobserved determinants of Y . Such an equation is known as the structural model in IV and related settings. The problem is that, if this structural equation is estimated by OLS, the estimate $\hat{\beta}_1$ will incorporate both the desired causal effect and any potential omitted variable bias that arises because X_i is potentially correlated with some of the factors included in the error ε_i . This omitted-variable bias is sometimes called a simultaneity bias or endogeneity bias—particularly in cases where there is feedback from Y_i to X_i , as discussed in the section titled “Instrumental Variables Design” above. Whatever the source of the potential correlation between X_i and ε_i , however, it can be analyzed in the omitted variables framework of equations (10)–(12).

The objective of IV estimation is to isolate the part of the variation in X_i attributable to variation in some other variable, Z_i (the instrumental variable or the instrument), and use only that variation in estimating the effect of X_i on Y_i . An appropriate instrumental variable has to satisfy three assumptions: (1) it has an effect on X_i , so there is a component of X_i that can be attributed to Z_i ; (2) it is uncorrelated with ε_i , the unobserved determinants of Y_i ; and (3) it has no direct effect on the outcome Y_i . An example of an instrumental variable that satisfies these requirements is a randomly assigned lottery outcome. For example, in a study of the effect of attending a charter school on test scores, the analysis showed that if access to over subscribed charter schools is determined by lottery, then an appropriate instrumental variable is an indicator for whether a student was assigned to the charter school by the admission lottery.¹⁵²

The IV method involves estimating two regression models. The first-stage model is a linear regression relating the variable of interest (X_i) to the instrumental variable:

$$X_i = \pi_0 + \pi_1 Z_i + u_i \quad (29)$$

152. See generally Chabrier et al., *supra* note 104.

From this model it is possible to form the predicted values of X_i based only on Z_i :

$$\hat{X}_i = \hat{\pi}_0 + \hat{\pi}_1 Z_i \quad (30)$$

The second-stage model is a linear regression of the outcome on the predicted values of X_i :

$$Y_i = \beta_0^{iv} + \beta_1^{iv} \hat{X}_i + \eta_i \quad (31)$$

The OLS estimate of the coefficient of $\hat{X}_i$ in the second-stage model, $\hat{\beta}_1^{iv}$, is the IV estimate of β in the structural model (28). Note that since $\hat{X}_i$ only depends on Z_i , the second-stage equation measures the effect of the part of $\hat{X}_i$ that is determined by Z_i on the outcome variable.

The IV estimate can be derived in another way. Substituting the first-stage equation (29) into the structural equation (28) yields an equation relating Y to Z :

$$Y_i = \underbrace{(\beta_0 + \beta_1 \pi_0)}_{\delta_0} + \underbrace{\beta_1 \pi_1}_{\delta_1} Z_i + \underbrace{(\varepsilon_i + \beta_1 u_i)}_{\xi_i} = \delta_0 + \delta_1 Z_i + \xi_i \quad (32)$$

This equation, known as the reduced-form model, can be estimated by OLS without concern about omitted variables bias because, under the assumption that Z_i is a valid instrumental variable, it is uncorrelated with ξ_i .¹⁵³ But equation (32) shows that the coefficient of the instrumental variable in the reduced-form model is $\delta_1 = \beta_1 \pi_1$. This occurs because under assumption #3 for a valid instrumental variable, the *only way* that Z_i affects Y_i is indirectly, through its effect on X_i . Since Z_i affects X_i with a coefficient of π_1 in the first-stage model, and X_i affects Y_i with a coefficient of β_1 in the structural model, the reduced-form effect of Z_i on Y_i is the product of these two coefficients. This reasoning suggests that one could obtain an estimate of β_1 by dividing the estimated reduced-form coefficient, $\hat{\delta}_1$, by the estimated first-stage coefficient $\hat{\pi}_1$. And in fact this ratio is exactly the IV estimate:

$$\hat{\beta}_1^{iv} = \frac{\hat{\delta}_1}{\hat{\pi}_1} \quad (33)$$

The expression for the IV estimate in equation (33) is particularly insightful in the case where X_i is a dummy variable indicating participation in a program or

153. Under assumption #2 for a valid instrumental variable, Z_i is uncorrelated with ε_i . Moreover, the error in the first-stage equation u_i is necessarily uncorrelated with the explanatory variable in that model, by a fundamental property of least squares. Thus Z_i is uncorrelated with the composite error in the reduced-form model, $\xi_i = \varepsilon_i + \beta_1 u_i$.

intervention (for example, enrollment in a charter school), and Z_i is also a dummy variable, indicating a condition that partly determines program participation (for example, whether student i was assigned to the charter school by lottery). In this case, the first-stage coefficient $\hat{\pi}_1$ is the difference in program participation rates between units with Z_i equal to 0 or 1:

$$\hat{\pi}_1 = \text{Mean}(X_i | Z_i = 1) - \text{Mean}(X_i | Z_i = 0), \quad (34)$$

and the reduced-form coefficient $\hat{\delta}_1$ is the difference in the mean of the outcome variable (e.g., an end-of-year test score) for the same two groups:

$$\hat{\delta}_1 = \text{Mean}(Y_i | Z_i = 1) - \text{Mean}(Y_i | Z_i = 0). \quad (35)$$

Thus, equation (33) implies that the IV estimator for the effect of program participation on the outcome is

$$\hat{\beta}_1^{iv} = \frac{\text{Mean}(Y_i | Z_i = 1) - \text{Mean}(Y_i | Z_i = 0)}{\text{Mean}(X_i | Z_i = 1) - \text{Mean}(X_i | Z_i = 0)} \quad (36)$$

The IV estimator takes the difference in mean outcomes between the group with $Z_i = 1$ and the group with $Z_i = 0$, and divides this by the difference in the fraction who participated in the program when Z_i was 1 or 0. Intuitively, the IV estimator is simply creating a *per unit* estimate of the treatment effect of the intervention, based on the differences between groups with different values of Z_i .

Determining the Precision of the Regression Results

Least squares regression algorithms provide not only parameter estimates that indicate the direction and magnitude of the effect of a change in the explanatory variable on the dependent variable, but also an estimate of the reliability of the parameter estimates and a measure of the overall goodness of fit of the regression model. Each of these factors is considered in turn.

Standard Errors of the Coefficients and t-Statistics

Estimates of the true but unknown parameters of a regression model are numbers that depend on the sample of observations under study. If a different sample

were used, a different estimate would be calculated.¹⁵⁴ If the expert continued to collect more and more samples and generated additional estimates, as might happen when new data became available over time, the estimates of each parameter would follow a probability distribution. This probability distribution can be summarized by a mean and a measure of dispersion around the mean, a standard deviation, which usually is referred to as the standard error of the coefficient, or the standard error (SE).¹⁵⁵

Suppose, for example, that an expert is interested in estimating the average price paid for a gallon of unleaded gasoline by consumers in a particular geographic area of the United States at a particular point in time. The mean price for a sample of 10 gas stations might be \$1.25, while the mean for another sample might be \$1.29, and the mean for a third, \$1.21. On this basis, the expert also could calculate the overall mean price of gasoline to be \$1.25 and an estimate of the standard deviation to be \$0.04.

Least-squares regression generalizes this result, by calculating means whose values depend on one or more explanatory variables. The standard error of a regression coefficient tells the expert how much parameter estimates are likely to vary from sample to sample. The greater the variation in parameter estimates from sample to sample, the larger the standard error and consequently the less reliable the regression results. Small standard errors imply results that are likely to be similar from sample to sample, whereas results with large standard errors show more variability.

Under appropriate assumptions, the ordinary least-squares estimators provide “best” determinations of the true underlying parameters.¹⁵⁶ In fact, OLS has several desirable properties. First, assuming that the error term in the regression model is uncorrelated with the covariates, least squares estimators are unbiased. Intuitively, this means that if the regression were calculated repeatedly with different samples, the average of the many estimates obtained for each coefficient would be the true parameter. Second, under the same assumption, least-squares estimators are consistent; if the sample were very large, the estimates obtained would come close to the true parameters. Third, least squares is efficient, in that its estimators have the smallest variance among all (linear) unbiased estimators.

If the further assumption is made that the probability distribution of each of the error terms is known, statistical statements can be made about the precision

154. The least squares formula that generates the estimates is called the least squares estimator, and its values vary from sample to sample.

155. See David H. Kaye & Hal S. Stern, *Reference Guide on Statistics and Research Methods*, “Randomized Controlled Experiments” section, in this manual.

156. The necessary assumptions of the regression model include (a) the model is specified correctly, (b) errors associated with each observation are drawn randomly from the same probability distribution and are independent of each other, (c) errors associated with each observation are independent of the corresponding observations for each of the explanatory variables in the model, and (d) no explanatory variable is correlated perfectly with a combination of other variables.

of the coefficient estimates. For relatively large samples (often, thirty or more data points will be sufficient for regressions with a small number of explanatory variables), the probability that the estimate of a parameter lies within an interval of 1.96 standard errors around the true parameter is approximately .95, or 95%. A frequent, although not always appropriate, assumption in statistical work is that the error term follows a normal distribution, from which it follows that the estimated parameters are normally distributed. The normal distribution has the property that the area within 1.96 standard errors of the mean is equal to 95% of the total area. Note that the normality assumption is not necessary for least squares to be used, because most of the properties of least squares apply regardless of normality.

In general, for any parameter estimate $\hat{\beta}$, the expert can construct an interval around $\hat{\beta}$ such that if the sampling procedure were conducted 100 times, approximately 95 of the resulting intervals would be expected to contain the true population mean. The 95% confidence interval¹⁵⁷ is given by¹⁵⁸

$$\hat{\beta} \pm 1.96(\text{SE of } \hat{\beta}) \quad (37)$$

The expert can test the hypothesis that a parameter is equal to 0 (often stated as testing the null hypothesis) by looking at its *t*-statistic, which is defined as

$$t = \hat{\beta} / \text{SE}(\hat{\beta}) \quad (38)$$

If the *t*-statistic is less than 1.96 in magnitude, the 95% confidence interval around $\hat{\beta}$ must include 0.¹⁵⁹ Because this means that the expert cannot reject the hypothesis that β equals 0, the estimate, whatever it may be, is said to be not statistically significant. Conversely, if the *t*-statistic is greater than 1.96 in absolute value, the expert concludes that the true value of β is unlikely to be 0 (intuitively, $\hat{\beta}$ is “too far” from 0 to be consistent with the true value of β being 0). In this case, the expert rejects the hypothesis that β equals 0 and calls the estimate statistically significant. If the null hypothesis β equals 0 is true, using a 95% confidence level will cause the expert to falsely reject the null hypothesis 5% of the time. Consequently, results often are said to be significant at the 5% level.¹⁶⁰

157. Confidence intervals are used commonly in statistical analyses because the expert can never be certain that a parameter estimate is equal to the true population parameter.

158. If the number of data points in the sample is small (perhaps less than 30), the 1.96 number must be adjusted upward.

159. The *t*-statistic applies to any sample size. As the sample size increases, the underlying distribution, which is the source of the *t*-statistic (Student's *t*-distribution), approximates the normal distribution.

160. A *t*-statistic of 2.57 in magnitude or greater is associated with a 99% confidence level, or a 1% level of significance, that includes a band of 2.57 standard deviations on either side of the estimated coefficient.

As an example, consider a more complete set of regression results associated with the salary regression described earlier:

$$\begin{array}{ccccccc} \hat{Y} = \$14,085 + \$2,323X_1 + \$1,675X_2 - \$36X_3 & & & & & & \\ (1,577) & (140) & (1,435) & (3.4) & & & \\ t = 8.9 & 16.5 & 1.2 & -10.8 & & & (39) \end{array}$$

The standard error of each estimated parameter is given in parentheses directly below the estimated coefficient, and the corresponding *t*-statistics appear below the standard error values.

Consider the coefficient on the dummy variable X_2 , representing the sex of a worker. It indicates that \$1,675 is the best estimate of the mean salary difference between men and women. However, the standard error of \$1,435 is large in relation to its coefficient \$1,675. Because the standard error is relatively large, the range of possible values for measuring the true salary difference, the true parameter, is great. In fact, a 95% confidence interval is given by the range negative \$1,138 to positive \$4,488. In other words, the expert can have 95% confidence that the true value of the coefficient lies between -\$1,138 and \$4,488. Because this range includes 0, the effect of sex on salary is said to be insignificantly different from 0 at the 5% level. The *t* value of 1.2 is equal to \$1,675 divided by \$1,435. Because this *t*-statistic is less than 1.96 in magnitude (a condition equivalent to the inclusion of a 0 in the above confidence interval), the sex variable again is said to be an insignificant determinant of salary at the 5% level of significance.

Note also that experience is a highly significant determinant of salary, because both the X_1 and the X_3 variables have *t*-statistics substantially greater than 1.96 in magnitude. More experience has a significant positive effect on salary, but the size of this effect diminishes significantly with experience.

Goodness of Fit

Reported regression results usually contain not only the point estimates of the parameters and their standard errors or *t*-statistics, but also other information that tells how closely the regression line fits the data. One statistic, the standard error of the regression (SER), is an estimate of the overall size of the regression residuals.¹⁶¹ An SER of 0 would occur only when all data points lie exactly on the regression line—an extremely unlikely possibility. Other things being equal, the larger the SER, the poorer the fit of the data to the model.

161. More specifically, it is a measure of the standard deviation of the regression error ϵ . It sometimes is called the root mean square error of the regression line.

For a normally distributed error term, the expert would expect approximately 95% of the data points to lie within two SERs of the estimated regression line, as shown in Figure 7.

Figure 7. Standard error of the regression (SER).

R -squared (R^2) is a statistic that measures the percentage of variation in the dependent variable that is accounted for by all the explanatory variables.¹⁶² Thus, R^2 provides a measure of the overall goodness of fit of the multiple regression equation. Its value ranges from 0 to 1. An R^2 of 0 means that the explanatory variables explain none of the variation of the dependent variable; an R^2 of 1 means that the explanatory variables explain all the variation. The R^2 is .56. This implies that the three explanatory variables explain 56% of the variation in salaries.

What level of R^2 , if any, should lead to a conclusion that the model is satisfactory? Unfortunately, there is no clear-cut answer to this question because the magnitude of R^2 depends on the characteristics of the data being studied and whether the data vary over time or over individuals. Typically, an R^2 is low in cross-sectional studies in which differences in individual behavior are explained. It is likely that these individual differences are caused by many factors that cannot be measured. As a result, the expert cannot hope to explain most of the variation. In time-series studies, in contrast, the expert is explaining the movement of aggregates over time. Because most aggregate time series have substantial

162. The variation is the square of the difference between each Y value and the average Y value, summed over all the Y values.

growth, or trend, in common, it will not be difficult to “explain” one time series using another time series, simply because both are moving together. It follows as a corollary that a high R^2 does not by itself mean that the variables included in the model are the appropriate ones.

Courts should be reluctant to rely solely on a statistic such as R^2 to choose one model over another. Alternative procedures and tests are available.¹⁶³ When utilizing probit or logit models, the R^2 is especially problematic, since (with the dependent variable taking on only two values) predictions will be spread across the 0–1 interval with relatively few values typically being close to either 0 or 1. As a result, R^2 values will be relatively low whether the estimated model coefficients are informative or not. One more instructive measure is the percentage of correct classifications with the prediction being 1 if the predicted value is greater than .5 and 0 otherwise. An alternative measure is a quasi- R -squared measure based on the log likelihood of the estimated model, relative to that of a model with no covariates.

Sensitivity of Least-Squares Regression Results

The least-squares regression line can be sensitive to extreme data points. This sensitivity can be seen most easily in Figure 8. Assume initially that there are only three data points, A, B, and C, relating information about X_1 to the variable Y . The least-squares line describing the best-fitting relationship between Points A, B, and C is represented by Line 1. Point D is called an outlier because it lies far from the regression line that fits the remaining points. When a new, best-fitting least-squares line is re estimated to include Point D, Line 2 is obtained. Figure 8 shows that the outlier, Point D, is an influential data point, because it has a dominant effect on the slope and intercept of the least-squares line. Because least squares minimizes the sum of squared deviations, the sensitivity of the line to individual points sometimes can be substantial.¹⁶⁴

163. These include F -tests and specification error tests. See Pindyck & Rubinfeld, *supra* note 23, at 88–95, 128–36, 194–98.

164. This sensitivity is not always undesirable. In some instances, it may be much more important to predict Point D when a big change occurs than to measure the effects of small changes accurately.

Figure 8. Least-squares regression.

What makes the influential data problem even more difficult is that the effect of an outlier may not be seen readily if deviations are measured from the final regression line. The reason is that the influence of Point D on Line 2 is so substantial that its deviation from the regression line is not necessarily larger than the deviation of any of the remaining points from the regression line.¹⁶⁵ Although they are not as popular as least squares, alternative estimation techniques that are less sensitive to outliers, such as robust estimation, are available. Alternatively, if the sample is relatively large, an expert may choose to remove the outliers before estimating the model.

165. The importance of an outlier also depends on its location in the dataset. Outliers associated with relatively extreme values of explanatory variables are likely to be especially influential. See, e.g., *Fisher v. Vassar College*, 70 F.3d 1420, 1436 (2d Cir. 1995) (court required to include assessment of “service in academic community,” because concept was too amorphous and not a significant factor in tenure review), *rev’d on other grounds*, 114 F.3d 1332 (2d Cir. 1997) (en banc). Conclusory statements of an outlier’s impact are insufficient. See *In re Nektar Therapeutics Sec. Litig.*, 34 F.4th 828, 836 (9th Cir. 2022) (“[t]he complaint does not allege with specificity what the Phase 1 EXCEL results would have been without outlier data”).

A Hypothetical Example

Jane Thompson filed suit in federal court alleging that officials in the police department discriminated against her and a class of other female police officers in violation of Title VII of the Civil Rights Act of 1964, as amended. On behalf of the class, Officer Thompson alleged that she was paid less than male police officers with equivalent skills and experience. Both the plaintiff and the defendant used expert economists with econometric expertise to present statistical evidence to the court in support of their positions.

The plaintiff's expert pointed out that the mean salary of the 40 female officers was \$30,604, whereas the mean salary of the 60 male officers was \$43,077. To show that this difference was statistically significant, the expert put forward a regression of salary (SALARY) on a constant term and a dummy indicator variable (FEM) equal to one for each female and zero for each male. The results were as follows:

$$\begin{array}{lcl} \text{SALARY} = & \$43,077 & - \$12,373 \times \text{FEM} \\ \text{St. Error} & (\$1,528) & (\$2,416) \\ p\text{-value} & <.01 & <.01 \\ R^2 = & .22 & \end{array}$$

The $-\$12,373$ coefficient on the FEM variable measures the mean difference between male and female salaries. Because the standard error is approximately one-fifth of the value of the coefficient, this difference is statistically significant at the 5% (and indeed at the 1%) level. If this is an appropriate regression model (in terms of its implicit characterization of salary determination), one can conclude that it is highly unlikely that the difference in salaries between men and women is due to chance.

The defendant's expert testified that the regression model put forward was the wrong model because it failed to account for the fact that males (on average) had substantially more experience than females. The relatively low R^2 was an indication that there was substantial unexplained variation in the salaries of male and female officers. An examination of data relating to years spent on the job showed that the average male experience was 8.2 years, whereas the average for females was only 3.5 years. The defense expert then presented a regression analysis that added an additional explanatory variable (i.e., a covariate), the years of experience of each police officer (EXP).

The new regression results were as follows:

SALARY = \$28,049 – \$3,860 × FEM + \$1,833 × EXP			
St. Error	(\$2,513)	(\$2,347)	(\$265)
p-value	<.01	<.11	<.01
R ² =	.47		

Experience is itself a statistically significant explanatory variable, with a *p*-value of less than .01. Moreover, the difference between male and female salaries, holding experience constant, is only \$3,860, and this difference is not statistically significant at the 5% level. The defense expert was able to testify on this basis that the court could not rule out alternative explanations for the difference in salaries other than the plaintiff’s claim of discrimination.

The debate did not end here. On rebuttal, the plaintiff’s expert made three distinct points. First, whether \$3,860 was statistically significant or not, it was practically significant, representing a salary difference of more than 10% of the mean female officers’ salaries. Second, although the result was not statistically significant at the 5% level, it was significant at the 11% level.

Third, and most importantly, the expert testified that the regression model was not correctly specified. Further analysis by the expert showed that the value of an additional year of experience was \$2,333 for males on average, but only \$1,521 for females. Based on supporting testimonial experience, the expert testified that one could not rule out the possibility that the mechanism by which the police department discriminated against females was by rewarding males more for their experience than females. The expert made this point clear by running an additional regression in which a further covariate was added to the model. The new variable was an interaction variable, measured as the product of the FEM and EXP variables. The regression results were as follows:

SALARY = \$35,122 – \$5,250 × FEM + \$2,333 × EXP – \$812 × FEM × EXP				
St. Error	(\$2,825)	(\$3,347)	(\$265)	(\$185)
p-value	<.01	<.11	<.01	<.01
R ² =	.65			

The plaintiff’s expert noted that for all males in the sample, FEM = 0, in which case the regression results are given by the equation

$$\text{SALARY} = \$35,122 + \$2,333 \times \text{EXP}$$

However, for females, FEM = 1, in which the corresponding equation is

$$\text{SALARY} = \$29,872 + \$1,521 \times \text{EXP}$$

It appears, therefore, that females are discriminated against not only when hired (i.e., when $EXP = 0$), but also in the reward they get as they accumulate more experience.

The debate between the experts continued, focusing less on the statistical interpretation of any one regression model, but more on the model choice itself, and not simply on statistical significance, but also to practical significance.

Glossary of Terms

alternative hypothesis. See hypothesis test.

association. The degree of statistical dependence between two or more events or variables. Events are said to be associated when they occur more frequently together than one would expect by chance.

bias. Any effect at any stage of investigation or inference tending to produce results that depart systematically from the true values (i.e., the results are either too high or too low). A biased estimator of a parameter differs on average from the true parameter.

coefficient. An estimated regression parameter.

consistent estimator. An estimator that tends to become more and more accurate as the sample size grows.

correlation. A statistical means of measuring the linear association between variables. Two variables are correlated positively if, on average, they move in the same direction; two variables are correlated negatively if, on average, they move in opposite directions.

covariate. A variable that is possibly predictive of an outcome under study; an explanatory variable.

cross-sectional analysis. A type of analysis in which each data point is associated with a different unit of observation (e.g., an individual or a firm) measured at a particular point in time.

degrees of freedom (DF). The number of observations in a sample minus the number of estimated parameters in a regression model. A useful statistic in hypothesis testing.

dependent variable. The variable to be explained or predicted in a multiple regression model.

dummy variable. A variable that takes on only two values, usually 0 and 1, with one value indicating the presence of a characteristic, attribute, or effect (1), and the other value indicating its absence (0).

endogenous variable. A covariate for which there are unobserved factors that affect both the covariate and the dependent variable.

error term. A variable in a multiple regression model that represents the cumulative effect of several sources of modeling error.

estimate. The calculated value of a parameter based on the use of a particular sample.

estimator. The sample statistic that estimates the value of a population parameter (e.g., a regression parameter); its values vary from sample to sample.

ex ante forecast. A prediction about the values of the dependent variable that go beyond the sample; consequently, the forecast must be based on predictions for the values of the explanatory variables in the regression model.

explanatory variable. A variable that is associated with changes in a dependent variable.

ex post forecast. A prediction about the values of the dependent variable made during a period in which all values of the explanatory and dependent variables are known. Ex post forecasts provide a useful means of evaluating the fit of a regression model.

F-test. A statistical test (based on an F -ratio) of the null hypothesis that a group of explanatory variables are jointly equal to 0. When applied to all the explanatory variables in a multiple regression model, the F -test becomes a test of the null hypothesis that R^2 equals 0.

feedback. When changes in an explanatory variable affect the values of the dependent variable, and changes in the dependent variable also affect the explanatory variable. When both effects occur at the same time, the two variables are described as being determined simultaneously.

fitted value. The estimated value for the dependent variable.

fixed-effects model. A regression model that includes a set of dummy variables that account for certain characteristics of individuals in the sample.

heteroscedasticity. When the error associated with a multiple regression model has a nonconstant variance; that is, the error values associated with some observations are typically high, while the values associated with other observations are typically low.

homoscedasticity. When the error associated with a multiple regression model has a constant variance.

hypothesis test. A statement about the parameters in a multiple regression model. The null hypothesis may assert that certain parameters have specified values or ranges; the alternative hypothesis would specify other values or ranges.

independence. When two variables are not correlated with each other (in the population).

independent variable. An explanatory variable that affects the dependent variable but that is not affected by the dependent variable.

influential data point. A data point whose deletion from a regression sample causes one or more estimated regression parameters to change substantially.

instrumental variable. A variable that is both highly correlated with the covariate that is believed to be endogenous and at the same time not directly affected by the dependent variable.

interaction variable. The product of two explanatory variables in a regression model; used in a particular form of nonlinear model.

intercept. The value of the dependent variable when each of the explanatory variables takes on the value of 0 in a regression equation.

least squares (or ordinary least squares). A common method for estimating regression parameters. Least squares minimizes the sum of the squared differences between the actual values of the dependent variable and the values predicted by the regression equation.

linear regression model. A regression model in which the effect of a change in each of the explanatory variables on the dependent variable is the same, no matter what the values of those explanatory variables.

logit model. A discrete dependent-variable regression model in which the estimated coefficients measure the effect of a change in the covariates on the logarithm of the odds that a particular choice will be made or an event will occur.

maximum likelihood estimation. An estimation method that determines values for the parameters of the regression model that maximizes the likelihood that the process described by the model produced the sample data that were observed.

mean; expected value. An average of the outcomes associated with a probability distribution, where the outcomes are weighted by the probability that each will occur.

mean squared error (MSE). The estimated variance of the regression error, calculated as the average of the sum of the squares of the regression residuals.

model. A mathematical representation of an actual situation.

multicollinearity. When two or more variables are highly correlated in a multiple regression analysis. Substantial multicollinearity can cause regression parameters to be estimated imprecisely, as reflected in relatively high standard errors.

multiple regression analysis. A statistical tool for understanding the relationship between two or more variables.

nonlinear regression model. A model having the property that changes in explanatory variables will have differential effects on the dependent variable as the values of the explanatory variables change.

normal distribution. A bell-shaped probability distribution having the property that about 95% of the distribution lies within two standard deviations of the mean.

null hypothesis. In regression analysis, the null hypothesis states that the results observed in a study with respect to a particular variable are no different from what might have occurred by chance, independent of the effect of that variable. See hypothesis test.

one-tailed test. A hypothesis test in which the alternative to the null hypothesis that a parameter is equal to 0 is for the parameter to be either positive or negative, but not both.

outlier. A data point that is more than some appropriate distance from a regression line that is estimated using all the other data points in the sample.

***p*-value.** The significance level in a statistical test; the probability of getting a test statistic as extreme or more extreme than the observed value. The larger the *p*-value, the more likely that the null hypothesis is valid.

parameter. A numerical characteristic of a population or a model.

perfect collinearity. When two or more explanatory variables are correlated perfectly.

population. All the units of interest to the researcher; also, universe.

practical significance. Substantive importance. Statistical significance does not ensure practical significance because, with large samples, small differences can be statistically significant.

probability distribution. The process that generates the values of a random variable. A probability distribution lists all possible outcomes and the probability that each will occur.

probability sampling. A process by which a sample of a population is chosen so that each unit of observation has a known probability of being selected.

probit model. A discrete dependent-variable regression model in which the estimated coefficients measure the effect of a change in a covariate on the probability that a particular choice will be made or an event will occur.

quasi-experiment (or natural experiment). A naturally occurring instance of observable phenomena that yield data that approximate a controlled experiment.

***R*-squared (R^2).** A statistic that measures the percentage of the variation in the dependent variable that is accounted for by all of the explanatory variables in a regression model. *R*-squared is the most used measure of goodness of fit of a regression model.

random-effects regression model. A regression model that views individual-specific constant terms as being randomly distributed across the individual units of observation.

random error term. A term in a regression model that reflects random error (sampling error) that is the result of chance. Consequently, the result obtained

in the sample differs from the result that would be obtained if the entire population were studied.

randomized controlled trial (RCT). A methodology in which the analyst randomly divides potential subjects into two groups: the treatment group, who receive an intervention, and the control group, who do not.

regression coefficient. The estimate of a population parameter obtained from a regression equation that is based on a particular sample; also, regression parameter.

regression residual. The difference between the actual value of a dependent variable and the value predicted by the regression equation.

robust estimation. An alternative to least-squares estimation that is less sensitive to outliers.

robust. When a statistic or procedure does not change much when data or assumptions are slightly modified.

sample. A selection of data chosen for a study; a subset of a population.

sampling error. A measure of the difference between the sample estimate of a parameter and the population parameter.

scatterplot. A graph showing the relationship between two variables in a study; each dot represents one subject. One variable is plotted along the horizontal axis; the other variable is plotted along the vertical axis.

serial correlation. The correlation of the values of regression errors over time.

simultaneity. When a covariate in a regression model affects the dependent variable and is also affected by the dependent variable.

slope. The change in the dependent variable associated with a one-unit change in an explanatory variable in a linear regression model.

spurious correlation. When two variables are correlated, but one is not the cause of the other.

standard deviation. The square root of the variance of a random variable. The variance is a measure of the spread of a probability distribution about its mean; it is calculated as a weighted average of the squares of the deviations of the outcomes of a random variable from its mean.

standard error of forecast (SEF). An estimate of the standard deviation of the forecast error; it is based on forecasts made within a sample in which the values of the explanatory variables are known with certainty.

standard error of the coefficient; standard error (SE). A measure of the variation of a parameter estimate about the true parameter. The standard error is a standard deviation that is calculated from the probability distribution of estimated parameters.

standard error of the regression (SER). An estimate of the standard deviation of the regression error; it is calculated as the square root of the average of the squares of the residuals associated with a particular multiple regression analysis.

statistical significance. A test used to evaluate the degree of association between a dependent variable and one or more explanatory variables. If the calculated p -value is smaller than 5%, the result is said to be statistically significant (at the 5% level). If p is greater than 5%, the result is statistically insignificant (at the 5% level).

t -statistic. A test statistic that describes how far an estimate of a parameter is from its hypothesized value (i.e., given a null hypothesis). If a t -statistic is sufficiently large (in absolute magnitude), an expert can reject the null hypothesis.

t -test. A test of the null hypothesis that a regression parameter takes on a particular value, usually 0. The test is based on the t -statistic.

time-series analysis. A type of multiple regression analysis in which each data point is associated with a particular unit of observation (e.g., an individual or a firm) measured at different points in time.

two-tailed test. A hypothesis test in which the alternative to the null hypothesis that a parameter is equal to 0 is for the parameter to be either positive or negative, or both.

variable. Any attribute, phenomenon, condition, or event that can have two or more values.

variable of interest. The explanatory variable that is the focal point of a particular study or legal issue.

Introduction

Sample surveys gather responses from a subset of a population to draw inferences about the population as a whole. They are used to describe or enumerate beliefs, attitudes, or behaviors of persons or other social units.¹ Surveys typically are offered in legal proceedings to establish or refute claims about the characteristics of those individuals or social units.² We focus here primarily on sample surveys with individuals reporting about themselves (e.g., their own beliefs) or their organizations (e.g., the company where they are employed). Such surveys must deal not only with issues of population definition, sampling, and measurement common to all surveys, but also with the specialized issues that arise in obtaining information from human respondents.

In principle, a survey can count or measure every member of the relevant population. A survey that does this full count is sometimes called a census. In practice, however, most surveys typically count or measure only a portion of the individuals or other units that the survey intends to describe. In either case, the goal is to provide information on the relevant population. Sample surveys can be carried out using probability or nonprobability sampling techniques. Although probability sampling offers important advantages over nonprobability sampling,³ various forms of nonprobability sampling are in wide use. Thus, in this reference guide, we discuss both probability samples and nonprobability samples, including their strengths and weaknesses for achieving various purposes.

As a method of data collection, surveys have several crucial potential advantages over less systematic approaches.⁴ When a survey is properly designed,

1. Sample surveys conducted by social scientists “consist of (relatively) systematic, (mostly) standardized approaches to collecting information on individuals, households, organizations, or larger organized entities through questioning systematically identified samples.” James D. Wright & Peter V. Marsden, *Survey Research and Social Science: History, Current Practice, and Future Prospects*, in *Handbook of Survey Research* 1, 3 (James D. Wright & Peter V. Marsden eds., 2d ed. 2010).

2. See, e.g., *Sanderson Farms, Inc. v. Tyson Foods, Inc.*, 547 F. Supp. 2d 491 (D. Md. 2008); *SMS Sys. Maint. Servs. v. Digital Equip. Corp.* 188 F.3d 11 22, 22–23 (1st Cir. 1999). For other examples, see *infra* notes 10–26 and accompanying text.

3. See section titled “The Sample as a Reflection of the Relevant Characteristics of the Population” below.

4. This does not mean that surveys can be relied on to address all questions. For example, if survey respondents had been asked in the days before the attacks of 9/11 to predict whether they would volunteer for military service if Washington, D.C., were to be bombed, their answers may not have provided accurate predictions. Although respondents might have willingly answered the question, their assessment of what they would actually do in response to an attack simply may have been inaccurate. Even the option of a “do not know” choice would not have prevented an error in prediction if they believed they could accurately predict what they would do. Thus, although such a survey would have been suitable for assessing the *predictions* of respondents, it might have provided a very inaccurate estimate of what an actual response to the attack would be. If a survey respondent has limited experience (e.g., a child predicting what she will do as an adult) or the hypothetical is far removed from reality or imaginable reality, the survey is unlikely to provide accurate predictions.

executed, and described, it (1) efficiently presents the responses of a group of individuals or other units (e.g., organizations) and (2) permits an assessment of the extent to which the measured responses of the individuals or other units are likely to adequately represent a relevant population of individuals or other units. All questions asked of respondents and all other measuring devices used (e.g., criteria for selecting eligible respondents) can be examined by the court and the opposing party for objectivity, clarity, and relevance, and all answers or other measures obtained can be analyzed for completeness and consistency.

So that the court and the opposing party can closely scrutinize the survey, the party offering the survey as evidence should describe in detail the design, execution, and analysis of the survey, including (1) a description of the population from which the sample was selected, demonstrating that it was a relevant population for the question at hand; (2) a description of how the sample was drawn and an explanation for why that sample design was appropriate; (3) a report on response rate and the ability of the sample to represent the target population; (4) evidence that respondents were attentive and honest in answering the questions on the survey; and (5) an evaluation of any sources of potential bias in respondents' answers or in the ability of the results from the sample to generalize to the relevant population.

The material covered in this reference guide is intended to assist judges in identifying, narrowing, and addressing issues bearing on the adequacy of surveys either offered as evidence or proposed as a method for developing information. Questions about a survey can be (1) raised from the bench during a pretrial proceeding to determine the admissibility of the survey evidence; (2) presented to the contending experts before trial for their joint identification of disputed and undisputed issues; (3) presented to counsel with the expectation that the issues will be addressed during the examination of the experts at trial; or (4) raised in bench trials to help the judge evaluate what weight, if any, the survey should be given.⁵

All sample surveys should address the issues concerning purpose and design (see section titled "Purpose and Design of the Survey" below), population definition and sampling (see section titled "Population Definition and Sampling" below), and disclosure and reporting (see section titled "Disclosure and Reporting" below). All questionnaire and interview surveys raise methodological issues involving survey questions and structure (see section titled "Survey Questions and Structure" below) and confidentiality (see section titled "Disclosure and Reporting" below). Interview surveys introduce additional issues, such as accuracy of data entry (see section titled "Accuracy of Data Entry" below) and interviewer training and qualifications (see

5. Lanham Act cases involving trademark infringement or deceptive advertising frequently require expedited hearings that request injunctive relief, and so judges may need to be more familiar with survey methodology when considering the weight to accord a survey in these cases than when presiding over cases being submitted to a jury. Even in a case being decided by a jury, however, the court must be prepared to evaluate the methodology of the survey evidence in order to rule on admissibility. See *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579, 589 (1993); Fed. R. Evid. 702.

section titled “Surveys Involving Interviewers” below). And online surveys raise special issues and questions (see section titled “Internet Surveys” below).

Use of Surveys in Court

Sixty years ago, the question of whether surveys were acceptable evidence was unsettled.⁶ Early doubts about the admissibility of surveys centered on their use of sampling and their status as hearsay evidence. Federal Rule of Evidence 703 settled both matters for surveys by redirecting attention to the “validity of the techniques employed.”⁷ The inquiry under Rule 703 focuses on whether facts or data are “of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject.”⁸

Because the survey method provides an economical and systematic way to gather information and draw inferences about a large number of individuals or other units, surveys are used widely in business, government, administrative settings, and judicial proceedings.⁹ Both federal and state courts have accepted survey evidence on a variety of issues. Our review of cases citing survey evidence over the ten-year period between 2012 and 2022 revealed cases involving legal issues in administrative law, copyright, criminal law, deceptive advertising, discrimination, employment, patent, trademark, and unfair competition, among others.

Some of these cases cited surveys conducted specifically for litigation, and some cited surveys not prepared for litigation. The topics of both litigation and nonlitigation surveys are diverse.¹⁰ Surveys appear even in the most routine of

7. Fed. R. Evid. 703 advisory committee note. This focus on the adequacy of the methodology used in conducting and analyzing results from a survey is also consistent with the Supreme Court’s discussion of admissible scientific evidence in *Daubert*, 509 U.S. 579; see also *General Elec. Co. v. Joiner*, 522 U.S. 136, 147 (1997).

8. Fed. R. Evid. 703 advisory committee note.

9. Some sample surveys are so well accepted that they may not even be recognized as surveys. For example, some U.S. Census Bureau data are based on sample surveys, including the widely relied-upon American Community Survey, <https://perma.cc/XLY8-R4YE>. Similarly, the Standard Table of Mortality, which is accepted as proof of the average life expectancy of an individual of a particular age and gender, is based on survey data. Surveys conducted by federal agencies are generally of high quality. Their demographic statistics are often used as benchmarks for nongovernmental research.

10. See, e.g., *Kittle-Aikeley v. Claycomb*, 807 F.3d 913, 926 (8th Cir. 2015) (survey to assess the seriousness of the drug abuse problem in schoolchildren to help justify the school’s decision to drug test its community college student body); *Miller v. Bonta*, 542 F. Supp. 3d 1009, 1021 (S.D. Cal. 2021), *vacated and remanded*, No. 21-55608, 2022 WL 3095986 (9th Cir. Aug. 1, 2022) (in a Second Amendment case, survey used to note that many people in California own firearms); *Missouri v. Biden*, 576 F. Supp. 3d 622, 634 (E.D. Mo. 2021) (survey used to predict workers’ response to a vaccine mandate for federal contractors); *United States v. Cloud*, No. 1:19-cr-02032-SMJ-1, 2021 U.S. Dist. LEXIS 235350, at *13 (E.D. Wash. Dec. 8, 2021) (survey used to determine whether a jury pool was sufficiently biased to warrant a change of venue); *Lord & Taylor LLC v. Zim Integrated Shipping Servs., Ltd.*, 108 F. Supp. 3d 197, 227 (S.D.N.Y. 2015) (survey used to note that 79% of

cases. Vocational experts testifying in Social Security Administration disability hearings regularly rely on a variety of surveys conducted by the Bureau of Labor Statistics, specifically the Occupational Requirements Survey,¹¹ the Occupational Employment Survey,¹² and the National Compensation Survey,¹³ to support their opinions on whether a person would be able to find gainful employment given their documented disabilities. One might think that reliance on these surveys is unexceptional, but federal courts have sometimes struggled to determine whether a given expert's use of survey data is scientifically valid.¹⁴

Employment and discrimination law cases sometimes incorporate survey evidence as well. These surveys may be conducted as part of a company's normal business operations and may be relevant to the performance of a particular employee or the feelings of a subgroup of employees.¹⁵ Other times the surveys may be conducted by plaintiffs to provide evidence of wage and working conditions.¹⁶

In cases in which courts set attorneys' fees, judges are charged with determining reasonable fees.¹⁷ Surveys frequently provide courts with evidence of the prevailing market rates.¹⁸

coastal residents thought the impact of Hurricane Sandy was worse than expected, informing whether it should be treated as an Act of God for contract purposes).

23. *In re Dial Complete Mktg. & Sales Pracs. Litig.*, 320 F.R.D. 326 (D.N.H. 2017) (alleged damages, claiming that the soap did not kill 99.9% of germs, but some smaller percentage).

24. *Apple, Inc. v. Samsung Elecs. Co.*, No. 11-CV-01846-LHK, 2012 U.S. Dist. LEXIS 90877, at *37–38, *42–43 (N.D. Cal. June 29, 2012); *SimpleAir, Inc. v. Google Inc.*, No. 2:14-CV-11, 2015 U.S. Dist. LEXIS 135915, at *6–7 (E.D. Tex. Oct. 5, 2015); *TV Interactive Data Corp. v. Sony Corp.*, 929 F. Supp. 2d 1006, 1020–22 (N.D. Cal. 2013); *Microsoft Corp. v. Motorola, Inc.*, 904 F. Supp. 2d 1109, 1119–20 (W.D. Wash. 2012).

25. See *infra* pp. 722–25.

technique has received widespread acceptance.²⁶ Such surveys can be valuable in assisting the court, but they must reflect the views of a representative group of recognized experts who have responded to questions about the relevant issue.

In addition, survey methodology has been used creatively to assist federal courts in managing mass torts litigation. For instance, faced with the prospect of conducting discovery concerning 10,000 plaintiffs, the plaintiffs and defendants in *Wilhoite v. Olin Corp.*²⁷ jointly drafted a discovery survey that was administered in person by neutral third parties, thus replacing interrogatories and depositions. It resulted in substantial savings in both time and cost. Greater use of this approach would be beneficial to all parties.

A Comparison of Survey Evidence and Individual Testimony

To illustrate the value of a survey, it is useful to compare the information that can be obtained from a competently done survey with the information obtained by other means. A survey is presented by a survey expert, who testifies about the responses of a substantial number of individuals who have been selected according to an explicit sampling plan and asked the same set of questions. In contrast, a party using a nonsurvey method generally identifies several witnesses who testify about their own characteristics, experiences, or impressions. Although the party has no obligation to select these witnesses in any particular way or to report on how they were chosen, the party is not likely to select witnesses whose attitudes or beliefs conflict with the party's interests. The witnesses who testify are aware of the parties involved in the case and have discussed the case with the party before testifying.

Although surveys are not the only means of demonstrating particular facts, presenting the results of a well-done survey through the testimony of an expert is an efficient way to inform the trier of fact about a large group of potential witnesses. In some cases, courts have described surveys as the most direct form of

26. For instance, courts determined that the polygraph test has failed to achieve general acceptance in the scientific community based on the inconsistent reactions revealed in several surveys. See *United States v. Scheffer*, 523 U.S. 303, 309–10 (1998); *United States v. Bishop*, 64 F. Supp. 2d 1149 (D. Utah 1999); *United States v. Varoudakis*, No. 97-10158-RGS, 1998 WL 151238 (D. Mass. Mar. 27, 1998); *State v. Shively*, 999 P.2d 952, *aff'd*, 999 P.2d 259 (Kan. 2000); *Lee v. Martinez*, 96 P.3d 291, 304–06 (N.M. 2004). In contrast, an eyewitness identification expert was permitted to testify about scientific studies of factors affecting the perceptual ability and memory of eyewitnesses based in part on survey evidence showing general acceptance of those findings by experts within the field. See *People v. Williams*, 830 N.Y.S.2d 452, 465–66 (N.Y. Sup. Ct. 2006).

27. *Wilhoite v. Olin Corp.*, No. CV-83-C-5021-NE (N.D. Ala. filed Jan. 11, 1983). The case ultimately settled before trial. See Francis E. McGovern & E. Allan Lind, *The Discovery Survey*, 51 Law & Contemp. Probs. 41, 49 (1988).

evidence that can be offered.²⁸ Indeed, several courts have drawn negative inferences from the absence of a survey, taking the position that failure to undertake a survey may strongly suggest that a properly done survey would not support the plaintiff's position.²⁹

Purpose and Design of the Survey

Addressing Relevant Questions

Key to evaluating any survey is assessing whether it is relevant to the disputed issues. Surveys conducted in the normal course of business and not in anticipation of, or in response to, litigation may have a lesser risk of bias in favor of the interests of the party conducting the survey, but such surveys may ask irrelevant questions, lack important quality controls, or be conducted on inappropriate populations.³⁰ In contrast, surveys conducted for litigation are more likely to be designed to address the legally relevant issues in the case (e.g., to estimate damages in an antitrust suit or to assess consumer confusion in a trademark case), but may have a greater risk of bias since they are typically solicited by one of the parties to aid in the case. Thus, the content and execution of a survey must be scrutinized whether or not the survey was explicitly designed to provide relevant data on the issue before the court.³¹

28. See, e.g., *Morrison Ent. Grp. v. Nintendo of Am.*, 56 F. App'x 782, 785 (9th Cir. 2003); *Monster, Inc. v. Dolby Lab's Licensing Corp.*, 920 F. Supp. 2d 1066, 1072 (N.D. Cal. 2013); *Heaven Hill Distilleries, Inc. v. Log Still Distilling, LLC*, No. 3:21-cv-190-BJB-CHL, 2021 U.S. Dist. LEXIS 240373 (W.D. Ky. Dec. 16, 2021) (survey is the "most persuasive evidence" of consumer recognition).

29. *Ortho Pharm. Corp. v. Cosprophar, Inc.*, 32 F.3d 690, 695 (2d Cir. 1994); *Henri's Food Prods. Co. v. Kraft, Inc.*, 717 F.2d 352, 357–58 (7th Cir. 1983); *Medici Classics Prods. LLC v. Medici Grp. LLC*, 590 F. Supp. 2d 548, 556 (S.D.N.Y. 2008); *Citigroup v. City Holding Co.*, No. 99 Civ. 10115 (RWS), 2003 U.S. Dist. LEXIS 1845 (S.D.N.Y. Feb. 10, 2003); *Chum Ltd. v. Lisowski*, 198 F. Supp. 2d 530 (S.D.N.Y. 2002); *Cairns v. Franklin Mint Co.*, 24 F. Supp. 2d 1013, 1041 (C.D. Cal. 1998) ("[A] plaintiff's failure to conduct a survey, assuming it has the financial resources to do so, may lead to an inference that the results of such a survey would be unfavorable.").

30. In *Craig v. Boren*, 429 U.S. 190 (1976), the state unsuccessfully attempted to use its annual roadside survey of the blood alcohol level, drinking habits, and preferences of drivers to justify prohibiting the sale of 3.2% beer to males under the age of 21 and to females under the age of 18. The data were biased because it was likely that the male would be driving if both the male and female occupants of the car had been drinking. As pointed out in 2 Joseph L. Gastwirth, *Statistical Reasoning in Law and Public Policy: Tort Law, Evidence, and Health* 527 (1988), the roadside survey would have provided more relevant data if all occupants of the cars had been included in the survey (and if the type and amount of alcohol most recently consumed had been requested so that the consumption of 3.2% beer could have been isolated).

31. See *Merisant Co. v. McNeil Nutritionals, LLC*, 242 F.R.D. 315 (E.D. Pa. 2007).

Role of Attorneys in Survey Design and Administration

An early handbook for judges recommended that survey interviews be “conducted independently of the attorneys in the case.”³² Some courts interpreted this to mean that any evidence of attorney participation is objectionable.³³ A better interpretation is that the attorney should not take part in survey implementation or interact with survey participants.³⁴ However, some attorney involvement in the survey design is often necessary to ensure that relevant questions are directed to a relevant population,³⁵ particularly if the survey expert is not an expert in the substantive area of law under dispute. Federal Rule of Civil Procedure 26(4)(b) does not allow an inquiry into the nature of communications between attorneys and experts, and so the role of attorneys in constructing surveys may not always be fully apparent. The key issues for the trier of fact are the design of the survey, the objectivity and relevance of the questions on the survey, the appropriateness of the population used to guide sample selection, and the method of sample selection. These aspects of the survey are visible to the trier of fact and can be judged on their quality, irrespective of who suggested them. In contrast, the survey administration itself, whether online or in an interview, may not be directly visible. Any potential bias is minimized by having interviewers and respondents blind to the purpose and sponsorship of the survey and by excluding attorneys from any part in administering questionnaires, conducting interviews, tabulating results, and interpreting the data.³⁶

Swann, *A History of the Evolution of Likelihood of Confusion Methodologies*, 113 Trademark Rep. 723 (2023) (generally on the importance of context in determining survey design methodology).

36. *Gibson*, 181 F. Supp. 2d at 1068.

Skill and Experience of the Experts Who Designed, Conducted, or Analyzed the Survey

Experts prepared to design, conduct, and analyze a survey generally should have graduate training in psychology (especially social, cognitive, or consumer psychology), sociology, political science, marketing, communication sciences, statistics, or a related discipline; that training should include courses in survey research methods, sampling, measurement, interviewing, and statistics. In some cases, professional experience in teaching or conducting and publishing survey research may provide the requisite background. In all cases, the expert must demonstrate an understanding of best practices in survey methodology, including sampling,³⁷ instrument design (questionnaire and interview construction), and statistical analysis.³⁸ Publication in peer-reviewed journals, authored books, fellowship status in professional organizations, faculty appointments, consulting experience, research grants, and membership on scientific advisory panels for government agencies or private foundations are indications of a professional's area and level of expertise. In addition, some surveys involving highly technical subject matter or specific (sub)populations may require experts to have some further specialized knowledge. Under these conditions, the survey expert also should be able to demonstrate sufficient familiarity with the topic and population (or assistance from an individual on the research team with suitable expertise) to design a survey instrument that will communicate clearly with relevant respondents.

Skill and Experience of the Experts Who Will Testify About Surveys Conducted by Others

Parties often call on an expert to testify about a survey conducted by someone else (e.g., by one of the parties to the suit, or by another entity when the survey was not conducted specifically for the case). The secondary expert's role may be to offer support for a survey commissioned by the party who calls the expert, to critique a survey presented by the opposing party, or to introduce findings or conclusions from a survey not conducted in preparation for litigation or by any of the parties to the litigation. The trial court should take into account the exact issue that the expert seeks to testify about and the nature of the expert's field of

37. The one exception is that sampling expertise would be unnecessary if the survey were administered to all members of the relevant population. *See, e.g.,* McGovern & Lind, *supra* note 27.

38. If survey expertise is being provided by several experts, a single expert may have general familiarity but not special expertise in all these areas.

expertise.³⁹ All experts who give opinions about the adequacy and interpretation of a survey not only should have general skills and experience with surveys and be familiar with all of the issues addressed in this reference guide, but also should demonstrate familiarity with the following properties of the survey being discussed:

1. Purpose of the survey;
2. Survey methodology,⁴⁰ including
 - a. the target population,
 - b. the sampling design used in conducting the survey,
 - c. the survey instrument (questionnaire or interview schedule), and
 - d. (for interview surveys) interviewer training and instruction;
3. Results, including rates and patterns of missing data; and
4. Statistical analyses used to interpret the results.

Population Definition and Sampling

The Survey Universe or Population

One of the first steps in designing or evaluating a survey is to identify the target population (or universe).⁴¹ The target population consists of all elements (e.g., individuals) whose characteristics or perceptions the survey is intended to represent. Thus, in trademark litigation, the relevant population in some disputes may include all prospective and past purchasers of the pertinent party's category of

39. For a discussion of the admissibility of expert opinion testimony, see Liesa L. Richter and Daniel J. Capra, *The Admissibility of Expert Testimony*, "Federal Rule of Evidence 702: An Overview" section, in this manual.

40. See *A & M Records, Inc. v. Napster, Inc.*, No. C 99-05183 MHP, 2000 U.S. Dist. LEXIS 20668, at *22-25 (N.D. Cal. Aug. 10, 2000) (holding that expert could not attest credibly that the surveys upon which he relied conformed to accepted survey principles because of his minimal role in overseeing the administration of the survey and limited expert report); *Hr'g Tr.* at 29-30, *Munchkin Inc. v. Playtex Prods., LLC*, No. CV11-503-AHM(RZx) (C.D. Cal. May 1, 2012), ECF No. 285 (excluding survey when the expert "didn't know how [the survey] was administered[.] . . . didn't know how the panel was selected [and] didn't know what the statistical technique was that was used to weigh the survey and provide weight to it"), cited in *Cohen v. Trump*, No. 3:13-cv-2519-GPC-WVG, 2016 U.S. Dist. LEXIS 117059, at *16-17 (S.D. Cal. Aug. 29, 2016).

41. Identification of the proper target population or universe is recognized uniformly as a key element in the development of a survey. See, e.g., *Manual for Complex Litigation*, Fourth, § 11.493 (2004), <https://www.uscourts.gov/file/3228/download> [hereinafter MCL 4th]; see also 3 McCarthy, *supra* note 35, § 32:166; Council of Am. Survey Rsch. Orgs., *Code of Standards and Ethics for Survey Research* § III.A.3 (2011), <https://perma.cc/698Z-CF86> [hereinafter CASRO]. (Note that CASRO merged with the Marketing Research Association to form the Insights Association in 2017.)

goods or services. Similarly, the population for a discovery survey may include all potential plaintiffs or all employees who worked for Company A between two specific dates. In a community survey designed to provide evidence for a motion for a change of venue, the relevant population consists of all jury-eligible citizens in the community in which the trial is to take place.⁴² The definition of the relevant population is crucial because there may be systematic differences in the responses of members of the population and nonmembers. For example, consumers who are prospective purchasers may know more about the product category than consumers who are not considering making a purchase.

The universe must be defined carefully.⁴³ For example, in a survey testing whether the defendant made misleading representations about their digital evidence–related software used by police departments, the appropriate universe consisted of potential purchasers of the software in the law enforcement community. Instead, the sample consisted of respondents who merely used photographs in their law enforcement work and had no influence on purchase decisions involving the relevant software or were even necessarily potential users of such software.⁴⁴ Defects in the universe may lead to misleading results that should reduce the weight that is given to the survey;⁴⁵ a survey should be excluded if it consists of respondents who do not substantially reflect the characteristics of the relevant population.⁴⁶

42. An additional relevant population may consist of jury-eligible citizens in the community where the party would like to see the trial moved. By questioning citizens in more than one community, the survey can test whether moving the trial is likely to reduce the level of animosity toward the party requesting the change of venue. *See* *United States v. Cloud*, No. 1:19-cr-02032-SMJ-1, 2021 U.S. Dist. LEXIS 260839, at *8–9 (E.D. Wash. Dec. 8, 2021) (order granting a motion for intra-district transfer from Yakima based in part on a telephone survey of jury-eligible respondents in Yakima, Richland, and Spokane); *United States v. Haldeman*, 559 F.2d 31, 140, 151 (MacKinnon, J., dissenting), 176–79 (app. A) (D.C. Cir. 1976) (court denied change of venue over the strong objection of Judge MacKinnon, who cited survey evidence that Washington, D.C., residents were substantially more likely to conclude, before trial, that the defendants were guilty); *see also* *People v. Venegas*, 31 Cal. Rptr. 2d 114, 117 (Cal. Ct. App. 1994) (change of venue denied because defendant failed to show that the defendant would face a less hostile jury in a different court).

The Sampling Frame as an Approximation of the Population

The target population consists of all the individuals or units whose responses the researcher would like to describe. The sampling frame is the source (or sources) from which the sample actually is drawn. The surveyor's job generally is easier if a complete list of every eligible member of the population is available (e.g., all plaintiffs in a discovery survey), so that the sampling frame lists all members of the target population. The survey expert should identify how the sampling frame was compiled—that is, the source(s) used to obtain the list of members of the population. Ideally, even if a list of every member of the population is not available, the survey expert will still have access to demographic characteristics of the full population (e.g., sex, race/ethnicity, age). In some cases, this is straightforward, such as when the population consists of all American residents (so the Census's American Community Survey can provide the demographic information). In other situations, population descriptions may be less easily obtained (e.g., the consumers of a particular product, whose demographic characteristics may be identifiable only from the marketing research of the company that produces the product). In practice, the target population often includes some members who cannot be contacted or who cannot be identified in advance. As a result, reasonable compromises are sometimes required in developing the sampling frame. The survey report should contain (1) a description of the target population, (2) a description of the sampling frame from which the sample is drawn, (3) a discussion of the difference between the two, and, importantly, (4) an evaluation of the likely consequences of that difference.

A survey that provides information about a wholly irrelevant population is itself irrelevant.⁴⁷ Courts are likely to exclude such a survey or accord it minimal

47. A survey aimed at assessing how persons in the trade respond to an advertisement should be conducted on a sample of persons in the trade and not on a sample of consumers. *See* *Home Box Off. v. Showtime/The Movie Channel*, 665 F. Supp. 1079, 1083–84 (S.D.N.Y. 1987), *aff'd in part and vacated in part*, 832 F.2d 1311 (2d Cir. 1987); *J & J Snack Food Corp. v. Earthgrains Co.*, 220 F. Supp. 2d 358, 371–72 (D.N.J. 2002); *Parks, LLC v. Tyson Foods, Inc.*, 186 F. Supp. 3d 405, 419–20 (E.D. Pa. 2016) (giving little weight to a survey aimed at consumers of the plaintiff's products when it should have been targeted at users of the defendant's). *But see* *Lon Tai Shing Co., LTD v. Koch & Lowy*, No. 90 Civ. 4464, 1990 U.S. Dist. LEXIS 19123, at *50–57 (S.D.N.Y. Dec. 14, 1990), in which the judge was willing to find likelihood of consumer confusion from a survey of lighting store salespersons questioned by a survey researcher posing as a customer. The court was persuaded that the salespersons who were misstating the source of the lamp, whether consciously or not, must have reasonably believed that the consuming public would be likely to rely on the salespersons' inaccurate statements about the name of the company that manufactured the lamp they were selling.

weight.⁴⁸ More commonly, however, the sampling frame and the target population have some overlap, but the overlap is imperfect. This is called coverage error, and it has two types: the sampling frame may be underinclusive by excluding part of the target population, or it may be overinclusive by including individuals who are not members of the target population. If the coverage is underinclusive, the survey's value depends on the extent to which the excluded population is likely to respond differently from the included population. Thus, a survey of spectators and participants at running events would be sampling a sophisticated subset of those likely to purchase running shoes. Because this subset would probably consist of the consumers most knowledgeable about the trade dress used by companies that sell running shoes, a survey based on this sampling frame would be likely to substantially overrepresent the strength of a particular design as a trademark. Worse still, the extent of that overrepresentation would be unknown and not susceptible to any reasonable estimation.⁴⁹

In some cases, it is difficult to determine whether a sampling frame that omits some members of the population distorts the results of the survey and, if so, the extent and likely direction of the bias. For example, a trademark survey was designed to test the likelihood of confusing an analgesic currently on the market with a new product that was similar in appearance.⁵⁰ The plaintiff's survey included only respondents who had used the plaintiff's analgesic, and the court found that the target population should have included users of other analgesics, "so that the full range of potential customers for whom plaintiff and defendants would compete could be studied."⁵¹ In this instance, it is unclear whether users of the plaintiff's product would be more or less likely to be confused than users of the defendants' product or users of a third analgesic, but the omission of users

48. See *Varner v. Dometic Corp.*, No. 16-22482-CIV-SCOLA/OTAZO-REYES, 2022 U.S. Dist. LEXIS 127353, at *27–30 (S.D. Fla. Feb. 2, 2022) (survey of consumers excluded because gas-absorption refrigerators are not sold directly to consumers, but rather to manufacturers and OEM and RV dealers); see also *In re Fluidmaster, Inc., Water Connector Components Prods. Liab. Litig.*, No. 14-cv-5696, 2017 WL 1196990, at *29 (N.D. Ill. Mar. 21, 2017); *Wells Fargo & Co. v. WhenU.com, Inc.*, 293 F. Supp. 2d 734 (E.D. Mich. 2003).

51. *Am. Home Prods.*, 656 F. Supp. at 1070.

of other analgesics made it impossible to assess the effect of that difference.⁵² If the sampling frame does not include important groups in the target population, the survey cannot provide information on how the unrepresented members of the target population would have responded.⁵³

An overinclusive sampling frame generally presents less of a problem for interpretation than does an underinclusive sampling frame.⁵⁴ If the survey expert can demonstrate that a sufficiently large and representative subset of respondents in the survey was drawn from the appropriate sampling frame, the responses obtained from that subset can be examined, and inferences about the relevant population can be drawn based on that subset.⁵⁵ If the relevant subset cannot be identified, however, an overbroad sampling frame will reduce (or eliminate) the value of the survey.⁵⁶

The Sample as a Reflection of the Relevant Characteristics of the Population

Identification of a survey population must be followed by selection of a sample that accurately represents that population.⁵⁷ The use of probability sampling techniques maximizes both the representativeness of the survey results and the

ability to assess the precision of estimates obtained from the survey. Probability samples range from simple random samples to complex multistage sampling designs that use stratification, clustering of population elements into various groupings, or both. In all forms of probability sampling, each element in the relevant population has a known, nonzero probability of being included in the sample.⁵⁸ These sample selection probabilities do not need to be the same for all population elements (i.e., some members may have a higher or lower chance of being selected than others). If the probabilities are unequal, however, compensatory adjustments should be made in the analysis. Failure to adjust by weighting to reflect the known distribution in the population on relevant characteristics may undermine representativeness and warrant exclusion of the survey.⁵⁹

Probability sampling offers two important advantages over nonprobability sampling. First, a probability sample can provide an unbiased estimate that summarizes the responses of all persons in the population from which the sample was drawn; that is, the expected value of the sample estimate is the population value being estimated. For instance, if a probability sample leads to an estimate that 80% of respondents were confused as to whether an analgesic was an existing or new option, the researcher could be confident that approximately 80% of those in the population would have that belief (within some margin of error). A probability sample can provide an unbiased estimate of the population even when the size of the sample is relatively small. The advantage of larger samples is that they provide more precision (smaller margins of error). In general, the absolute size of the sample, rather than its size relative to the population, determines the precision of the estimate.⁶⁰

Second, probability sampling allows the researcher to calculate a confidence interval that explicitly provides information on the reliability of the sample estimate of the population value (i.e., the value one would obtain if everyone in the population responded). The difference between the estimate and the exact value

58. See Thomas Piazza, *Fundamentals of Applied Sampling*, in *Handbook of Survey Research*, *supra* note 1, at 139, 145.

59. *Fish v. Kobach*, 309 F. Supp. 3d 1048, 1059–61 (D. Kan. 2018), *aff'd sub nom.* *Fish v. Schwab*, No. 18–3133, 2020 U.S. App. LEXIS 13723 (10th Cir. Apr. 29, 2020) (expert's survey intended to represent the eligible voting population of Kansas was excluded, in part, for failure to weight responses to reflect the distribution of educational attainment and household income level in the population).

60. An exception to this rule applies when a population is (identifiably) finite and the sample size is large relative to the population size, typically taken to occur when the sample size is greater than 5% of the total population (e.g., the population strictly includes 1,000 people, and the sample includes more than 50 people). In this case, it is appropriate to adjust the standard error/margin of error by the finite population correction (FPC) factor. The FPC factor incorporates both the size of the sample and its share of the population in determining the degree of precision. See William G. Cochran, *Sampling Techniques* 24–25 (3d ed. 1977).

is called the sampling error.⁶¹ Thus, suppose a survey collected responses from a simple random sample of 400 dentists selected from the population of all dentists licensed to practice in the United States and found that 20% of them mistakenly believed that a new toothpaste, Goldgate, was manufactured by the makers of Colgate. A survey expert could properly compute a confidence interval around the 20% estimate obtained from this sample. If the survey were repeated a large number of times, and a 95% confidence interval was computed each time, 95% of the confidence intervals would include the actual percentage of dentists in the entire population who would believe that Goldgate was manufactured by the makers of Colgate.⁶² In this example, the margin of error is $\pm 4\%$, and so the confidence interval is the range between 16% and 24%—that is, the estimate (20%) plus or minus 4%.

All sample surveys (i.e., surveys that do not measure responses from every member of the population) produce estimates of population values, not exact measures of those values. Assuming a probability sample, a confidence interval describes how stable the mean response in the sample is likely to be. The width of the confidence interval depends on three primary characteristics:

1. Size of the sample (larger samples produce narrower intervals);
2. Variability of the response being measured (more variability leads to wider intervals); and
3. Confidence level the researcher wants to have.⁶³

Traditionally, scientists adopt the 95% level of confidence, which means that if one hundred samples of the same size were drawn, the confidence interval expected for ninety-five of the samples would be expected to include the true population value.⁶⁴

Stratified probability sampling uses what is known about the population characteristics to correct for imbalances produced by random sampling. Consider the dentist example presented earlier: if it is known that 60% of dentists have at least

61. See the glossary of this chapter, and David H. Kaye & Hal S. Stern, *Reference Guide on Statistics and Research Methods*, in this manual, for a more detailed definition of sampling error.

62. Actually, because survey interviewers would be unable to locate some dentists, and some dentists would be unwilling to participate in the survey, technically the population to which this sample would be projectable would be all dentists with current addresses who would be willing to participate in the survey if they were asked. The expert should be prepared to discuss possible sources of bias due to, for example, an address list that is not current.

63. When the sample design does not use a simple random sample, the confidence interval will be affected.

64. To increase the likelihood that the confidence interval contains the actual population value (e.g., from 95% to 99%) without increasing the sample size, the width of the confidence interval can be expanded. An increase in the confidence interval brings an increase in the confidence level. For further discussion of confidence intervals, see the glossary to the current chapter, and David H. Kaye & Hal S. Stern, *Reference Guide on Statistics and Research Methods*, in this manual.

fifteen years of experience and 40% have fewer years, the researcher could randomly sample dentists within each of those separate categories to obtain a sample that reflected those proportions. This would ensure the sample was unbiased with respect to years of experience—that proportion would be set by the researcher—and would therefore reduce sampling error.⁶⁵ Disproportionate sampling from subgroups may be used to enable the survey to provide separate estimates for particular subgroups but should be weighted (as discussed below) to reflect the population as a whole when conducting an overall analysis.

The last decade has seen a dramatic rise in the availability of nonprobability samples. Most of these samples come in one of three general varieties. The first variety is drawn from large nonprobability internet panel samples overseen by a vendor. For these panels, individuals opt in (e.g., via advertisements) to receive compensation for taking surveys. The companies that oversee these panels can produce a set of respondents that consists of members of the target population (e.g., the population of elementary school teachers) and matches the distribution of that population on specified characteristics (e.g., percentage of women and minorities). These samples vary in their ability to hit benchmarks, but some perform quite well.⁶⁶ Regardless, these samples differ from probability samples because they are not drawn from a list of the entire population. Instead, there is an attempt to identify relevant respondents and to balance the sample to resemble the population on certain observable features (e.g., the sample and population have the same distribution of gender, age, income).

The second source of nonprobability samples is crowdsourcing labor market platforms, the best-known of which is Amazon's Mechanical Turk (MTurk). Researchers can directly use MTurk or analogous platforms to hire individuals to complete tasks, including taking surveys, for direct compensation. Here, researchers can try to draw samples that match populations on observable variables, but it is often difficult since these platforms do not easily allow for the kind of selective participant invitations that permit managed panels to build custom samples.

The third source of nonprobability samples are purposive samples. These use nonprobability methods designed to target hard-to-reach populations (for whom probability sampling is extremely difficult or impossible), such as low-income people, young people, Indigenous people, and people in poor health.⁶⁷ These sampling methods are sometimes the subject of judicial concerns about researcher bias in selecting respondents, as these methods require the researcher to engage

67. Hard-to-Survey Populations (Roger Tourangeau et al. eds., 2014). Abdolreza Shaghghi et al., *Approaches to Recruiting 'Hard-To-Reach' Populations into Research: A Review of the Literature*, 1 Health Promotion Persps. 86, 94 (2011), <https://doi.org/10.5681/hpp.2011.009>.

in active and targeted outreach.⁶⁸ They also require particular attention to language and survey mode.⁶⁹

Generally speaking, researchers employ nonprobability samples because they are substantially less expensive, often allow for larger samples (due to the lower cost), may include a higher number of individuals from less prevalent subgroups (e.g., members of racial or ethnic minority groups) that could be of interest, and/or offer the only option for hard-to-reach populations. Indeed, the use of nonprobability samples has been common in litigation for some time. For instance, an overwhelming majority of the consumer surveys conducted for Lanham Act litigation present results from nonprobability samples,⁷⁰ and the standard modern practice is for these surveys to be conducted online using professionally managed nonprobability internet panels (i.e., the first type discussed above).⁷¹ A common rationale for admitting such surveys into evidence is that they are used widely in marketing research and that “results of these studies are used by major American companies in making decisions of considerable consequence.”⁷²

Nonprobability samples are appropriate for some types of litigation surveys but still carry important limitations. In many cases, researchers cannot compute response rates for nonprobability samples because they are unaware of how many potential respondents viewed the invitation to participate in the survey and decided not to do so (e.g., researchers often just post participation invitations to those in a labor market without knowing how many people viewed it). In contrast, when trying to assess the base rate of some variable in the national population, probability samples offer superior accuracy relative to nonprobability samples

68. See, e.g., *Branson v. All. Coal, LLC*, No. 4:19-CV-00155-JHM-HBB, 2022 U.S. Dist. LEXIS 123731, at *23–24 (W.D. Ky. July 13, 2022) (rejecting the use of purposive sampling in a class certification survey: “Put simply, the inclusion of purposefully selected data questions whether the data accurately represents the population as a whole. To preserve the reliability of the discovery data, no party shall select certain opt-in plaintiffs from whom to collect information or depose.”).

on validated demographic measures such as sex, age, race, and ethnicity,⁷³ as well as validated behavioral measures such as vaccine uptake.⁷⁴ This is because probability samples are more representative of the underlying population. In evaluating the representativeness of a nonprobability sample relative to the population, the expert should consider both observable and nonobservable sample demographics. On critical variables, it may be necessary to include the joint distributions of the measured variables (e.g., the percentage of minority women).⁷⁵ More generally, there is always the possibility of unobserved relevant factors even in a well-conducted nonprobability survey.⁷⁶ For instance, a nonprobability sample with appropriate quotas may still not include typical members from each quota group. This can lead to inaccuracies in point estimates. Nonprobability samples can provide unbiased estimates if the sample is representative on all variables that correlate with the outcome of interest, or has been weighted to be representative, but this can be challenging when it comes to unobserved factors.⁷⁷

Ultimately, the importance of using a probability sample depends on the survey's goal. If the survey is designed to make a causal inference based on differences between randomly assigned experimental conditions (40% of people in

73. Bo MacInnis et al., *The Accuracy of Measurements with Probability and Nonprobability Survey Samples: Replication and Extension*, 82 Pub. Op. Q. 707 (2018), <https://doi.org/10.1093/poq/nfy038>. The authors compare the accuracy of probability surveys (RDD telephone and internet), internet surveys that combine nonprobability and probability samples, and internet surveys that are fully nonprobability (but with different types of compensation). This study is the most extensive of its kind, using a set of fifty measures and forty benchmark variables from federal face-to-face surveys with high response rates. The analyses showed that probability samples provide more accurate estimates of population quantities than nonprobability samples as well as samples that combined methods.

76. The court in *Kinetic Concepts, Inc. v. BlueSky Medical Corp.*, No. SA-03-CA-0832, 2006 U.S. Dist. LEXIS 60187, at *14–17 (W.D. Tex. Aug. 11, 2006), found the plaintiff's survey using a nonprobability sample to be admissible and permitted the plaintiff's expert to present results from a survey using a convenience sample. The court then assisted the jury by providing an instruction on the differences between probability and convenience samples and the estimates obtained from each.

77. See, e.g., Robert M. Groves et al., *Survey Methodology* (2d ed. 2009). Groves and colleagues point out that using statistical significance tests and confidence intervals with nonprobability samples is technically inappropriate since it becomes impossible to obtain an unbiased estimate of sampling variance. That said, they accept that nonprobability samples can approximate probability samples when the researcher knows what population attributes correlate with the key statistics and ensures that the sample is balanced on those attributes (i.e., using quotas). *Id.* at 409–10. Vasia Vehovar and colleagues agree: "We thus recommend to be more openly accepting of the reality of using a standard statistical inference approach as an approximation in non-probability settings" as long as the nature of how the sample is drawn is clear. Vasia Vehovar et al., *Non-Probability Sampling*, in *The SAGE Handbook of Survey Methodology* (2016), <https://doi.org/10.4135/9781473957893>.

the experimental condition were confused by defendant's advertising, but only 20% by control advertising), a survey-experiment using a nonprobability sample of relevant respondents will generally suffice. If the aim is to obtain a precise measure of a particular feature of a population, however, a nonprobability sample faces challenges.⁷⁸ An expert should consider the potential biases in the sample and whether they impact factors correlated with the variable being estimated, to assess the likely magnitude of the biases (i.e., how much they are likely to affect the estimates). The expert should be prepared to explain how observable and unobservable sample characteristics might impact their estimate.

When using a nonprobability sample in an experimental context (i.e., a survey-experiment), the primary concern about the characteristics of the sample is whether they modify the causal relationship being tested in the survey.⁷⁹ For instance, if more and less experienced dentists react the same way to the name Goldgate for toothpaste—if experience does not moderate (that is, change) the effect of the name—a survey-experiment that does not include more experienced dentists will still produce results that generalize across experience level. In contrast, if reaction to the name does vary with experience—if experience *does* moderate the reaction—a sample that includes only less experienced dentists will produce a biased result. The survey expert should identify any potential sample characteristics that may moderate the effects being assessed and demonstrate that the sampling approach takes them into account.

In sum, the historic gold standard was a probability sample because it could provide unbiased estimates of the population. Yet, increased costs of probability samples, more ways to obtain nonprobability samples, challenges with hard-to-reach populations, and nonresponse bias (discussed below) have all led to greater use of nonprobability samples. When such samples are used, it is vital to clarify how the sample compares to known-probability benchmarks (e.g., demographic

78. However, even if the initial sampling approach uses a probability sample, systematic non-response can undermine the representativeness of the sample and hence the accuracy of a precise estimate. This effect has been demonstrated by studies of the effect of a two-stage process to recruit survey participants in which the initial invitation used probability sampling through U.S. Postal Service mailings, phone contact, and modest incentives, and a follow-up effort involving FedEx mailings, in-person recruitment by field interviewers, and enhanced incentives attempted to recruit initial nonresponders. Comparisons of the two groups indicated small but statistically significant differences in reported political views and income level. The importance of such differences will depend on the claim being made for the accuracy of the estimate. Ipek Bilgen et al., *The Undercounted: Measuring the Impact of 'Nonresponse Follow-up' on Research Data* (2019), <https://perma.cc/P5RS-268Q>.

79. See James N. Druckman & Cindy D. Kam, *Students as Experimental Participants: A Defense of the 'Narrow Data Base'*, in *Cambridge Handbook of Experimental Political Science* (2011); James N. Druckman, *Experimental Thinking: A Primer on Social Science Experiments* (2022).

characteristics and other features that could influence the outcome being studied), what adjustments may have been made (e.g., weights; see below) and how biases may influence inferences—particularly when the goal is to arrive at a precise estimate of a population value. Nonprobability samples tend to be on stronger footing when used in an experimental context, but even here it is vital for the researcher to discuss potential variables that could moderate the experimental effect and whether the sampling approach influenced the impact of those moderators.

Nonresponse as a Potential Source of Bias

Even when a sample is drawn randomly from a complete list of elements in the target population (i.e., a probability sample), responses or measures are typically obtained from only part of the sample. If this lack of response is distributed randomly, valid inferences about the population can be drawn with assurance using the measures obtained from the available sample. But nonresponse often is not random. For example, persons who are single typically have three times the “not at home” rate in U.S. Census Bureau surveys as do people living with family.⁸⁰ Nonresponse also occurs when contact with the sampled individual is made, but that person declines to participate. This problem arose recently in political polls where Republicans seemed less likely to participate than Democrats.⁸¹ Efforts to increase response rates include making several attempts to contact potential respondents, sending advance letters,⁸² and providing financial or nonmonetary incentives for participating in the survey.⁸³

The key to evaluating the effect of nonresponse in a survey is to determine the extent to which nonrespondents differ from respondents in a way that would impact the results of the survey. If nonresponse has biased the pattern of responses, the size and direction of that bias need to be assessed. On some occasions, it may be possible to anticipate systematic patterns of nonresponse. For example, high-volume medical professionals may be less willing to respond to a survey than those with lower-volume practices. If the survey includes questions about volume of

practice, the expert can assess how experience level may have affected the pattern of results.⁸⁴

Although high response rates are desirable because they reduce the potential impact of nonresponse bias, they are increasingly difficult to achieve. Survey nonresponse rates have risen substantially in the twenty-first century, along with the costs of obtaining responses, and so the issue of nonresponse has attracted considerable attention from survey researchers.⁸⁵

Researchers have developed a variety of approaches to adjust for nonresponse, including weighting obtained responses in proportion to known demographic characteristics of the target population (which we discuss below), comparing the pattern of responses from early and late responders to mail surveys or the pattern of responses from easy-to-reach and hard-to-reach responders in telephone surveys, and imputing estimated responses to nonrespondents based on known characteristics of those who have responded. All of these techniques can only approximate the response patterns that would have been obtained if nonrespondents had responded. Nonetheless, they are useful for testing the robustness of the estimates obtained from responders.

To assess the general impact of the lower response rates, researchers have compared results obtained from surveys with varying response rates.⁸⁶ Surprisingly comparable results have been obtained in many surveys with varying response rates, suggesting that surveys may achieve reasonable estimates even with relatively low response rates. The key is whether nonresponse is associated with systematic differences in response that cannot be adequately modeled or assessed. Generally, the representativeness of a sample (regardless of response rate) matters much more for accurate inference than the response rate.⁸⁷ Determining whether

84. In *People v. Williams*, 830 N.Y.S.2d 452 (N.Y. Sup. Ct. 2006), a published survey of experts in eyewitness research was used to show general acceptance of various eyewitness phenomena. See Saul Kassin et al., *On the "General Acceptance" of Eyewitness Testimony Research: A New Survey of the Experts*, 56 Am. Psychologist 405 (2001), <https://doi.org/10.1037/0003-066X.56.5.405>. The survey included questions on the publication activity of respondents and compared the responses of those with high and low research productivity. Productivity levels in the respondent sample suggested that respondents constituted a blue-ribbon group of leading researchers. *Williams*, 830 N.Y.S.2d at 457, 459 n.26. See also *Pharmacia Corp. v. Alcon Lab'ys, Inc.*, 201 F. Supp. 2d 335 (D.N.J. 2002).

the level of nonresponse in a survey seriously impairs inferences drawn from the results generally requires an analysis of the determinants of nonresponse. For example, even a survey with a high response rate may seriously underrepresent some portions of the population, such as the unemployed or the poor. The survey expert should be prepared to provide evidence on the potential impact of nonresponse on the survey results.

In surveys that include sensitive or difficult questions, some respondents may refuse to provide answers or may provide incomplete answers.⁸⁸ To assess the impact of nonresponse to a particular question, the survey expert should analyze the differences between those who answered and those who did not answer. Procedures to address the problem of missing data include recontacting respondents to obtain the missing answers and using a respondent's other answers to predict the missing response (i.e., imputation).⁸⁹

Survey researchers commonly use weights, even with many probability samples, to address coverage gaps and control for differential nonresponse among subgroups. Weighting adjustments can sometimes improve the accuracy of survey results.⁹⁰ Responses are weighted to reflect distributions in the target population, typically demographics.⁹¹ When the population includes all Americans, the U.S. Census or American Community Survey can provide demographic population figures that can guide how to weight the survey responses. For instance, if the population consists of 50% men but the sample contains only 40% men, then male sample respondents will be weighted to count more in computations from the sample (and women will be counted less) to better approximate the target

Scott Keeter, *Evidence About the Accuracy of Surveys in the Face of Declining Response Rates*, in *The Palgrave Handbook of Survey Research* 19–22 (David L. Vannette & Jon A. Krosnick eds., 2018), https://doi.org/10.1007/978-3-319-54395-6_4.

88. See Roger Tourangeau et al., *The Psychology of Survey Response* (2000); *California v. Ross*, 358 F. Supp. 3d 965 (N.D. Cal. 2019) (surveys were used to show that if a question on citizenship was included in the 2020 census, some individuals would be less likely to participate or answer the citizenship question, and that this refusal was likely to be higher in the Latinx community).

Kobach*, 309 F. Supp. 3d 1048, 1089 (D. Kan. 2018) (criticizing an expert for not assigning weights to their results given the differences between their sample's demographics and the expected population demographics); *California v. Ross*, 358 F. Supp. 3d 965, 984 (N.D. Cal. 2019) (commenting that the expert used weighting to balance the demographics of the sample).

population.⁹² When responses are weighted, it is crucial to be transparent about how the data were weighted, and to acknowledge that weighting reduces statistical power and, hence, the precision of the estimates.⁹³

There are three main challenges with survey weights. First, the survey expert needs to know the true proportions in the population (how many are men, aged 18–35, college educated, etc.), or the sample weights will be largely guesses. Weighting cannot compensate for lack of surveyor knowledge about the underlying distributions in the population. Second, weighting does not actually increase sample size. If a sample of forty African American respondents is weighted at 1.5 (meaning each counts as one and a half people for purposes of analysis), the size of their subsample (and consequently the number used to calculate the margin of error of that subsample) is still forty, not sixty. In fact, weighting decreases the precision of estimates, leading to larger confidence intervals. Finally, weighting cannot correct for unobserved factors. If the survey has recruited unrepresentative members of a subpopulation (for example, atypical Republicans), weighting cannot somehow make them representative. This may be a particular problem when weighting is used to substantially amplify the responses of a small number of people.⁹⁴

Precautions Taken to Ensure That Only Qualified Respondents Were Included in the Survey

In a carefully executed survey, each potential respondent is questioned on the attributes that determine their eligibility to participate in the survey. Thus, the initial questions screen potential respondents to determine if they are members of the target population of the survey (e.g., Does she own a dog? Does he live within ten miles of where he works?). The screening questions must be drafted so that they do not appeal to or deter specific groups within the target population or convey information that will influence a respondent's answers on the main survey (i.e., create a context effect). For example, if respondents must be prospective or recent purchasers of Sunshine orange juice in a trademark survey

92. The process often involves iteratively adjusting for multiple demographics. The idea is to assign an adjustment weight to each respondent such that those from underrepresented groups receive weights greater than 1 and those from overrepresented groups receive weights less than 1. There are a host of ways to weight, and caps should be placed on how much a given observation can be weighted so that one respondent does not have a grossly disproportionate effect on the outcomes. See Matthew DeBell, *Computation of Survey Weights*, in *The Palgrave Handbook of Survey Research* 519–27 (2018).

93. Thomas Piazza, *Fundamentals of Applied Sampling*, in *Handbook of Survey Research*, *supra* note 1. See also *Texas v. Holder*, 888 F. Supp. 2d 113, 131 (D.D.C. 2012) (criticizing an expert for inconsistent use of weighting).

94. Nate Cohn, *How One 19-Year-Old Illinois Man Is Distorting National Polling Averages*, N.Y. Time, Oct. 12, 2016, <https://perma.cc/76R7-J363>.

designed to assess consumer confusion with Sun Time orange juice, potential respondents might be asked to name the brands of orange juice they have purchased recently or expect to purchase in the next six months. They should not be asked specifically if they recently have purchased, or expect to purchase, Sunshine orange juice, because this may affect their responses on the survey either by implying who is conducting the survey or by supplying them with a brand name that otherwise would not occur to them.

The content of a screening questionnaire (or “screener”) can also set the context for the questions that follow. In *Pfizer, Inc. v. Astra Pharmaceutical Products, Inc.*,⁹⁵ physicians were asked a screening question to determine whether they prescribed particular drugs. The survey question that followed the screener asked, “Thinking of the practice of cardiovascular medicine, what first comes to mind when you hear the letters XL?” The court found that the screener conditioned the physicians to respond with the name of a product (a drug) rather than a function (long acting).⁹⁶

The criteria for determining whether to include a potential respondent in the survey should be objective and clearly conveyed, preferably using written instructions addressed to those who administer the screening questions. These instructions and the completed screening questionnaire should be made available to the court and the opposing party along with the interview or survey form for each respondent. Computerized administration, described below, has allowed for this to be automated.

Survey Questions and Structure

Clarity, Precision, and Lack of Bias in the Framing of the Survey Questions

Although it seems obvious that questions on a survey should be clear and precise, phrasing questions to reach that goal is often difficult. Even questions that appear clear can convey unexpected meanings and ambiguities to potential respondents. For example, the question “What is the average number of days each week you have butter?” appears to be straightforward. Yet some respondents wondered whether margarine counted as butter, and when the question was revised to include the introductory phrase “not including margarine,” the reported frequency of butter use dropped dramatically.⁹⁷

97. Floyd J. Fowler, Jr., *How Unclear Terms Affect Survey Data*, 56 Pub. Op. Q. 218, 225–26 (1992), <https://doi.org/10.1086/269312>.

When unclear questions are included in a survey, they may threaten the validity of the survey by systematically distorting responses if respondents are misled in a particular direction, or by inflating random error if respondents guess because they do not understand the question.⁹⁸ If the crucial question is sufficiently ambiguous or unclear, it may be the basis for rejecting the survey. For example, a survey was designed to assess community sentiment that would warrant a change of venue in trying a case for damages sustained when a hotel skywalk collapsed.⁹⁹ The court found that the question “Based on what you have heard, read or seen, do you believe that in the current compensatory damage trials, the defendants, such as the contractors, designers, owners, and operators of the Hyatt Hotel, should be punished?” could neither be correctly understood nor easily answered.¹⁰⁰ The court noted that the phrase “compensatory damages,” although well-defined for attorneys, was unlikely to be meaningful for laypersons.¹⁰¹

Pilot work is a standard and valuable way to improve the quality of a survey.¹⁰² When there is any doubt whether a term or phrase will be clear to respondents, researchers should pretest to assess understanding, which may include focus groups or cognitive interviewing.¹⁰³

The value of pilot work is greatest when the issues and questions in the survey differ from the issues and questions addressed in previous surveys, or when the target population differs significantly from previously surveyed populations.¹⁰⁴

100. *See id.* at 102, 103.

101. *See id.* at 103. When there is any question about whether some respondents will understand a particular term or phrase, the term or phrase should be defined explicitly in the survey.

102. *See* Jon A. Krosnick & Stanley Presser, *Questions and Questionnaire Design*, in *Handbook of Survey Research*, *supra* note 1, at 294 (“No matter how closely a questionnaire follows recommendations based on best practices, it is likely to benefit from pretesting. . . .”). *See also* Jean M. Converse & Stanley Presser, *Survey Questions: Handcrafting the Standardized Questionnaire* 51 (1986); Fred W. Morgan, *Judicial Standards for Survey Research: An Update and Guidelines*, 54 J. Mktg. 59, 64 (1990), <https://doi.org/10.1177/002224299005400104>; OMB Standards and Guidelines for Statistical Surveys, Standard 1.4, Pretesting Survey Systems (2006), <https://perma.cc/D8XZ-4UX7> (specifying that to ensure that all components of a survey function as intended, pretests of survey components should be conducted unless those components have previously been successfully fielded); American Association for Public Opinion Research, *Best Practices* (2022), <https://perma.cc/Y3HU-XCHK> (“Before fielding a survey, it is important to pretest the questionnaire.”).

103. Cognitive interviewing includes a combination of think-aloud and verbal probing techniques. Gordon B. Willis et al., *Is the Bandwagon Headed to the Methodological Promised Land? Evaluating the Validity of Cognitive Interviewing Techniques*, in *Cognition and Survey Research* 136 (Monroe G. Sirken et al. eds., 1999). *See also* Gordon B. Willis, *Cognitive Interviewing in Survey Design: State of the Science and Future Directions*, in *The Palgrave Handbook of Survey Research* 103–07 (2018). *See also* Tourangeau et al., *supra* note 88, at 326–27.

104. Ivan R. Ross, *The Use of Pilot Tests and Pretests in Consumer Surveys*, in *Trademark and Deceptive Advertising Surveys* 13, 26 (Shari Diamond & Jerre Swann eds., 2d ed. 2022).

In many pretests or pilot tests,¹⁰⁵ the proposed survey is administered to a small sample (usually between twenty-five and seventy-five)¹⁰⁶ of the same type of respondents who would be eligible to participate in the full-scale survey. Some courts have explicitly recognized the value of pretests¹⁰⁷ and that lack of pretesting may suggest a weakness in the survey.¹⁰⁸

Litigants would be more likely to conduct pilot work and disclose it in expert reports if courts recognized that pilot work can maximize the likelihood that respondents understand the questions they are being asked. Moreover, the Federal Rules of Civil Procedure may require that a testifying expert disclose pilot work that serves as a basis for the expert's opinion. The situation is more complicated when a nontestifying expert conducts the pilot work and the testifying expert learns about the pilot testing only indirectly through the attorney's advice about the relevant issues in the case. Some commentators suggest that attorneys are obligated to disclose such pilot work.¹⁰⁹

What Respondents and Interviewers Knew About the Survey Purpose and Its Sponsorship

One way to protect the objectivity of survey administration is to avoid telling respondents or interviewers who is sponsoring the survey. Respondents who know the identity of the sponsor of the survey may adjust their responses, and interviewers who know the identity of the survey's sponsor may affect results inadvertently by communicating to respondents their expectations or what they believe are the preferred responses of the survey's sponsor. To ensure objectivity in the administration of the survey, it is standard interview practice in surveys conducted for litigation to do double-blind research whenever possible: Both the interviewer and the respondent are blind to the sponsor of the survey and its

105. The terms *pretest* and *pilot test* are sometimes used interchangeably to describe pilot work done in the planning stages of research. When they are distinguished, the difference is that a pretest tests the questionnaire, whereas a pilot test generally tests proposed collection procedures as well.

106. Converse & Presser, *supra* note 102, at 69. Converse and Presser suggest that a pretest with twenty-five respondents is appropriate when the survey uses professional interviewers.

107. See, e.g., *Zippo Mfg. Co. v. Rogers Imports, Inc.*, 216 F. Supp. 670 (S.D.N.Y. 1963); *Scott v. City of New York*, 591 F. Supp. 2d 554, 560 (S.D.N.Y. 2008) (“[T]he survey went through multiple pretests in order to insure its usefulness and statistical validity.”); *Estes Park Taffy Co. v. Original Taffy Shop, Inc.*, No. 15-cv-01697-CBS, 2017 U.S. Dist. LEXIS 88113, at *9 (D. Colo. June 8, 2017).

108. *GOLO, LLC. v. Goli Nutrition, Inc.*, No.20-667-RGA, 2020 U.S. Dist. LEXIS 158508, at *28 (D. Del. Sept. 1, 2020) (including lack of pretesting in a list of potential weaknesses in an expert's method).

109. See Yvonne C. Schroeder, *Pretesting Survey Questions: The Procedural and Ethical Ramifications*, 11 Am. J. Trial Advoc. 195, 197–201 (1987).

purpose. Thus, the survey instrument provides no explicit or implicit clues about the sponsorship of the survey (e.g., a sponsor's letterhead) or the expected responses (e.g., reversing the usual order of the yes and no response boxes on a key question, potentially increasing the likelihood that *no* will be checked).¹¹⁰

Nonetheless, in some situations (e.g., on some government surveys), disclosure of the survey's sponsor to respondents (and thus to interviewers) is required. Such surveys call for an evaluation of the likely biases introduced by interviewer or respondent awareness of the survey's sponsorship. In evaluating the consequences of sponsorship awareness, it is important to consider (1) whether the sponsor has views and expectations that are apparent and (2) whether awareness is confined to the interviewers or involves the respondents. For example, if a survey concerning attitudes toward gun control is sponsored by the National Rifle Association, it is clear that responses opposing gun control are likely to be preferred. In contrast, if the survey on gun control attitudes is sponsored by the Department of Justice, the identity of the sponsor may not suggest the kinds of responses the sponsor expects or would find acceptable.¹¹¹ When a survey involves interviewers who are well-trained, their awareness of sponsorship may be a less serious threat than respondents' awareness.¹¹²

In most situations, the survey expert can follow the traditional CASRO Code of Standards and Ethics¹¹³ and promise the respondent anonymity in the interest of obtaining the most accurate and candid responses. Moreover, in most situations, there is no need to disclose the identity of the survey sponsor. In some cases, however, respondents to a survey are involved in litigation (e.g., class-action wage and hour cases) and are likely to recognize that a survey asking them questions about relevant issues (such as unpaid overtime) is being sponsored by a party to the litigation. They may even be unwilling to participate in the survey unless they are told that the attorney representing them is sponsoring it. This creates a difficult problem for survey researchers. To get an acceptable response rate, it may be necessary to reveal who is sponsoring the survey. But this revelation may incentivize respondents to adjust their answers for potential financial gain, and promising anonymity may exacerbate this issue. If the survey is conducted by a friendly party, one approach that can be used to bolster accuracy is to tell respondents

110. See *Centaur Commc'ns, Ltd. v. A/S/M Commc'ns, Inc.*, 652 F. Supp. 1105, 1111 n.3 (S.D.N.Y.) (pointing out that reversing the usual order of response choices, "yes or no," to "no or yes" may confuse interviewers as well as introduce bias), *aff'd*, 830 F.2d 1217 (2d Cir. 1987).

111. See, e.g., Stanley Presser et al., *Survey Sponsorship, Response Rates, and Response Effects*, 73 Soc. Sci. Q. 699, 701 (1992) (different responses to a university-sponsored telephone survey and a newspaper-sponsored survey for questions concerning attitudes toward the mayoral primary, an issue on which the newspaper had taken a position).

112. See, e.g., Seymour Sudman et al., *Modest Expectations: The Effects of Interviewers' Prior Expectations on Responses*, 6 Soc. Methods & Rsch. 171, 181 (1977), <https://doi.org/10.1177/004912417700600203>.

113. CASRO, *supra* note 41, § I.A.

that their responses may not be anonymous and thus that exaggeration or other inaccuracies may be detected. It is unclear what the best practice is in this case, and the survey expert should be prepared to justify their choices.

Handling Respondents with No Opinions and Reducing Respondent Guessing

Some survey respondents may have no opinion about an issue under investigation, either because they have never thought about it before or because the question mistakenly assumes a familiarity with the issue. For example, some respondents in a consumer survey may not have noticed that the commercial they are being questioned about guaranteed the quality of the product being advertised, and thus they may have no opinion on the kind of guarantee it indicated. The following three alternative question structures will affect how those respondents answer and how their responses are counted.

First, the survey can ask all respondents to answer the question (e.g., “Did you understand the guarantee offered by Clover to be a 1-year guarantee, a 60-day guarantee, or a 30-day guarantee?”). Faced with a direct question, particularly one that provides response alternatives, the respondent obligingly may supply an answer even if (in this example) the respondent did not notice the guarantee. Such answers will reflect only what the respondent can glean from the question, or they may reflect pure guessing.

Second, the survey can use a quasi-filter question to reduce guessing by providing “don’t know” or “no opinion” options as part of the question (e.g., “Did you understand the guarantee offered by Clover to be for more than a year, a year, or less than a year, or don’t you have an opinion?”).¹¹⁴ By signaling to the respondent that it is acceptable not to have an opinion, the question reduces the demand for an answer and, as a result, the inclination to hazard a guess just to comply. Respondents are more likely to choose a “no opinion” option if it is mentioned explicitly by an interviewer than if it is merely accepted when the respondent spontaneously offers it as a response. Similarly, in an online survey, explicitly providing “don’t know” as a potential response rather than accepting it only if the respondent writes it in as an “other” response can increase the use of that option. The consequence of this change in format can be substantial. Studies indicate that, although the relative distribution of the respondents selecting the *listed* choices is unlikely to change dramatically, presentation of an explicit “don’t

114. Norbert Schwarz & Hans-Jürgen Hippler, *Response Alternatives: The Impact of Their Choice and Presentation Order*, in *Measurement Errors in Surveys* 41, 45–46 (Paul P. Biemer et al. eds., 1991); *Spangler Candy Co. v. Tootsie Roll Indus., LLC*, 372 F. Supp. 3d 588, 599 (N.D. Ohio 2019) (“Because [the expert] offered a ‘Don’t Know/No Opinion’ option for each closed-ended question, I conclude the questions were not unduly suggestive or guess-inducing.”).

know” or “no opinion” alternative commonly leads to a 20% to 25% increase in the proportion of respondents selecting that response.¹¹⁵

Finally, the survey can include full-filter questions—that is, questions that lay the groundwork for the substantive question by first asking respondents if they have an opinion about the issue or happened to notice the feature that the interviewer is preparing to ask about (e.g., “Based on the commercial you just saw, do you have an opinion about how long Clover stated or implied that its guarantee lasts?”).¹¹⁶ The survey then asks the substantive question only of those respondents who have indicated that they have an opinion on the issue.

Which of these three approaches is used and the way it is used can affect the rate of “no opinion” responses that the substantive question will evoke.¹¹⁷ Respondents are more likely to say that they do not have an opinion on an issue if a full filter is used than if a quasi-filter is used.¹¹⁸ However, in maximizing respondent expressions of “no opinion,” full filters may produce an underreporting of opinions. Some evidence indicates that full-filter questions discourage respondents who actually have opinions from offering them by conveying the implicit suggestion that respondents can avoid difficult follow-up questions by saying that they have no opinion.¹¹⁹

In general, then, a survey that uses full filters provides a conservative estimate of the number of respondents holding an opinion, while a survey that uses neither full filters nor quasi-filters may overestimate the number of respondents with opinions if some respondents offering opinions are guessing. The strategy of including a “no opinion” or “don’t know” response as a quasi-filter avoids both of these extremes, although some research suggests that even a quasi-filter may discourage a substantive answer from a respondent who would be able to provide one.¹²⁰

One solution that some survey researchers use is to provide respondents with a general instruction not to guess at the beginning of an interview, rather than supplying a “don’t know” or “no opinion” option as part of the options attached to each question.¹²¹ Another approach is to eliminate the “don’t know” option and to add follow-up questions that measure the strength of the respondent’s

opinion.¹²² More generally, survey experts can conduct pilot tests or cognitive interviews to assess whether many in the population in fact lack any opinion or the relevant knowledge to arrive at an opinion. If a substantial majority of people do have an opinion, it may be appropriate to exclude a “don’t know” option and thus avoid reducing data quality by encouraging less motivated respondents to use that response. In contrast, if many people do not have formed opinions or the knowledge required to arrive at them, the option should be included.¹²³ The survey expert should be prepared to explain why the “don’t know” option was included or excluded.

Use of Open-Ended and Closed-Ended Questions

The questions that make up a survey instrument may be open-ended, closed-ended, or a combination of both. Both are valid choices in appropriate situations. Open-ended questions require the respondent to formulate and express an answer in their own words (e.g., “What was the main point of the commercial?”). Closed-ended questions provide the respondent with an explicit set of responses from which to choose; the choices may be as simple as *yes* or *no* (e.g., “Is Colby College coeducational?”¹²⁴) or as complex as a range of alternatives (e.g., “The two pain relievers have (1) the same likelihood of causing gastric ulcers; (2) about the same likelihood of causing gastric ulcers; (3) a somewhat different likelihood of causing gastric ulcers; (4) a very different likelihood of causing gastric ulcers; or (5) none of the above.”¹²⁵). When a survey involves in-person interviews, the interviewer may show the respondent these choices on a showcard that lists them.

Open-ended and closed-ended questions may elicit very different responses.¹²⁶ Most responses are less likely to be volunteered by respondents who are asked an

124. *President & Trs. of Colby College v. Colby College—N.H.*, 508 F.2d 804, 809 (1st Cir. 1975).

125. This question is based on one asked in *American Home Products Corp. v. Johnson & Johnson*, 654 F. Supp. 568, 581 (S.D.N.Y. 1987), that was found to be a leading question by the court, primarily because the choices suggested that the respondent had learned about aspirin’s and ibuprofen’s relative likelihoods of causing gastric ulcers. In contrast, in *McNeilab, Inc. v. American Home Products Corp.*, 501 F. Supp. 517, 525 (S.D.N.Y. 1980), the court accepted as nonleading the question, “Based only on what the commercial said, would Maximum Strength Anacin contain more pain reliever, the same amount of pain reliever, or less pain reliever than the brand you, yourself, currently use most often?”

126. Howard Schuman & Stanley Presser, *Question Wording as an Independent Variable in Survey Analysis*, 6 *Socio. Methods & Rsch.* 151 (1977), <https://doi.org/10.1177/004912417700600202>; Schuman & Presser, *supra* note 115, at 79–112; Converse & Presser, *supra* note 102, at 33.

open-ended question than they are to be chosen by respondents who are presented with a closed-ended question. The response alternatives in a closed-ended question may remind respondents of options that they would not otherwise consider or which simply do not come to mind as easily.¹²⁷

The advantage of open-ended questions is that they give the respondent fewer hints about expected or preferred answers. Response choices in a closed-ended question, in addition to reminding respondents of options that they might not otherwise consider, may direct the respondent away from or toward a particular response. For example, a commercial reported that in shampoo tests with more than 900 women, the sponsor's product received higher ratings than other brands.¹²⁸ According to a competitor, the commercial deceptively implied that each woman in the test rated more than one shampoo, when in fact each woman rated only one. To test consumer impressions, the survey showed the commercial and asked: "How many different brands mentioned in the commercial did each of the 900 women try?"¹²⁹ Respondents were given the choice of "one," "two," "three," "four," or "five or more." The fact that four of the five choices in the closed-ended question provided a response that was greater than one implied that the correct answer was probably more than one.¹³⁰

An open-ended question may also suggest that the answer is more than one, however. By asking "how many different brands," the question suggests (1) that the viewer should have received some message from the commercial about the number of brands each woman tried, and (2) that different brands were tried. Instead, a nonleading version of the question would have simply asked: "How many brands mentioned in the commercial did each of the 900 women try?"

127. For example, when respondents in one survey were asked, "What is the most important thing for children to learn to prepare them for life?", 62% picked "to think for themselves" from a list of five options, but only 5% spontaneously offered that answer when the question was open-ended. Schuman & Presser, *supra* note 115, at 104–07. An open-ended question presents the respondent with a free-recall task, whereas a closed-ended question is a recognition task. Recognition tasks in general reveal higher performance levels than recall tasks. Mary M. Smyth et al., *Cognition in Action* 25 (1987). In addition, there is evidence that respondents answering open-ended questions may be less likely to report some information that they would reveal in response to a closed-ended question when that information seems self-evident or irrelevant.

128. See *Vidal Sassoon, Inc. v. Bristol-Myers Co.*, 661 F.2d 272, 273 (2d Cir. 1981).

129. This was the wording of the closed-ended question in the survey discussed in *Vidal Sassoon*, 661 F.2d at 275–76.

130. Ninety-five percent of the respondents who answered the closed-ended question in the plaintiff's survey said that each woman had tried two or more brands. The open-ended question was never asked. *Vidal Sassoon*, 661 F.2d at 276. Norbert Schwarz, *Assessing Frequency Reports of Mundane Behaviors: Contributions of Cognitive Psychology to Questionnaire Construction*, in *Research Methods in Personality and Social Psychology* 98 (Clyde Hendrick & Margaret S. Clark eds., 1990), suggests that respondents often rely on the range of response alternatives as a frame of reference when they are asked for frequency judgments. See, e.g., Roger Tourangeau & Tom W. Smith, *Asking Sensitive Questions: The Impact of Data Collection Mode, Question Format, and Question Context*, 60 Pub. Op. Q. 275, 292 (1996), <https://doi.org/10.1086/297751>.

rather than “How many *different* brands” did each try? Similarly, an open-ended question that asks, “[W]hich company or store do you think puts out this shirt?” indicates to the respondent that the appropriate answer is the name of a company or store. The question would be leading if the respondent would have considered other possibilities (e.g., an individual or website if the question had not provided the frame of a company or store).¹³¹ Thus, the wording of a question, open-ended or closed-ended, can be leading, and the degree of suggestiveness of each question must be considered in evaluating the objectivity of a survey.

Closed-ended questions have some additional potential weaknesses that arise if the choices are not constructed properly. If the respondent is asked to choose one or more responses from among several choices, the response or responses chosen will be meaningful only if the list of choices is exhaustive—that is, if the choices cover all possible answers a respondent might give to the question. If the list of possible choices is incomplete, a respondent may be forced to choose one that does not express their opinion.¹³² The omission of a relevant choice option can only be partially attenuated by telling respondents explicitly that they are not limited to the choices presented, because most respondents nevertheless will select an answer from among the listed ones.¹³³

One form of closed-ended question format that can produce some distortion is the popular agree/disagree, true/false, or yes/no question. Although this format is appealing because it is easy to write and score these questions and their responses, the format is also seriously problematic. With its simplicity comes acquiescence: “[T]he tendency to endorse any assertion made in a question, regardless of its content,” is a systematic source of bias that has produced an inflation effect of 10% across a number of studies.¹³⁴ Only when control groups or control questions are added to the survey design, or when multiple items are counterbalanced, can this question format provide reasonable response estimates.¹³⁵

One challenge with open-ended responses is translating them into meaningful numeric metrics.¹³⁶ Imagine that a researcher asks respondents what they think about self-driving cars. If the researcher were interested in the prevalence and nature of safety concerns about self-driving cars, they would need a mechanism for translating the varied open-ended responses into a set of binary values: each possible safety concern was listed or not. This requires developing a list of different types of concerns such that each concern is unique (e.g., can malfunction, inability of driver to have control, etc.), and each has a text label. The list

136. Groves et al., *supra* note 77, at 332–44.

should also be exhaustive (cover all written answers) and include both a code for responses that do not refer to safety issues (e.g., reflects technological evolution) and also a code for nonresponses (e.g., left blank). In some cases, a respondent may give more than one answer, and that response should be coded in more than one category (e.g., “can malfunction and has no human control”). The researcher should be transparent on the construction of the coding system, which may be based on a priori categories or constructed based on the answers the respondents have given. Moreover, unless there are substantial data privacy concerns, the full open-ended answers should be made available to the other party for analysis.¹³⁷

The coding system should be clear enough that different coders would assign the same responses to the same categories in the vast majority of cases. In most academic research, this is accomplished by having multiple coders who are blind to the hypotheses and purpose of the project, giving them detailed instructions and training, and measuring inter coder reliability. Although this approach constitutes the best way to ensure reliable coding, because the raw data underlying the coding and the coding itself are made available to the court and the opposing party in litigation, the court and opposing party can directly examine and evaluate the appropriateness of the coding. It is therefore not uncommon for coding of simple measures in litigation to dispense with having multiple blind coders (though the resultant coding should be given close scrutiny).¹³⁸

Although many courts prefer open-ended questions on the ground that they are likely to be less leading, the value of any open-ended or closed-ended question depends on the information it conveys in the question and, in the case of closed-ended questions, in the choices provided. Open-ended questions are more appropriate when the survey is attempting to gauge what comes first to a respondent’s mind, but closed-ended questions are more suitable for assessing choices between well-identified options or obtaining ratings on a clear set of alternatives.

137. Mary B. Vardigan & Peter Granda, *Archiving, Documentation, and Dissemination*, in *Handbook of Survey Research* 707 (Peter V. Marsden & James D. Wright eds., 2d ed. 2010); see also section titled “Disclosure and Reporting” *infra*. Partial redaction of a response might be appropriate if the response was individually identifiable and the content sensitive. For example, a complaint about a named supervisor in an employment survey would fall in this category.

138. See, e.g., *Revlon Consumer Prods. Corp. v. Jennifer Leather Broadway, Inc.*, 858 F. Supp. 1268, 1276 (S.D.N.Y. 1994) (inconsistent scoring and subjective coding led court to find survey so unreliable that it was entitled to no weight), *aff’d*, 57 F.3d 1062 (2d Cir. 1995); *Rock v. Zimmerman*, 959 F.2d 1237, 1253 n.9 (3d Cir. 1992) (court found that responses on a change-of-venue survey incorrectly categorized respondents who believed the defendant was insane as believing he was guilty); *Coca-Cola Co. v. Tropicana Prods., Inc.*, 538 F. Supp. 1091, 1094–96 (S.D.N.Y.) (plaintiff’s expert stated that respondents’ answers to the open-ended questions revealed that 43% of respondents thought Tropicana was portrayed as fresh-squeezed; the court’s own tabulation found no more than 15% believed this was true), *rev’d on other grounds*, 690 F.2d 312 (2d Cir. 1982); see also *Cumberland Packing Corp. v. Monsanto Co.*, 140 F. Supp. 2d 241 (E.D.N.Y. 2001) (court examined verbatim responses that respondents gave to arrive at a confusion level substantially lower than the level reported by the survey expert).

Use of Probes to Clarify Ambiguous or Incomplete Answers

When questions allow respondents to express their opinions in their own words, some of the respondents may give ambiguous or incomplete answers. If the survey is administered online, some probes (e.g., “Why did you choose that answer?”) can be programmed into the survey instrument and automatically administered as part of the survey. If interviewers are asking the questions, they may be instructed to probe to obtain a more complete response or clarify the meaning of the ambiguous response. Interviewers should be instructed what clarification, if any, they can provide. The record should reflect both what the respondent said initially, what the interviewer said in the attempt to get or provide clarification, and how the respondent answered the probe; this information will allow the court and the opposing party to evaluate whether the probe affected the views expressed by the respondent.

If the survey involves interviewers who are permitted to administer follow-up questions, they must be given explicit instructions on when they should probe and what they should say in probing.¹³⁹ Standard probes used to draw out all that the respondent has to say (e.g., “Any further thoughts?”; “Anything else?”; “Can you explain that a little more?”; or “Could you say that another way?”) are relatively noncontroversial and can be programmed into an online survey instrument. But probing should be limited. Persistent continued requests for further responses to the same or nearly identical questions may convey the idea to the respondent that they have not yet produced the “right” answer, particularly if the probes are administered by a live interviewer.¹⁴⁰

Potential Order Effects

The order in which questions are asked on a survey and the order in which response alternatives are provided in a closed-ended question can influence the answers.¹⁴¹ For example, although asking a general question before a more specific

139. Floyd J. Fowler, Jr. & Thomas W. Mangione, *Standardized Survey Interviewing: Minimizing Interviewer-Related Error* 41–42 (1990), <https://doi.org/10.4135/9781412985925>.

140. *See, e.g., Johnson & Johnson-Merck Consumer Pharms. Co. v. Rhone-Poulenc Rorer Pharms., Inc.*, 19 F.3d 125, 135 (3d Cir. 1994); *Am. Home Prods. Corp. v. Procter & Gamble Co.*, 871 F. Supp. 739, 748 (D.N.J. 1994).

141. *See* Schuman & Presser, *supra* note 115, at 23, 56–74; Krosnick & Presser, *supra* note 102, at 278–81. In *R.J. Reynolds Tobacco Co. v. Loew's Theatres, Inc.*, 511 F. Supp. 867, 875 (S.D.N.Y. 1980), the court recognized the biased structure of a survey that disclosed the tar content of the cigarettes being compared before questioning respondents about their cigarette preferences. Not surprisingly, respondents expressed a preference for the lower tar product. *See also* *E. & J. Gallo Winery v. Pasatiempos Gallo, S.A.*, 905 F. Supp. 1403, 1409–10 (E.D. Cal. 1994) (court recognized

question on the same topic is unlikely to affect the response to the specific question, reversing the order of the questions may influence responses to the general question. As a rule, then, surveys are less likely to be subject to order effects if the questions move from the general (e.g., “What do you recall being discussed in the advertisement?”) to the specific (e.g., “Based on your reading of the advertisement, what companies do you think the ad is referring to when it talks about rental trucks that average five miles per gallon?”).¹⁴²

The mode of questioning can influence the form that an order effect takes. When respondents are shown response alternatives visually, as in mail surveys and self-administered online surveys or in face-to-face interviews when respondents are shown a card containing response alternatives, they are more likely to select the first choice offered (a primacy effect).¹⁴³ In contrast, when response alternatives are presented orally, as in telephone surveys, respondents are more likely to choose the last choice offered (a recency effect).¹⁴⁴ Although these effects are typically small, no general formula is available that can adjust values to correct for order effects, because the size and even the direction of the order effects may depend on the nature of the question being asked and the choices being offered. To control for order effects, the order of the response choices in a survey should be rotated, randomized, or counterbalanced,¹⁴⁵ so that no response alternative will have an inflated chance of being selected because of its position.

Appropriate Inclusion of Control Groups, Control Questions, or Other Comparisons

Many surveys are designed not simply to describe attitudes, beliefs, or reported behaviors, but to determine the source of those attitudes, beliefs, or behaviors. That is, the purpose of the survey is to test a causal proposition. For example, how does a trademark or the content of a commercial affect respondents’ perceptions or understanding of a product or commercial? Thus, the question is not merely whether consumers hold inaccurate beliefs about Product A, but whether exposure to the commercial misleads the consumer into thinking that Product A

that earlier questions referring to playing cards, board or table games, or party supplies, such as confetti, increased the likelihood that respondents would include these items in answers to the questions that followed).

142. This question was accepted by the court in *U-Haul International, Inc. v. Jartran, Inc.*, 522 F. Supp. 1238, 1249 (D. Ariz. 1981), *aff’d*, 681 F.2d 1159 (9th Cir. 1982).

143. Krosnick & Presser, *supra* note 102, at 280.

144. *Id.*

145. See, e.g., *Winning Ways, Inc. v. Holloway Sportswear, Inc.*, 913 F. Supp. 1454, 1465–67 (D. Kan. 1996) (failure to rotate the order in which the jackets were shown to the consumers led to reduced weight for the survey); *Procter & Gamble Pharms., Inc. v. Hoffmann-La Roche, Inc.*, No. 06 Civ. 0034 (PAC), 2006 U.S. Dist. LEXIS 64363 (S.D.N.Y. Sept. 6, 2006).

is a superior pain reliever. Yet if consumers already believe, before viewing the commercial, that Product A is a superior pain reliever, a survey that simply records consumers' impressions after they view the commercial may reflect those preexisting beliefs rather than impressions produced by the commercial.

Some surveys attempt to reduce the impact of preexisting impressions on respondents' answers by instructing respondents to focus solely on the stimulus as a basis for their answers. Thus, the survey includes a preface (e.g., "based on the commercial you just saw") or directs the respondent's attention to the mark at issue (e.g., "these stripes on the package"). Such efforts are likely to be only partially successful. It is often difficult for respondents to identify accurately the source of their impressions.¹⁴⁶ The more routine the idea being examined in the survey, the more likely it is that the respondent's answer is influenced by (1) preexisting impressions; (2) general expectations about what commercials typically say (e.g., the product being advertised is better than its competitors); or (3) guessing, rather than by the actual content of the commercial message or the trademark being evaluated. A similar limitation occurs when respondents are asked to explain why they chose a particular response: they can justify their choice, but may not be able to report accurately what actually led them to make that choice.

With respondents randomly assigned to one or more appropriate comparison conditions, the survey expert can draw clear causal inferences about the influence of the stimulus.¹⁴⁷ In the simplest version of such a survey-experiment (as discussed above), respondents are assigned randomly to one of two conditions.¹⁴⁸ For example, respondents assigned to the experimental condition view an allegedly deceptive commercial, and respondents assigned to the control condition view the same commercial with the allegedly deceptive material removed or an alternative commercial that does not contain the allegedly deceptive material.¹⁴⁹

146. See Richard E. Nisbett & Timothy D. Wilson, *Telling More Than We Can Know: Verbal Reports on Mental Processes*, 84 *Psych. Rev.* 231 (1977), <https://doi.org/10.1037/0033-295X.84.3.231>.

147. See Shari S. Diamond, *Using Psychology to Control Law: From Deceptive Advertising to Criminal Sentencing*, 13 *L. & Hum. Behavior* 239, 244–46 (1989), <https://doi.org/10.1007/BF01067028>; Jacob Jacoby & Constance Small, *Applied Marketing: The FDA Approach to Defining Misleading Advertising*, 39 *J. Mktg.* 65, 68 (1975), <https://doi.org/10.1177/002224297503900413>. See also R. Charles Henn, *Why Ask Why? A Critical Assessment of an Historical Survey Artifact*, 113 *Trademark Rep.* 772, 773–76 (2023).

148. Random assignment should not be confused with random selection. When respondents are assigned randomly to different treatment groups (e.g., respondents in each group watch a different commercial), the procedure ensures that within the limits of sampling error the two groups of respondents will be equivalent, on average, except for the different treatments they receive. Respondents selected for a mall intercept study, and not from a probability sample, may be assigned randomly to different treatment groups. Random selection, in contrast, describes the method of selecting a sample of respondents in a probability sample. See section titled "The Sample as a Reflection of the Relevant Characteristics of the Population" above.

149. This alternative commercial could be a "tombstone" advertisement that includes only the name of the product or a more elaborate commercial that does not include the claim at issue.

Respondents in both the experimental and control groups answer the same set of questions about the allegedly deceptive message. The effect of the commercial's allegedly deceptive message is evaluated by comparing the responses made by the experimental group members with those of the control group members. If 40% of the respondents in the experimental group responded indicating a belief in the deceptive claim, whereas only 8% of the respondents in the control group gave that response, the difference between 40% and 8% (within the limits of sampling error¹⁵⁰) can be attributed to the allegedly deceptive commercial.

A survey-experimental design with an appropriate control group can account for more than preexisting beliefs.¹⁵¹ Other sources of systematic and random error can influence responses to survey questions. Thus, if a respondent is asked "Have you heard of a security company named Titan Alarm?" some individuals will say they have, even if they have not. A control group can help address this type of error as well; this and other background noise should have produced similar response levels in the experimental and control groups, so comparing average scores in those groups should control for those sources of error. In addition, a leading question may cause participants to be more likely to endorse or reject a particular statement. But if respondents who viewed the allegedly deceptive commercial respond differently than respondents who viewed the control commercial, the difference cannot be merely the result of a leading question, because both groups answered the same question. The ability to evaluate the effect of the wording of a particular question makes the control group design particularly useful in assessing responses to closed-ended questions,¹⁵² which may encourage guessing or particular responses. Thus, the focus is not on the absolute response level in the experimental group, but on the difference between the responses from the experimental group and those from the control group.¹⁵³

In designing a survey-experiment, the expert should select a stimulus for the control group that shares as many characteristics with the experimental stimulus as possible, with the key exception of the characteristic whose influence is being assessed.¹⁵⁴ Although a survey with an imperfect control group may provide

150. For a discussion of sampling error, see the glossary to the current chapter and David H. Kaye and Hal S. Stern, *Reference Guide on Statistics and Research Methods*, in this manual.

151. For a more extensive discussion of controls, see Shari Seidman Diamond, *Control Foundations: Rationale and Approaches*, in *Trademark and Deceptive Advertising Surveys* 239 (Shari Diamond & Jerre Swann eds., 2d ed. 2022).

152. The Federal Trade Commission has long recognized the need for some kind of control for closed-ended questions, although it has not specified the type of control that is necessary. See *In re Stouffer Foods Corp.*, 118 F.T.C. 746, 808–09 (Sept. 26, 1994).

153. See, e.g., *CytoSport, Inc. v. Vital Pharms., Inc.*, 617 F. Supp. 2d 1051, 1075–76 (E.D. Cal. 2009) (net confusion level of 25.4% obtained by subtracting 26.5% in the control group from 51.9% in the test group).

154. See, e.g., *Skechers USA, Inc. v. Vans, Inc.*, No. CV-07-01703 DSF (PLAx), 2007 WL 4181677, at *8–9 (C.D. Cal. Nov. 20, 2007) (in trade dress infringement case, control stimulus should have retained design elements not at issue); *Procter & Gamble Pharms., Inc. v. Hoffman-LaRoche*,

better information than a survey with no control group at all, the choice of an appropriate control group requires care and should influence the admissibility of the survey and the weight that the survey receives. For example, a control stimulus should not be less attractive than the experimental stimulus if the survey is designed to measure how familiar the experimental stimulus is to respondents, because attractiveness may affect perceived familiarity.¹⁵⁵ Nor should the control stimulus share with the experimental stimulus the feature whose impact is being assessed. If the control stimulus in a case of alleged trademark infringement is itself a likely source of consumer confusion, for example, reactions to the experimental and control stimuli may not differ because both cause respondents to express a similar level of confusion.¹⁵⁶ In an extreme case, an inappropriate control may do nothing more than control for the effect of the nature or wording of the survey questions (e.g., acquiescence).¹⁵⁷ That generally will not be enough to rule out other explanations for different or similar responses to the experimental and control stimuli. Finally, it may sometimes be appropriate to have more than one control group to assess precisely what is causing the response to the experimental stimulus (e.g., in the case of an allegedly deceptive ad, whether it is a misleading graph or a misleading claim by the announcer, or in the case of allegedly infringing trade dress, whether it is the style of the font used or the coloring of the packaging).¹⁵⁸

Courts have increasingly come to recognize the central role that control groups play in evaluating causal claims.¹⁵⁹ Litigants have taken the cue, and most

Inc., No. 06 Civ 0034 (PAC), 2006 U.S. Dist. LEXIS 64363, at *87–88 (S.D.N.Y. Sept. 6, 2006) (in false advertising action, disclaimer was inadequate substitute for appropriate control group).

Mar. 31, 2022) (“[W]ithout a control group it is impossible to establish cause and effect.”); *Longoria v. Million Dollar Corp.*, No. 18–CV–02266–PAB–NYW, 2021 U.S. Dist. LEXIS 38478, at *27 (D. Colo. Mar. 2, 2021) (survey excluded because “a causal study . . . requires a control group”); *SmithKline Beecham Consumer Healthcare, L.P. v. Johnson & Johnson-Merck*, No. 01 Civ. 2775 (DAB), 2001 U.S. Dist. LEXIS 7061, at *37–39 (S.D.N.Y. June 1, 2001) (survey to assess implied falsity of a commercial not probative in the absence of a control group);

experts recognize the need to submit a survey with a control group (i.e., a survey-experiment) if they wish to make a causal claim and rule out other explanations for the responses to the survey questions.¹⁶⁰

A less common control methodology is a control question. Rather than administering a control stimulus to a separate group of respondents, the survey asks all respondents one or more control questions along with the question about the product or service at issue. This technique is used to evaluate whether a brand name is generic. The genericness survey presents survey respondents with a series of product or service names and asks them to indicate in each instance whether they believe the name is a brand name or a common name. By showing that 68% of respondents considered Teflon a brand name (a proportion similar to the 75% of respondents who recognized the acknowledged trademark Jell-O as a brand name, and markedly different from the 13% who thought aspirin was a brand name), the makers of Teflon demonstrated that their respondents understood the difference between brands and product categories (so-called common names) and that the Teflon mark at issue was perceived as a brand name; they retained their trademark.¹⁶¹ It is crucial to control for order effects in such designs.

The issue of appropriate comparisons is especially salient in the context of conjoint analysis, which has been used in some patent and false-advertising cases. In cases of patent infringement, the plaintiff must submit an estimate of the damages produced by the defendant's infringement. When the infringement involves a multicomponent product, the plaintiff must apportion damages to determine the value of the patented component at issue.¹⁶² Similarly, in class actions involving false advertising, damages depend on the value to consumers that can be attributed to the deceptive portion of the advertisement.¹⁶³ To estimate these damages, survey experts have increasingly turned to conjoint analysis. When done

Am. Home Prods. Corp. v. Procter & Gamble Co., 871 F. Supp. 739, 749 (D.N.J. 1994) (discounting survey results based on failure to control for participants' preconceived notions); *ConAgra, Inc. v. Geo. A. Hormel & Co.*, 784 F. Supp. 700, 728 (D. Neb. 1992) ("Since no control was used, the . . . study, standing alone, must be significantly discounted."), *aff'd*, 990 F.2d 368 (8th Cir. 1993).

160. William, R. Shadish et al., *Experimental and Quasi-Experimental Designs for Generalized Causal Inference* (2002); James N. Druckman, *Experimental Thinking: A Primer on Social Science Experiments* (2022).

161. *E.I. DuPont de Nemours & Co. v. Yoshida Int'l, Inc.*, 393 F. Supp. 502, 526–27 & n.54 (E.D.N.Y. 1975); *see also* *Donchez v. Coors Brewing Co.*, 392 F.3d 1211, 1218 (10th Cir. 2004) (respondents evaluated eight brand and generic names in addition to the disputed name); *Reinalt-Thomas Corp. v. Mavis Tire Supply, LLC*, 391 F. Supp. 3d 1261, 1271–73 (N.D. Ga. 2019). A similar approach is used in assessing secondary meaning. *See, e.g., T-Mobile US, Inc. v. AIO Wireless LLC*, 991 F. Supp. 2d 888 (S.D. Tex. 2014).

162. For example, in *Apple, Inc. v. Samsung Electronics Co., Ltd.*, No. 11-CV-01846-LHK, 2014 U.S. Dist. LEXIS 29721 (N.D. Cal. Mar. 6, 2014), Apple used a conjoint survey to isolate the costs associated with Samsung's alleged patent infringement regarding iPhone and iPad features.

163. *E.g., Price v. L'Oréal U.S., Inc.*, No. 17-Civ-614 (LGS), 2020 Dist. LEXIS 153255 (S.D.N.Y. Aug. 24, 2020).

well, conjoint analysis can provide useful information, but there are many decisions made in designing a conjoint analysis that can undermine reliability and bias the resulting estimates.¹⁶⁴

In contrast to a survey that asks respondents directly how much they would be willing to pay (WTP) for a given feature or attribute of a product, a task that may be difficult for consumers, a conjoint survey-experiment typically presents respondents with choices between products with different randomly assigned profiles consisting of combinations of features.¹⁶⁵ Suppose the survey is designed to determine the value of a patented component of a washing machine that shuts off the machine automatically in response to overflow (automatic shutoff). The respondent will be presented with a series of choices between washing machines that may, for example, vary on brand (LG, General Electric, Whirlpool), number of settings (eight, ten, twelve), color (white, beige, stainless steel), capacity (3, 4, 4.5 cu. ft.), and price (\$400, \$598, \$648). Each respondent makes their choice in response to several sets (profiles) of products where the attributes (e.g., brand, number of settings) have randomly assigned levels (e.g., LG, General Electric, Whirlpool; eight, ten, twelve) for each profile. A regression is then used to compute part worths, the value that each feature adds to the total product. As in any survey, it is crucial to identify the appropriate universe of individuals likely to purchase the product. For instance, it would be inappropriate to conduct the washing machine conjoint survey on college students who can be assumed to have no intention of purchasing a washing machine in the near future.

Although conjoint analysis offers a potentially useful method for assessing WTP for a single feature of a multifeature product as a result of its experimental nature, the design of the profiles can lead to misleading results. The first issue is what features to include in the product profiles. If important features of the product are omitted (e.g., in the washing machine example, whether the machine is front-loading or top-loading) and the profiles include predominantly less important features e.g., door shape as round versus square, maximum spin speed), the estimated values for the component of interest are likely to be inflated.¹⁶⁶ Thus, an important preliminary step by the expert designing a conjoint analysis is to assess the importance of the various features of the product.¹⁶⁷

164. Bernard Chao & Sydney Donovan, *Does Conjoint Analysis Reliably Value Patents?*, 58 Am. Bus. L.J. 225 (2021), <https://doi.org/10.1111/ablj.12182>. See also Suneal Bedi & David Reibstein, *Damaged Damages: Errors in Patent and False Advertising Litigation*, 73 Ala. L. Rev. 385 (2021); David Franklyn & Adam Kuhn, *The Problem of Mop Heads in the Era of Apps: Toward More Rigorous Standards of Value Apportionment in Contemporary Patent Law*, 98 J. Pat. & Trademark Off. Soc'y 182 (2016).

165. Some conjoint analyses ask respondents for rankings or ratings, but asking them to make choices is the most generally accepted approach because it is more reflective of what they would do in the marketplace. Bedi & Reibstein, *supra* note 164, at 399 nn.76 & 77.

166. Bedi & Reibstein, *supra* note 164.

167. In *Apple, Inc. v. Samsung Electronics Co.*, No. 11-CV-01846-LHK, 2014 U.S. Dist. LEXIS 29721 (N.D. Cal. Mar. 6, 2014), the conjoint survey used by Apple included seven attributes;

An additional challenge in designing a conjoint survey is to ensure that the features are described clearly and accurately, while simultaneously not drawing substantially more attention to features than consumers might naturally devote to them in the real world. This allows respondents to understand what each feature is and ensures that their understanding matches the meanings and definitions used in the case.¹⁶⁸ If a feature is unclear (e.g., electronic spinner), the respondent cannot make an informed decision that takes that feature into account. It also is essential, as with any survey, that the population be carefully chosen.¹⁶⁹

Further, if the conjoint analysis is being used to identify prices, there is some controversy on how to capture supply-side aspects of the pricing that reflect the market. Given that market conditions may have changed due to the infringement, this can present a challenge.¹⁷⁰

Samsung critiqued it for excluding other important attributes such as brand name and battery life. In *MacDougall v. American Honda Motor Co.*, No. 20–56060, 2021 U.S. App. LEXIS 37780 (9th Cir. Dec. 21, 2021), the court of appeals reversed after the district court had rejected the use of a conjoint survey for “the reduction of the amount of vehicle attributes in the final survey from thirty-three to four The more limited a consumer’s choice of vehicle features, the more artificially inflated the importance of the remaining features. . . .” *MacDougall v. Am. Honda Motor Co.*, No. SACV 17–1079 JGB, 2020 U.S. Dist. LEXIS 166786, at *22 (C.D. Cal., Sept. 11, 2020). Including thirty-three attributes may be too many, but at issue here was the lack of justification for the four chosen (it was unclear how the pretest led to choosing those four). On appeal, the court found that the attributes chosen go to weight and not admissibility; however, the lack of a reasonable basis for attribute choice can seriously undermine the value of the analysis. There often is an inevitable tradeoff between overwhelming respondents with too many attributes and capturing those that are most important. The expert should explicitly provide reasons for the specific inclusion and exclusion of attributes.

168. For instance, in *Price*, the court rejected an analysis that used the term “Kerantindose Pro-Keratin+Silk” to isolate the impact of “Kerantindose” and “Pro-Keratin” since it includes “+Silk.” 2020 Dist. LEXIS 153255. In *Allegra v. Luxottica Retail North America*, 341 F.R.D. 373 (E.D.N.Y. Dec. 13, 2021), the court rejected the use of a conjoint survey that it said failed to properly describe the allegedly fraudulent omission in the advertising.

169. In *Cardenas v. Toyota Motor Corp.*, 418 F. Supp. 3d 1090 (S.D. Fla. 2019), the case involved a defect in a nonhybrid Toyota. The defendants argued that hybrid purchasers should not have been included. The crucial question was whether purchasers of hybrid cars would differ in their assessments from nonhybrid purchasers, which the court determined was a question of weight rather than admissibility. The analysis of subgroup effects is tricky because respondent subgroups may differ in the evaluations of comparison points and thus analyses needed to account for those distinctions; see Thomas Leeper et al., *Measuring Subgroup Preferences in Conjoint Experiments*, 28 Pol. Analysis, 207–21 (2020), <https://doi.org/10.1017/pan.2019.30>.

170. J. Gregory Sidak & Jeremy O. Skog, *Using Conjoint Analysis to Apportion Patent Damages*, 25 Fed. Cir. Bar J. 581 (2016). More generally, how to estimate supply side considerations is a matter of some debate. In *Cardenas v. Toyota Motor Corp.*, the court acknowledged differing opinions on whether the appropriate pricing information should emulate actual market prices and sales during the class period or the probable prices and sales in the situation where the relevant attribute took on the value that was under contention (the relevant attribute in this case was an odor emitted from a car’s HVAC system). The court ruled that the approach to incorporating supply-side information does not go to admissibility, but could affect weight. See also *Colangelo v. Champion*

Some aspects of conjoint analysis are controversial. These include whether it is always necessary to give respondents the choice of declining to select any of the products offered in the profiles presented (i.e., “none of the above”). If the relevant population includes people who may prefer not to make the purchase, inclusion is warranted, but note there is a danger that respondents may choose the “no purchase” option to avoid assessing the products.¹⁷¹ Similarly, there is some dispute about how many features of a product can be listed (e.g., can respondents process and respond to more than seven features?).

As with any survey, the expert should be prepared to explain the choices made in constructing the survey design. In light of the complexity of conjoint survey experimental designs and the controversial nature of some of the decisions the expert needs to make, a detailed explanation of those decisions is warranted to guide the court in evaluating whether the survey is admissible (or what weight to give it).

Benefits and Limitations Associated with the Mode of Data Collection Used in the Survey

Four primary methods have traditionally been used to collect survey data: (1) in-person interviews, (2) telephone interviews, (3) mail questionnaires, and (4) internet surveys. The choice of any data collection method for a survey should be justified by its strengths and weaknesses.

Common across in-person, telephone, and internet surveys is the use of computer-assisted techniques.¹⁷² The interviewer conducting a computer-assisted interview (CAI), whether by telephone (CATI) or face-to-face (computer-assisted personal interviewing, or CAPI), follows the computer-generated script for the interview and enters the respondent’s answers as the interview proceeds. A primary advantage of CATI and other CAI procedures is that skip patterns can be built into the program. If, for example, the respondent answers “yes” when asked whether she has ever been the victim of a burglary, the computer will generate further questions about the burglary; if she answers

Petfoods USA, Inc., No. 6:18-CV-122 (LEK/ML), 2022 U.S. Dist. LEXIS 60489, at *25 (N.D.N.Y. Mar. 31, 2022) (“[T]here is a legitimate difference of opinions, both among judges and experts, about the significance of supply side information in calculating loss of value.”) (citing *In re Fisher-Price Rock ‘n’ Play Sleeper Mktg.*, 567 F. Supp. 3d 406, 415 (W.D.N.Y. 2021)).

171. Daniel McFadden, *Stated Preference Methods and Their Applicability to Environmental Use and Non-use Valuations*, in *Contingent Valuation of Environmental Goods: A Comprehensive Critique*, 153–87 (Daniel McFadden & Kenneth Train eds., 2017). See also Moshe Ben-Akiva et al., *Foundations of Stated Preference Elicitation: Consumer Behavior and Choice-Based Conjoint Analysis*, 10 *Founds. & Trends in Econometrics* 1 (2019), <http://dx.doi.org/10.1561/08000000036>.

172. Wright & Marsden, *supra* note 1, at 13–14.

no, the program will automatically skip the follow-up burglary questions. Interviewer errors in following the skip patterns are therefore avoided, making CAI procedures particularly valuable when the survey involves complex branching and skip patterns.¹⁷³ CAI procedures also can be used to control for order effects by having the program rotate the order in which the questions or choices are presented and facilitate the implementation of complex experiments with many conditions by randomly generating many potential factors at once.¹⁷⁴

CAI procedures also include audio computer-assisted self-interviewing (ACASI) in which the respondent listens to recorded questions over the telephone or reads questions from a computer screen while listening to recorded versions of them through headphones. The respondent then answers verbally or directly on a keypad. ACASI procedures are particularly useful for collecting sensitive information (e.g., illegal drug use and other HIV risk behavior).¹⁷⁵ This is also useful in face-to-face interviews where the respondent can avoid having to reveal their (potentially sensitive) answer to the interviewer since they enter it themselves.

All CAI procedures require additional planning to take advantage of the potential for improvements in data quality. When a CAI protocol is used in a survey presented in litigation, the party offering the survey should supply for inspection the computer program that was used to generate the interviews. Moreover, CAI procedures do not eliminate the need for close monitoring of interviews to ensure that interviewers are accurately reading the questions in the interview protocol and accurately entering the respondent's answers (or that the respondent is paying attention and using the program correctly in entering their own answers).

In-Person Interviews

Although costly, in-person interviews generally are the preferred method of data collection, especially when visual materials must be shown to the respondent under controlled conditions. When the questions are complex and the interviewers are skilled, in-person interviewing provides the maximum opportunity to clarify or probe. Unlike a mail survey, in-person, telephone, and web-based surveys have the capability to implement complex skip sequences (in which the respondent's answer determines which question will be asked next) and the power to control the order in which the respondent answers the questions. In-person

173. Willem E. Saris, *Computer-Assisted Interviewing* 20, 27 (1991).

174. See, e.g., *Intel Corp. v. Advanced Micro Devices, Inc.*, 756 F. Supp. 1292, 1296–97 (N.D. Cal. 1991) (survey designed to test whether the term *386* as applied to a microprocessor was generic used a CATI protocol that tested reactions to five terms presented in rotated order).

175. See, e.g., P.C. Cooley et al., *Automating Telephone Surveys: Using T-ACASI to Obtain Data on Sensitive Topics*, 16 *Computs. in Hum. Behav.* 1 (2000), <https://perma.cc/L94R-AXKY>.

interviewers also can directly verify who is completing the survey, a check that is unavailable in mail and web-based surveys. As described below in the “Selection and Training of the Interviewers” section, appropriate interviewer training, as well as monitoring of the implementation of interviewing, is necessary if these potential benefits are to be realized. Objections to the use of in-person interviews arise primarily from their high cost or, on occasion, from evidence of inept or biased interviewers. The latter concern is somewhat mitigated by computer assistance, described above.

Telephone Interviews

Telephone surveys offer a comparatively fast and lower-cost alternative to in-person surveys and can be particularly useful when the population is large and geographically dispersed. Telephone interviews (unless supplemented with mailed materials) should be used only when it is unnecessary to show the respondent any visual materials. Thus, an attorney may present the results of a telephone survey of jury-eligible citizens in a motion for a change of venue in order to provide evidence that community prejudice raises a reasonable suspicion of potential jury bias.¹⁷⁶ Similarly, potential confusion between a restaurant called McBagel’s and the McDonald’s fast-food chain was established in a telephone survey. Over objections from defendant McBagel’s that the survey did not show respondents the defendant’s print advertisements, the court found likelihood of confusion based on the survey, noting that “by soliciting audio responses [the telephone survey] was closely related to the radio advertising involved in the case.”¹⁷⁷ In contrast, when words are not sufficient because, for example, the survey is assessing reactions to the trade dress or packaging of a product that is alleged to promote confusion, a telephone survey alone does not offer a suitable vehicle for questioning respondents.¹⁷⁸

176. See, e.g., *State v. Baumruk*, 85 S.W.3d 644 (Mo. 2002) (overturning the trial court’s decision to ignore a survey that found about 70% of county residents remembered the shooting that led to the trial, and that of those who had heard about the shooting, 98% believed that the defendant was either definitely guilty or probably guilty); *State v. Erickstad*, 620 N.W.2d 136, 140 (N.D. 2000) (denying change-of-venue motion based on media coverage, concluding that “defendants [need to] submit qualified public opinion surveys, other opinion testimony, or any other evidence demonstrating community bias caused by the media coverage”). For a discussion of surveys used in motions for change of venue, see Neal Miller, *Facts, Expert Facts, and Statistics: Descriptive and Experimental Research Methods in Litigation, Part II*, 40 Rutgers L. Rev. 467, 470–74 (1988); National Jury Project, *Jurywork: Systematic Techniques* (2d ed. 2008).

177. *McDonald’s Corp. v. McBagel’s, Inc.*, 649 F. Supp. 1268, 1278 (S.D.N.Y. 1986).

178. See *Thompson Med. Co. v. Pfizer Inc.*, 753 F.2d 208 (2d Cir. 1985); *Inc. Publ’g Corp. v. Manhattan Mag., Inc.*, 616 F. Supp. 370 (S.D.N.Y. 1985), *aff’d without op.*, 788 F.2d 3 (2d Cir. 1986).

In evaluating the sampling used in a telephone survey, the trier of fact should consider:

1. Whether (when prospective respondents are not business personnel) some form of random-digit dialing¹⁷⁹ was used instead of or to supplement telephone numbers obtained from telephone directories, because a high percentage of all residential telephone numbers in some areas may be unlisted;¹⁸⁰
2. What types of phones were included—that is, landlines, cell phones, or both. Over ninety-six percent of American adults live in households with cell phones, leading to a shift in sampling procedures that sometimes rely only on cell phones.¹⁸¹
3. Whether the sampling procedures required the interviewer to sample within the household or business, instead of allowing the interviewer to administer the survey to any qualified individual who answered the telephone;¹⁸² and
4. Whether interviewers were required to call back multiple times at several different times of the day and on different days to increase the likelihood of contacting individuals or businesses with different schedules and, as a result, to reduce nonresponse levels.¹⁸³

Telephone surveys that do not include these procedures may not provide precise measures of the characteristics of a representative sample of respondents, but may be adequate for providing rough approximations. The vulnerability of the survey depends on the information being gathered. More elaborate procedures are advisable for achieving a representative sample of respondents if the survey instrument requests information that is likely to differ for individuals with listed

179. “Random-digit” dialing provides coverage of households with both listed and unlisted telephone numbers by generating numbers at random from the sampling frame of all possible telephone numbers. James M. Lepkowski, *Telephone Sampling Methods in the United States*, in *Telephone Survey Methodology* 81–91 (Robert M. Groves et al. eds., 1988).

180. Studies comparing listed and unlisted household characteristics show some important differences. *Id.* at 76.

181. Between 2% and 3% of the U.S. population has only landline access. Stephen J. Blumberg & Julian V. Luke, *Wireless Substitution: Early Release of Estimates from the National Health Interview Survey, January–June 2020* (U.S. Dep’t of Health & Hum. Servs., Feb. 2021), at 4, <https://perma.cc/5TSM-V88J>; see also Courtney Kennedy et al., *Implications of Moving Public Opinion Surveys to a Single-Frame Cell-Phone Random-Digit-Dial Design*, 82 Pub. Op. Q. 279 (2018), <https://doi.org/10.1093/poq/nfy016> (“Analysis of more than 250 survey questions show[ed] that when landlines [were] excluded, estimates change[d] by less than one percentage point, on average.”).

182. This is a consideration only if the survey is sampling individuals. If the survey is seeking information on the household, more than one individual may be able to answer questions on behalf of the household.

183. This applies equally to in-person interviews.

telephone numbers versus individuals with unlisted telephone numbers, individuals rarely at home versus those usually at home, or groups who are more versus less likely to rely on landlines or cell phones.

The report submitted by a survey expert who conducts a telephone survey should specify:

- The procedures that were used to identify potential respondents, including both the procedures used to select the telephone numbers that were called and the procedures used to identify the qualified individual to question;
- The number of telephone numbers for which no contact was made; and
- The number of contacted potential respondents who refused to participate in the survey (and how many follow-up attempts were made).¹⁸⁴

Like computer-assisted personal interviewing (CAPI),¹⁸⁵ computer-assisted telephone interviewing (CATI) facilitates the administration and data entry of large-scale surveys.¹⁸⁶ A computer protocol may be used to generate and dial telephone numbers as well as to guide the interviewer.

Mail Questionnaires

In general, mail surveys tend to be substantially less costly than both in-person and telephone surveys.¹⁸⁷ Procedures that raise response rates for mail surveys include multiple mailings, highly personalized communications, prepaid return envelopes, incentives or gratuities, assurances of confidentiality, first-class outgoing postage, and follow-up reminders.¹⁸⁸

A mail survey will not produce a high rate of return unless the recruitment process begins with an accurate and up-to-date list of names and addresses for

184. Additional disclosure and reporting features applicable to surveys in general are described in the section titled “Completeness and Accuracy of All Relevant Information in the Survey Report” below.

Op. Q.* 66, 71 (1995), <https://doi.org/10.1086/269458>; see generally Don A. Dillman et al., *Internet, Mail, and Mixed-Mode Surveys: The Tailored Design Method* (3d ed. 2009).

the target population. Even if the sampling frame is adequate, the sample may be unrepresentative if some individuals are more likely to respond than others (i.e., differential nonresponse). For example, if a survey targets a population that includes individuals with literacy problems, these individuals will tend to be underrepresented. Open-ended questions are generally of limited value on a mail survey because they depend entirely on the respondent to answer fully and do not provide the opportunity to probe or clarify unclear answers. Similarly, if eligibility to answer some questions depends on the respondent's answers to previous questions, such skip sequences may be difficult for some respondents to follow. Finally, because respondents complete mail surveys without supervision, survey personnel are unable to prevent respondents from discussing the questions and answers with others before completing the survey or to control the order in which respondents answer the questions. Although skilled design of questionnaire format, question order, and the appearance of the individual pages of a survey can minimize these problems, if it is crucial to have respondents answer questions in a particular order, a mail survey cannot be depended on to provide adequate data.

Internet Surveys

Over the past two decades there has been a massive increase in the use of internet surveys. One recent analysis found that the overwhelming majority of expert reports reviewed in the trademark and false advertising space were based on online surveys.¹⁸⁹ As of 2024, “an estimated” 96% of U.S. adults have access to the internet, including 99% of those between the ages of eighteen and forty-nine.¹⁹⁰ Although concerns remain about internet survey administration, and especially internet administration through online panels, many of those concerns can be mitigated through quality-control measures.

The benefits of internet administration are clear. The cost of conducting surveys online is a small fraction of the cost of hiring human interviewers to speak with potential respondents; the speed with which a researcher can find, screen, and survey hundreds of respondents online is far greater than in non-internet-based environments (e.g., via the mail); and there is less risk of interviewer bias and error when questions are presented by computer on a screen and respondents

189. Kugler & Henn, *supra* note 71, at 293–94.

190. Pew Rsch. Ctr., Internet, Broadband Fact Sheet (Nov. 2024), <https://www.pewinternet.org/fact-sheet/internet-broadband>. Of those age fifty to sixty-four, 98% had internet access. The sixty-five-plus group was lower at 90%. The same research shows that 79% of the U.S. population has broadband internet at home, while an additional 15% do not have broadband but do have internet access via smartphone. In 2011, only 79% of Americans had internet access. *Id.*

type their own responses.¹⁹¹ Further, internet surveys may be particularly appropriate when the goal of the researcher is to simulate everyday commercial conduct that now frequently occurs online.

Computer administration also allows careful randomization of survey items, branching survey logic, and the display of complicated visual and auditory stimuli. In addition, the structure permits the survey to remind, or even require, the respondent to answer a question before the next question is presented. A further advantage of computer-administered surveys over interviewer-administered surveys is that they eliminate interviewer error because the computer presents the questions and the respondent records their own answers.

One major question for internet surveys is the adequacy of the sampling approach. The evaluation of this will depend on the type of internet survey involved, because the samples used in web-based surveys vary in fundamental ways. At one extreme is the list-based web survey. This web-based survey is sent to a closed set of potential respondents drawn from a list that consists of the email addresses of the target individuals (e.g., all employees at a company where each employee has a known email address). Here there is no reason not to use the tools of probability sampling, described above.

At the other extreme is the self-selected web pseudosurvey in which web users in general, or those who happen to visit a particular website, are all invited to express their views on a topic and they participate simply by volunteering. Participants are very likely to self-select on the basis of the nature of the topic, substantially distorting the results. These self-selected pseudosurveys resemble reader polls published in magazines and do not meet standard criteria for legitimate surveys admissible in court.¹⁹² Occasionally, proponents of such polls tout the large number of respondents as evidence of the weight the results should be given, but the size of the sample cannot cure the likely participation bias in such voluntary polls.¹⁹³

Between these two extremes is a large category of web-based survey approaches that researchers have developed to address concerns about sampling bias and nonresponse error. Many of these use the professionally managed non-probability panels described above. These companies recruit diverse panels of respondents. Some respondents come from other well-traveled sites; others are

191. Reg Baker et al., *Research Synthesis: AAPOR Report on Online Panels*, 74 Pub. Op. Q. 711, 739 (2010), <https://doi.org/10.1093/poq/nfq048> (“Overall, the research reported here generally suggests higher data quality for computer administration than for oral administration.”).

192. See, e.g., *Merisant Co. v. McNeil Nutritionals, LLC*, 242 F.R.D. 315 (E.D. Pa. 2007) (report on results from AOL “instant poll” excluded).

193. See Mick P. Couper, *Web Surveys: A Review of Issues and Approaches*, 64 Pub. Op. Q. 464, 480–81 (2000), <https://doi.org/10.1086/318641> (a self-selected web survey conducted by the National Geographic Society through its website attracted 50,000 responses; a comparison of the Canadian respondents with data from the Canadian General Social Survey telephone survey conducted using random digit dialing showed marked differences on a variety of response measures).

pursued because their qualifications make them valuable for marketing studies. When a researcher contracts with a panel provider, the company can sift through its database to invite an appropriate mix of people to participate in a given survey. Those invited do not know the topic of the survey in advance (i.e., they are not opting in based on the topic). The final sample can be balanced to match desired demographics either through recruitment quotas or through response weighting.¹⁹⁴ The researcher using such data should obtain the procedures used by the vendor to ensure the quality of the data and make it available to the opposing party and the trier of fact. For example, what steps did the vendor take to minimize fraudulent respondents¹⁹⁵ and minimize duplicative respondents? Did the vendor themselves outsource the sampling?¹⁹⁶

Generally, a researcher conducting an internet survey must take active steps to ensure an honest and attentive sample. On the most technical level, use of CAPTCHA¹⁹⁷ questions can weed bots out from the sample; panel providers can audit their panels to verify participant demographics, or at least check that self-reported demographics are consistent over time,¹⁹⁸ and survey platforms, which host the actual survey questions, can use cookies and other means to prevent multiple submissions from the same person or computer.¹⁹⁹ As with many other issues in the online space, there is constant evolution in the fraud-detection domain. A researcher should ensure that they, and their panel provider, are using current best practices to detect fraudulent responses and be prepared to explain how these responses work and their known impact.

Moving beyond the technology and into the survey itself, the researcher should take further steps to ensure an attentive sample. In the trademark space, a

197. CAPTCHA is an acronym for “Completely Automated Public Turing test to tell Computers and Humans Apart.” The respondent may be asked to decipher a set of distorted letters or complete a categorization task that would be difficult to automate.

198. Courtney Kennedy et al., *Pew Rsch. Ctr., Evaluating Online Nonprobability Surveys* 36 (May 2, 2016), <https://perma.cc/VJ4L-BTJF>:

Most panels are double opt-in, meaning potential panelists first enter an email address and then respond to an email sent from the panel provider in order to confirm the email account. Depending on the vendor, other quality control features include IP address validation and digital fingerprinting, which guards against a single person having multiple accounts in a given panel.

199. “The most common technique for identifying duplicate respondents is digital fingerprinting. Specific applications of this technique vary, but they all involve the capture of technical information about a respondent’s IP address, browser, software settings, and hardware configuration to construct a unique ID for that computer.” Baker et al., *supra* note 191, at 756 (emphasis omitted).

few checks are particularly common.²⁰⁰ One method of measuring attention in a traditional likelihood-of-confusion survey is to include a free-response question prompting participants to explain a prior answer. If the participant responds with gibberish or irrelevant responses, they are either not paying attention or not taking the survey seriously.²⁰¹ A similar check is possible in a Teflon survey testing whether a mark is generic.²⁰² There, a participant is asked whether each in a list of terms is a “brand name” or a “common name.” A participant who responds that all terms are brand names or all are common names, that is, who gives a straight-line response, should be excluded. They either do not understand the task or are not trying to do it. For surveys aimed at purchasers of a particular product, it is common to ask which, of a list of products, they have bought in the past X months. A researcher can include nonexistent products on those lists, screening out people who implausibly claim to have purchased them.

The science behind these efforts to ensure honest responding is ever-evolving. A researcher should employ some of the above mechanisms in any online survey, and should be prepared to justify their choices. A court should not treat the methods described here as a comprehensive checklist, however. No particular check is independently necessary or sufficient, but use of appropriate checks is required to ensure quality when the respondent is completing the survey online.

Mixed-Format Surveys

A final approach to data collection does not depend on a single mode, but instead involves a mixed-mode approach. By combining modes, the survey design may increase the likelihood that all sampled members of the target population will be contacted. For example, a person without a landline may be reached by mail or email. Similarly, response rates may be increased if members of the target population are more likely to respond to one mode of contact versus another. For example, a person unwilling to be interviewed by phone may respond to a written or email contact. If a mixed-mode approach is used, the questions and structure of the questionnaires are likely to differ across modes, and the expert should be prepared to address the potential impact of mode on the answers obtained.²⁰³

Surveys Involving Interviewers

Selection and Training of the Interviewers

When interviews are used to question survey respondents, the results are trustworthy only if “sound interview procedures were followed by competent interviewers.”²⁰⁴ Properly trained interviewers receive detailed written instructions on everything they are to say to respondents, any stimulus materials they are to use in the survey, and how they are to complete the interview form. These instructions should be made available to the opposing party and to the trier of fact. Interviewers should be instructed to record verbatim the respondent’s answers, to indicate explicitly whenever they repeat a question to the respondent, and to record any statements they make to the respondent or supplementary questions they ask.

Interviewers require training to ensure that they can follow directions in administering the survey questions and employ optimal interviewing techniques (e.g., pausing to give the respondent enough time to answer, resisting invitations to express their own beliefs or opinions, knowing when and how to use probes). Although procedures vary, there is evidence that interviewer performance suffers with less than a day of training in general interviewing skills and techniques for new interviewers.²⁰⁵ Additional training is needed when the interviewer is responsible for last-stage sampling (i.e., selecting the particular respondents to be interviewed in an unbiased fashion). Further, in-person interviews also should be conducted in situations without distractions and where others cannot overhear the answers. Failure to follow these dictates was one ground used by a court to reject as inadmissible a survey that purported to demonstrate consumer confusion.²⁰⁶

Some compromises may be accepted when surveys must be conducted swiftly. In trademark and deceptive advertising cases, the plaintiff’s usual request is for a preliminary injunction, because a delay means irreparable harm. Nonetheless, careful instruction and training of interviewers who administer the survey, as well as monitoring and validation to ensure quality control²⁰⁷ and complete disclosure of the methods used for all of the procedures followed, are crucial

206. *Toys “R” Us*, 559 F. Supp. at 1204 (some interviews apparently were conducted in a bowling alley; some interviewees waiting to be interviewed overheard the substance of the interview while they were waiting).

207. See section titled “Procedures Used to Ensure and Determine That the Survey Was Administered to Minimize Error and Bias” below.

elements that, if compromised, seriously undermine the trustworthiness of any survey.

Procedures Used to Ensure and Determine That the Survey Was Administered to Minimize Error and Bias

Three methods are used to ensure that the survey instrument was implemented in an unbiased fashion and according to instructions. The first, monitoring the interviews as they occur, is done most easily when telephone surveys are used, but can occur in the field via recordings (if respondents consent to it). Second, validation of interviews occurs when respondents in a sample are recontacted to ask whether the initial interviews took place and to determine whether the respondents were qualified to participate in the survey. The standard procedure for validation of in-person interviews is to telephone a random sample of about 10% to 15% of the respondents.²⁰⁸ This validation procedure does not determine whether the initial interview as a whole was conducted properly, but it warns interviewers that their work is being checked and can detect gross failures in the administration of the survey. In computer-assisted interviews, further validation information can be obtained from the timings that can be automatically recorded when an interview occurs.

A third way to verify that the interviews were conducted properly is to examine the work done by each individual interviewer. By reviewing the interviews and individual responses recorded by each interviewer and comparing patterns of response across interviewers, researchers can identify any response patterns or inconsistencies that warrant further investigation. When interviewers conduct the survey, the identity of the interviewer (or a unique code) should be included in the data provided to the opposing party and trier of fact.

When a survey is conducted at the request of a party for litigation rather than in the normal course of business, a heightened standard for validation checks may be appropriate. Thus, independent validation of a random sample of interviews by a third party rather than by the field service that conducted the interviews increases the trustworthiness of the survey results.²⁰⁹

208. See, e.g., *Davis v. S. Bell Tel. & Tel. Co.*, No. 89-2839-CIV-NESBITT, 1994 U.S. Dist. LEXIS 13257, at *16 (S.D. Fla. Feb. 1, 1994); *Nat'l Football League Props., Inc. v. N.J. Giants, Inc.*, 637 F. Supp. 507, 515 (D.N.J. 1986).

209. In *Rust Environment & Infrastructure, Inc. v. Teunissen*, 131 F.3d 1210, 1218 (7th Cir. 1997), the court criticized a survey in part because it “did not comport with accepted practice for independent validation of the results.”

Accuracy of Data Entry

Analyzing the results of a survey requires that the data obtained on each sampled element be recorded and often coded before the results can be tabulated and processed. Procedures for data entry should include checks for completeness, checks for reliability and accuracy, and rules for resolving inconsistencies. Accurate data entry is maximized when responses are verified by duplicate entry and comparison, and when data-entry personnel are unaware of the purposes of the survey.

The need for these checks and rules to control mistakes in data entry is particularly great when data collected from survey respondents are combined with data on those same respondents obtained from institutional databases or records (e.g., a survey of jurors is combined with court data on their jury service).²¹⁰ In such cases, both data entries and matches need to be closely scrutinized.

Disclosure and Reporting

Early Disclosure About the Survey Methodology and Results

Objections to the definition of the relevant population, the method of selecting the sample, and the wording of questions generally are raised for the first time when the results of the survey are presented. By that time, it is often too late to correct methodological deficiencies that could have been addressed in the planning stages of the survey. The plaintiff in a trademark case²¹¹ submitted a set of proposed survey questions to the trial judge, who ruled that the survey results would be admissible at trial while reserving the question of the weight the evidence would be given.²¹² The Seventh Circuit called this approach a commendable procedure and suggested that it would have been even more desirable if the parties had “attempt[ed] in good faith to agree upon the questions to be in such a survey.”²¹³

210. See generally Jan Van den Broeck et al., *Data Cleaning: Detecting, Diagnosing, and Editing Data Abnormalities*, 2 PLoS Med 2(10): e267, <https://doi.org/10.1371/journal.pmed.0020267>. See also Mary R. Rose & Marc A. Musick, *How Can You Tell if There Is a Crisis? Data and Measurement Challenges in Assessing Jury Representation*, 98 Chicago-Kent L. Rev. 35, 42 (2023).

211. *Union Carbide Corp. v. Ever-Ready, Inc.*, 392 F. Supp. 280, 291 (N.D. Ill. 1975), *rev'd*, 531 F.2d 366 (7th Cir. 1976).

212. Before trial, the presiding judge was appointed to the court of appeals, so the case was tried by another district court judge.

213. *Union Carbide*, 531 F.2d at 386. On one occasion, the Seventh Circuit recommended filing a motion in limine, asking the district court to determine the admissibility of a survey based on an examination of the survey questions and the results of a preliminary survey before the party undertakes the expense of conducting the actual survey. *Piper Aircraft Corp. v. Wag-Aero, Inc.*,

The *Manual for Complex Litigation, Second*, recommended that parties be required, “before conducting any poll, to provide other parties with an outline of the proposed form and methodology, including the particular questions that will be asked, the introductory statements or instructions that will be given, and other controls to be used in the interrogation process.”²¹⁴ The parties then were encouraged to attempt to resolve any methodological disagreements before the survey was conducted.²¹⁵ Although this passage in the second edition of the *Manual* has been cited with apparent approval,²¹⁶ the prior agreement that the *Manual* recommends has occurred rarely, and the *Manual for Complex Litigation, Fourth*, recommends, but does not advocate requiring, prior disclosure and discussion of survey plans.²¹⁷ As the *Manual* suggests, however, early disclosure can enable the parties to raise prompt objections that may permit corrective measures to be taken before a survey is completed.²¹⁸

Rule 26 of the Federal Rules of Civil Procedure requires extensive disclosure of the basis of opinions offered by testifying experts. However, Rule 26 does not produce disclosure of all survey materials, because parties are not obligated to disclose information about nontestifying experts. Parties considering whether to commission or use a survey for litigation are not obligated to present a survey that produces unfavorable results. Prior disclosure of a proposed survey instrument places the party that ultimately would prefer not to present the survey in the position of presenting damaging results or leaving the impression that the results are not being presented because they were unfavorable. Anticipating such a situation, parties do not decide whether an expert will testify until after the results of the survey are available.

Nonetheless, courts can encourage early disclosure and discussion even if they do not lead to agreement between the parties. In *McNeilab, Inc. v. American Home Products Corp.*,²¹⁹ Judge William C. Conner encouraged the parties to submit their survey plans for court approval to ensure their evidentiary value; the plaintiff did

741 F.2d 925, 929 (7th Cir. 1984). On another occasion, the parties jointly developed a survey administered by a neutral third-party survey firm. *Scott v. City of New York*, 591 F. Supp. 2d 554, 560 (S.D.N.Y. 2008) (survey design, including multiple pretests, negotiated with the help of the magistrate judge).

so and altered its research plan based on Judge Conner's recommendations. Parties can anticipate that changes consistent with a judicial suggestion are likely to increase the weight given to, or at least the prospects of admissibility of, the survey.²²⁰

Completeness and Accuracy of All Relevant Information in the Survey Report

The completeness of the survey report is one indicator of the trustworthiness of the survey and the professionalism of the expert who is presenting the results of the survey. The American Association for Public Opinion Research (AAPOR), a professional organization that brings together producers and users of survey data, offers standards for disclosure to be reported with any survey results.²²¹ The following list, which draws on the AAPOR guidelines, describes the elements that a survey report generally should include:

1. The purpose of the survey, its research sponsor, and those who conducted the research;
2. A definition of the target population;
3. A description of how the sample was recruited, including the method of selection (and how much of the population is covered); population quotas used, if any; respondent compensation, if any; the method (mode) of interview; the number of callbacks; respondent eligibility or screening criteria and method; and other pertinent information (e.g., the name of the vendor, if used);
4. A description of the results of sample implementation, including the number of
 - a. potential respondents contacted,
 - b. potential respondents not reached,
 - c. noneligibles,
 - d. refusals,
 - e. incomplete interviews or terminations, and
 - f. completed interviews and final sample size;
5. The dates of data collection;
6. The exact wording of the questions used, including a copy of the actual questionnaire (and screenshots of the questionnaire as viewed by

220. Larry C. Jones, *Developing and Using Survey Evidence in Trademark Litigation*, 19 Memphis St. U. L. Rev. 471, 481 (1989).

221. AAPOR also provides professional ethics guidelines as well as a transparency initiative where survey organizations can be certified as publicly disclosing their basic research methods and making them public, <https://perma.cc/4GPB-7QKK>.

respondents if administered electronically), interviewer instructions, and visual exhibits, with any cross-condition variations or randomizations marked;²²²

7. A description of any weighting or estimating procedures used;
8. A description of data-processing procedures (e.g., validity checks such as measures of the time respondents took to complete the survey, any data-imputation procedures, criteria for removing any responses);
9. Estimates of the sampling error, where appropriate (i.e., in probability samples);
10. Statistical tables clearly labeled and identified regarding the source of the data, including the number of raw cases forming the base for each table, row, or column;
11. Copies of interviewer instructions, validation results, and code books, including coding instructions for free-response data;²²³ and
12. Acknowledgment of limitations to the survey.

As a general rule, any research should provide such information or explain why doing so is not possible. Additional information to include in the survey report may depend on the nature of sampling design. For example, reported response rates along with the exact time each interview occurred may assist in evaluating the likelihood that nonresponses biased the results. In a survey designed to assess the duration of employee pre-shift activities, workers were approached as they entered the workplace; records were not kept on refusal rates or the timing of participation in the study. Thus, it was impossible to rule out the plausible hypothesis that individuals who arrived early for their shift with more time to spend on pre-shift activities were more likely to participate in the study.²²⁴

222. The questionnaire itself can often reveal important sources of bias. See *Marria v. Broadus*, 200 F. Supp. 2d 280, 289 (S.D.N.Y. 2002) (court excluded survey sent to prison administrators based on questionnaire that began, “We need your help. We are helping to defend the NYS Department of Correctional Service in a case that involves their policy on intercepting Five-Percenter literature. Your answers to the following questions will be helpful in preparing a defense.”).

223. Failure to supply this information substantially impairs a court’s ability to evaluate a survey. *In re Prudential Ins. Co. of Am. Sales Pracs. Litig.*, 962 F. Supp. 450, 532 (D.N.J. 1997) (citing the first edition of this manual). *But see Fla. Bar v. Went for It, Inc.*, 515 U.S. 618, 626–28 (1995), in which a majority of the Supreme Court relied on a summary of results prepared by the Florida Bar from a consumer survey purporting to show consumer objections to attorney solicitation by mail. In a strong dissent, Justice Kennedy, joined by three other justices, found the survey inadequate based on the document available to the court, pointing out that the summary included “no actual surveys, few indications of sample size or selection procedures, no explanations of methodology, and no discussion of excluded results . . . no description of the statistical universe or scientific framework that permits any productive use of the information the so-called Summary of Record contains.” *Id.* at 640 (Kennedy, J., dissenting).

224. See *Chavez v. IBP, Inc.*, No. CT-01-5093-RHW, 2004 U.S. Dist. LEXIS 28837 (E.D. Wash. Aug. 18, 2004).

Researchers should also ask, and disclose, whether respondents have previously participated in similar prior surveys. Many nonprobability samples come from vendors with online panels where respondents participate in multiple surveys over time. There also are vendors who have established analogous online panels with probability samples.²²⁵ Some evidence suggests that repeat respondents from these panels differ from fresh sample draws.²²⁶ Vendors often do not provide information on prior participation—something about which a researcher can inquire prior to using a given vendor. Even if not, researchers can, on their own, attempt to identify “professional respondents” and consider whether they might bias inferences (e.g., by measuring prior participation and evaluating its effect on outcomes).²²⁷ If the expert asks participants whether they have participated in previous studies on the same topic, or obtains that information from other sources, the results obtained from the experienced and naive participants can be compared. Currently, many experts take the sensible approach of simply excluding participants who report having completed similar prior surveys. Regardless, researchers should always disclose prior participation and its possible effects or be explicit that such information does not exist and explain why it was not obtained.²²⁸

When the presenting party has access to the raw data from a survey, that data should generally be made available to opposing counsel upon request. This dataset should include responses from all participants whose data were ultimately used in the original expert’s report and also all participants whose data were excluded by the original expert for reasons of quality after the completion of the survey, with an indication of why they were excluded (i.e., data-processing procedures).²²⁹ If a researcher wishes to exclude unusually fast and slow responses, they should disclose this in the report and provide the data from those respondents as well.²³⁰ This permits an opposing expert to rerun statistical analyses and determine if any debatable analytic choices made by the original expert had substantial effects on the report’s conclusions.

225. Online Panel Research: A Data Quality Perspective (Mario Callegaro et al, eds., 2014).

226. Andrew Halpern-Manners & John Robert Warren, *Panel Conditioning in Longitudinal Studies: Evidence From Labor Force Items in the Current Population Survey*, 49 *Demography* 1499 (2012), <https://doi.org/10.1007/s13524-012-0124-x>.

227. D. Sunshine Hillygus et al., *Professional Respondents in Nonprobability Online Panels*, in *Online Panel Research: A Data Quality Perspective* 219–37 (2014).

228. K.H. Jamieson et al., *Protecting the Integrity of Survey Research*, 2 *PNAS Nexus* 1 (2023), <https://doi.org/10.1093/pnasnexus/pgad049>. More generally, these authors supplement AAPOR’s code by suggesting researchers should provide details on question order, details on respondent attrition (i.e., dropping out of the survey), and so on.

229. For example, an expert may exclude respondents who responded with gibberish to free-response items or who completed the survey much more quickly than did other participants.

230. The issue of completion time-based exclusions is explored at greater length in Kugler & Henn, *supra* note 71, at 305–06. At present, there is no agreed-upon standard for identifying “too fast” responses; most researchers appear to be using rules of thumb (for example, excluding those who took less than one third the median time). *Id.*

The public (and, presumably, also judges) sometimes express concern that surveys are not sufficiently reliable, generally citing polling accuracy in recent elections.²³¹ Election pollsters have the unenviable task of modeling a changing electorate's intended behavior in a circumstance where it matters a great deal whether the correct answer is 49% support or 51% support. Other surveys do not require this level of precision relative to a specified standard (i.e., greater than 50%). Rather, the relevant estimate the survey is seeking to reflect is whether approximately 20% of people (vs. 40%, 60%, or even 5%) in the target market are confused by a given advertisement. Thus, the accuracy of a survey estimate should be assessed in light of the degree of precision needed for the context.

Though transparency is very important, some information must be removed from data files before they are shared beyond the survey expert to protect participant confidentiality. All identifying information, such as the respondent's name, address, and telephone number, should be omitted. In the case of internet surveys, it is appropriate to also remove the participant's panel ID number, IP address, and precise geolocation information; these might all be linked to the participant's identity.²³² Keeping the survey duration and survey start time in the file may aid analysis, however, and will not compromise participant anonymity in most cases.

Greater efforts to promote participant anonymity are appropriate in cases where the population surveyed is small or otherwise susceptible to easy reidentification. If a survey is conducted of a workplace, for example, it may be that the total population numbers only in the hundreds. The identity of a respondent of any given age, ethnicity, and gender may therefore be narrowed down to one of only a few possibilities.²³³ Much greater care should be taken to protect participant anonymity in such cases. Possibilities include omitting data fields that the opposing expert does not expect to use in their own analyses, or restricting access

231. See, e.g., Scott Keeter et al., Pew Rsch. Ctr., *What 2020's Election Poll Errors Tell Us About the Accuracy of Issue Polling* (Mar. 2, 2021), <https://perma.cc/LDF9-KUWK> (commenting on this concern and evaluating it). For a discussion of the accuracy of 2020 polling, see American Association of Public Opinion Research, *Task Force on 2020 Pre-Election Polling: An Evaluation of the 2020 General Election Polls*, <https://perma.cc/64K9-GVDJ> (not reaching firm conclusions, but suggesting that this may have been due to greater nonresponse among Trump voters and difficulty in accounting for new voters in screening).

232. IP addresses are sometimes used to detect whether individuals took the survey more than once. If so, shared data should indicate which respondents shared an IP address but should generally not include the IP address itself.

233. This problem also arises in the case of privacy statutes such as HIPAA and FERPA, where deidentified data can be shared but identifiable data is tightly restricted. The Department of Education reviews a number of questions that may be relevant to a school or workplace survey in their FERPA guidance, <https://perma.cc/CCD3-47Y8> (updated May 2013).

to the data to ensure that it is not shared beyond the opposing expert—and particularly not with the ultimate client.²³⁴

The respondents questioned in a survey generally do not testify in legal proceedings and are unavailable for cross-examination. Indeed, one of the advantages of a survey is that it avoids a repetitious and unrepresentative parade of witnesses. To verify that interviews occurred with qualified respondents, standard survey practice includes validation procedures,²³⁵ the results of which should be included in the survey report.

Conflicts may arise when an opposing party asks for survey respondents' names and addresses so that they can re-interview some respondents. The party introducing the survey or the survey organization that conducted the research generally resists supplying such information.²³⁶ Professional surveyors as a rule promise confidentiality to increase participation rates and encourage candid responses although, to the extent that identifying information is collected, such promises may not effectively prevent a lawful inquiry. Because failure to extend confidentiality may bias both the willingness of potential respondents to participate in a survey and their responses, the professional standards for survey researchers generally prohibit disclosure of respondents' identities. "The use of survey results in a legal proceeding does not relieve the Survey Research Organization of its ethical obligation to maintain in confidence all Respondent-identifiable information or lessen the importance of Respondent anonymity."²³⁷ Although no surveyor–respondent privilege currently is recognized, the need for surveys and the availability of other means to examine and ensure their trustworthiness argue for deference to legitimate claims for confidentiality in order to avoid seriously compromising the ability of surveys to produce accurate information.²³⁸ In

234. In the case of a workplace survey, the client might well be the current employer of the survey participant.

P. 26(c) giving court the authority to enter

general, the better approach is for the opposing party to conduct their own survey rather than re-interrogate the participants in the previous one.

Concluding Observations

As this chapter has shown, judges have a variety of factors to consider when determining whether a survey should be admitted and how much weight it should be given. The *Manual for Complex Litigation, Fourth (MCL4)*, published in 2004, suggested a set of relevant factors for judges to evaluate.²³⁹ In the past twenty years since the *MCL4* was published, survey methods have evolved (e.g., with the growth of internet and other computer technology, and recognition of the importance of survey-experimental methodology for causal inference), but these factors remain important. Thus, we close by presenting an updated list that clarifies and builds on the list of factors presented in the *MCL4*.²⁴⁰

Relevant factors include whether:

- the population was properly chosen and defined;
- the sampling frame and the sample itself were representative of that population;
- the data and details on data collection were fully and accurately reported;
- the survey questions asked were clear and not leading;
- the survey was conducted by qualified persons following proper procedures;
- the data were analyzed following accepted statistical principles;
- statements about causal relationships were supported by sufficient evidence about causality; and
- the results were presented in accordance with statistical standards.²⁴¹

“any order which justice requires to protect a party or persons from annoyance, embarrassment, oppression, or undue burden or expense”) (citation omitted).

239. MCL 4th, *supra* note 41, § 11.493.

240. The *Manual for Complex Litigation* distinguished between factors to be considered regarding admissibility and factors to be considered in assigning weight. As all of the factors can affect either admissibility or weight, depending on their quality, we have combined them in one set.

241. These include, where appropriate, information on sampling error and confidence intervals.

Glossary of Terms

The following terms and definitions were adapted from a variety of sources, including *Handbook of Survey Research* (Peter H. Rossi et al. eds., 1st ed. 1983; Peter V. Marsden & James D. Wright eds., 2d ed. 2010); *Measurement Errors in Surveys* (Paul P. Biemer et al. eds., 1991); Willem E. Saris, *Computer-Assisted Interviewing* (1991); Seymour Sudman, *Applied Sampling* (1976).

branching. A questionnaire structure that uses the answers to earlier questions to determine which set of additional questions should be asked (e.g., citizens who report having served as jurors on a criminal case are asked different questions about their experiences than citizens who report having served as jurors on a civil case).

CAI (computer-assisted interviewing). A method of conducting interviews in which an interviewer asks questions and records the respondent's answers by following a computer-generated protocol.

CAPI (computer-assisted personal interviewing). A method of conducting face-to-face interviews in which an interviewer asks questions and records the respondent's answers by following a computer-generated protocol.

CATI (computer-assisted telephone interviewing). A method of conducting telephone interviews in which an interviewer asks questions and records the respondent's answers by following a computer-generated protocol.

closed-ended question. A question that provides the respondent with a list of choices and asks the respondent to choose from among them.

cluster sampling. A sampling technique allowing for the selection of sample elements in groups or clusters, rather than on an individual basis; it may significantly reduce field costs and may increase sampling error if elements in the same cluster are more similar to one another than are elements in different clusters.

confidence interval. An indication of the probable range of error associated with a sample value obtained from a probability sample.

conjoint survey. Survey-experiment designed to identify and estimate the causal effects of many treatment components simultaneously by using an orthogonal, fractional factorial design.

context effect. When a previous question influences the way the respondent perceives and answers a later question.

convenience sample. A sample of elements selected because they were readily available.

coverage error. Any inconsistencies between the sampling frame and the target population.

double-blind research. Research in which the respondent and the interviewer are not given information that will alert them to the anticipated or preferred pattern of response.

full-filter question. A question asked of respondents to screen out those who do not have an opinion on the issue under investigation before asking them the question proper.

mall intercept survey. A survey conducted in a mall or shopping center in which potential respondents are approached by a recruiter (intercepted) and invited to participate in the survey.

margin of error. An indication of the likely precision of an estimate from a probability sample; used to compute a confidence interval.

multistage sampling design. A sampling design in which sampling takes place in several stages, beginning with larger units (e.g., cities) and then proceeding with smaller units (e.g., households or individuals within these units).

nonprobability sample. Any sample that does not qualify as a probability sample.

open-ended question. A question that requires the respondent to formulate their own response.

order effect. A tendency of respondents to choose an item based in part on the order of response alternatives on the questionnaire (see primacy effect and recency effect).

parameter. See population value.

pilot test. A small field test replicating the field procedures planned for the full-scale survey; although the terms *pilot test* and *pretest* are sometimes used interchangeably, a pretest tests the questionnaire, whereas a pilot test generally tests proposed collection procedures as well.

population. The totality of elements (objects, individuals, or other social units) that have some common property of interest; the target population is the collection of elements that the researcher would like to study. Also, universe.

population value, population parameter. The actual value of some characteristic in the population (e.g., the average age); the population value is estimated by taking a random sample from the population and computing the corresponding sample value.

pretest. A small preliminary test of a survey questionnaire. See pilot test.

primacy effect. A tendency of respondents to choose early items from a list of choices; the opposite of a recency effect.

probability sample. A type of sample selected so that every element in the population has a known nonzero probability of being included in the sample; a simple random sample is a probability sample.

probe. A follow-up question that an interviewer asks to obtain a more complete answer from a respondent (e.g., “Anything else?” “What kind of medical problem do you mean?”).

quasi-filter question. A question that offers a “don’t know” or “no opinion” option to respondents as part of a set of response alternatives; used to screen out respondents who may not have an opinion on the issue under investigation.

random sample. See probability sample.

recency effect. A tendency of respondents to choose later items from a list of choices; the opposite of a primacy effect.

sample. A subset of a population or universe selected so as to yield information about the population as a whole.

sampling error. The estimated size of the difference between the result obtained from a sample study and the result that would be obtained by attempting a complete study of all units in the sampling frame from which the sample was selected in the same manner and with the same care.

sampling frame. The source or sources from which the objects, individuals, or other social units in a sample are drawn.

secondary meaning. A descriptive term that becomes protectable as a trademark if it signifies to the purchasing public that the product comes from a single producer or source.

simple random sample. The most basic type of probability sample; each unit in the population has an equal probability of being in the sample, and all possible samples of a given size are equally likely to be selected.

skip pattern, skip sequence. A sequence of questions in which some should not be asked (should be skipped) based on the respondent’s answer to a previous question (e.g., if the respondent indicates that he does not own a car, he should not be asked what brand of car he owns).

stratified sampling. A sampling technique in which the researcher subdivides the population into mutually exclusive and exhaustive subpopulations, or strata; within these strata, separate samples are selected. Results can be combined to form overall population estimates or used to report separate within-stratum estimates.

survey-experiment. A survey with randomly assigned control and treatment groups, enabling the researcher to test a causal proposition.

survey population. See population.

trade dress. A distinctive and nonfunctional design of a package or product protected under state unfair competition law and the federal Lanham Act § 43(a), 15 U.S.C. § 1125(a) (1946) (amended 1992).

universe. See population.

Introduction

This reference guide identifies areas of dispute that arise when economic losses are at issue in legal proceedings. We focus on explaining the issues in these disputes rather than taking positions on their proper resolution. We discuss the application of economic analysis within established legal frameworks for damages, cover topics in economics that arise in measuring damages, and, where useful, provide citations to cases that illustrate the principles and techniques discussed in the text.

We begin with a brief discussion of qualifications for damages experts. We then set forth the standard general approach to quantification of economic damages, with particular focus on translating the legal theory of the harmful event into an analysis of the economic impact of that event and choosing the measure of economic damages. Next, we consider disputes that may arise between the parties regarding damages estimation. Such disputes may concern basic issues (e.g., proper damages measure and losses caused), valuation issues (e.g., damages arising on single or multiple dates, and the use of market or other data to estimate damages), other issues (e.g., data validity, prejudgment interest, disaggregation), and limitations on damages. We also discuss damages in class actions as well as the application of damages principles to specific types of cases.

We use brief examples to illustrate the disputes that can arise and provide intuition for relevant economic issues. These examples are not full case descriptions; they are deliberately stylized, attempting to capture the types of disagreements about damages that arise in practical experience, although they are purely hypothetical. In many examples, the dispute involves factual and economic as well as legal issues. We do not try to resolve the disputes in these examples; hopefully the examples will help clarify the legal and factual disputes that need to be resolved before or at trial.

Damages Experts' Qualifications

Experts who quantify damages come from a variety of backgrounds. The expert should be trained and experienced in quantitative analysis. For economists, the common qualification is a Ph.D. degree. Damages experts with business or accounting backgrounds often have M.B.A. or other advanced degrees, or C.P.A. credentials. Both the method of damages estimation used and the substance of the damages claim dictate the specific areas of specialization the expert should have. In some cases, participation in original research and authorship of professional publications may add to the qualifications of an expert. However, relevant research and publications are not likely to be on the topic of damages measurement per se, but rather on topics and methods encountered in damages analysis.

Professional training and experience in areas relevant to the substance of the damages claim may be required. For example, in antitrust, a background in industrial organization (i.e., competition economics) may be helpful; in securities damages, a background in finance may assist the expert; and in the case of lost earnings, an expert may benefit from training in labor economics.

An analysis by even the most qualified expert may face a motion to exclude under Federal Rule of Evidence 702 as interpreted by the *Daubert* line of cases.¹ Under Rule 702, an expert witness who is “qualified . . . by knowledge, skill, experience, training, or education,” is allowed to testify when

- (a) the expert’s scientific, technical, or other specialized knowledge will help the trier of fact to understand the evidence or to determine a fact in issue; (b) the testimony is based on sufficient facts or data; (c) the testimony is the product of reliable principles and methods; and (d) the expert has reliably applied the principles and methods to the facts of the case.

These criteria, which are intended to exclude testimony that is irrelevant or is based on untested and unreliable theories, are often applied to damages analyses. Examples include the following:

- A proposed damages expert may be qualified generally to opine on damages issues but may lack the qualifications necessary to offer an opinion in the context of the particular matter at hand. For example, a labor economist may lack the proper education, training, and experience to opine on damages in a securities matter.
- A proposed expert may have used a methodology that is incorrect as a matter of economics; the results may have been based on insufficient data (e.g., too few observations); or a theoretically sound analysis may not have been properly applied, even if large amounts of data were used in the analysis.
- All or part of a damages analysis may no longer be relevant if certain legal claims have been dismissed, or expert opinion on damages simply may not be needed at all, such as where damages may be determined using a simple mathematical formula.

Even if a motion to exclude fails, it can be an effective way for a party to probe an opposing expert’s damages analysis prior to trial. For this reason, among others, motions to exclude proposed expert damages testimony have become relatively commonplace.

1. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993); *Kumho Tire Co. v. Carmichael*, 526 U.S. 137 (1999). For a discussion of emerging standards of scientific evidence, see Liesa L. Richter & Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual.

The Standard General Approach to Quantification of Economic Damages

In this section, we review the general principles of the standard approach to the estimation of economic damages and basic issues that arise in such estimation. For each principle, there are several areas of potential dispute. The sequence of issues discussed here is intended to identify most of the areas of disagreement between the damages analyses of opposing parties with respect to these principles.

General Principles

We begin by setting forth the standard general approach to damages quantification, with particular focus on defining the harmful event and the alternative, or but-for, scenario. In most cases, the goal of measurement of economic damages is to estimate the plaintiff's loss of economic value caused by the defendant's harmful act. The loss of value may arise from a single event, such as overpayment for a consumer product, or it may take the form of a reduced stream of profits or earnings over time. The losses are net of any costs avoided because of the harmful act.

In principle, then, economic damages are the difference between (1) the plaintiff's economic position assuming that the alleged harmful act had not occurred, and (2) the plaintiff's actual economic position as a result of the harmful act.² The former considers the plaintiff's economic position absent any past and future effects of the harmful act. We refer to this as the plaintiff's but-for economic position in the but-for world. The latter considers the plaintiff's actual economic position given the occurrence of the harmful act. We refer to this as the plaintiff's actual economic position in the actual world.

Figure 1 illustrates the structure of the standard damages study. We begin by estimating the plaintiff's losses as of the appropriate valuation date. The appropriate valuation date may vary depending on the nature of the loss and the plaintiff's theory of recovery (e.g., breach of contract, tort, fraud, etc.). Losses are the difference between the plaintiff's but-for economic position and the plaintiff's actual economic position as of the valuation date. Note that the plaintiff's but-for economic position may require estimating past losses as well as future losses, again

2. Damages are sometimes measured based on the defendant's gain rather than the plaintiff's losses. If measured based on the defendant's gain, economic damages are the difference between (1) the defendant's actual economic position as a result of the harmful act, and (2) the defendant's economic position assuming that the alleged harmful act had not occurred.

Figure 1. Damages studies generally adopt this framework. We therefore use it as the basic model for this reference guide.

determining their value as of the valuation date. The plaintiff may be entitled to prejudgment interest through the judgment date on their damages as of the valuation date.³

Isolating the Effect of the Harmful Act

The first step in a damages study is the translation of the legal theory of the harmful event into an analysis of the economic impact of that event. As noted above, in most cases, the analysis considers the difference between what the plaintiff's economic position would have been if the harmful event had not occurred and the plaintiff's actual economic position as of the valuation date.

The characterization of the harmful event begins with a clear statement of what occurred in the actual world. This characterization also will include a description of the but-for world, including the defendant's proper actions in place of their unlawful actions and a statement about the economic situation of all relevant parties absent the wrongdoing, with the defendant's proper actions replacing the unlawful ones. Damages measurement then determines the plaintiff's hypothetical economic position in the but-for world. Economic damages are the difference between that value and the actual value that the plaintiff achieved.

3. The plaintiff may also be due postjudgment interest, which is interest on the damages award from the date of judgment to the date the defendant satisfies the judgment.

Because the but-for world differs from what actually happened only with respect to the harmful act and its reasonably foreseeable economic consequences, damages measured in this way isolate the change in the plaintiff's economic position caused by the harmful act and exclude any change in the plaintiff's economic position arising from other causes.⁴ Thus, a proper construction of the but-for world and measurement of the plaintiff's economic position in the but-for world by definition include in damages only the loss caused by the harmful act.

Properly translating the legal theory of the harmful act into an analysis of the economic impact of that event is a fundamental step in the estimation of economic damages. Failure to do so may result in the damages analysis being discounted or excluded altogether. For example, in *Comcast Corp. v. Behrend*, the U.S. Supreme Court found that the plaintiffs' expert had put forth a damages model that "failed to measure damages resulting from the particular anti-trust injury on which . . . liability in this action is premised."⁵ Citing the discussion in the prior edition of this reference guide, the Court determined that the expert's "methodology . . . identifies damages that are not the result of the wrong" and measures damages "caused by factors unrelated to an accepted theory of . . . harm."⁶

4. Reasonable foreseeability is a legal doctrine that courts use to determine whether the consequences of a legal or contractual breach are too remote to be borne by the defendant. Reasonable foreseeability is not a measure of damages, but rather an upper limit on damages. The use of "reasonable" here relates to the legal concept of the "reasonable person" or "economic person," and concerns actions that a reasonable person or economically rational actor under similar circumstances would take. See, e.g., Richard A. Posner, *Economic Analysis of Law* (2d ed. 1977); Steven Shavell, *Foundations of Economic Analysis of Law* (2004); Israel Gilead & Michael D. Green, *Positive Externalities and the Economics of Proximate Cause*, 74 Wash. & Lee L. Rev. 1517 (2017); John Fabian Witt & Morgan Savage, *Foreseeability Conventions*, 44 Cardozo L. Rev. 1075 (2023); Russ VerSteeg, *Perspectives on Foreseeability in the Law of Contracts and Torts: The Relationship Between "Intervening Causes" and "Impossibility"*, 2011 Mich. St. L. Rev. 1497 (2011). Reasonable foreseeability is not a term of art in the field of economics. While determinations regarding reasonable foreseeability may impact the damages analysis, application of the concept is not within the purview of the damages expert. As such, the damages expert may require assumptions from counsel as to whether a particular outcome is a reasonably foreseeable consequence of the alleged harmful act.

5. *Comcast Corp. v. Behrend*, 569 U.S. 27, 46 (2013).

6. *Id.* at 38 ("The first step in a damages study is the translation of the legal theory of the harmful event into an analysis of the economic impact of that event." The district court and the court of appeals ignored that first step entirely" (citations omitted)). See also *In re POM Wonderful LLC*, No. ML 10-02199 DDP RZX, 2014 WL 1225184, at *5 (C.D. Cal. March 24, 2014) (damages expert "made no attempt, let alone an attempt based upon sound methodology, to explain how Defendant's alleged misrepresentations caused any amount of damages"); *In re Domestic Drywall Antitrust Litig.*, No. 13-MD-2437, 2017 WL 3700999, at *14 (E.D. Pa. Aug. 24, 2017) (expert's damages model was "riddled with assumptions that divorce the model from the facts").

General Categories of Damages Measures

In most cases, damages are measured based on one or more of the following six categories: (1) expectation, (2) reliance, (3) restitution, (4) statutory, (5) liquidated, and (6) punitive.⁷ We discuss each of these in turn.

1. *Expectation*: Plaintiff restored to the same financial position as if the defendant had performed as promised.

Expectation damages typically apply to breach-of-contract claims, where the wrongdoing is the failure to perform as promised and the but-for scenario hypothesizes the absence of that wrongdoing—that is, proper performance by the defendant. Expectation damages are an amount sufficient to place the plaintiff in the same economic position as if the defendant had fulfilled the promise or bargain.⁸

2. *Reliance*: Plaintiff restored to the same position as if the relationship with the defendant or the defendant's misrepresentation (and resulting harm) had not existed in the first place.

Reliance damages generally apply to torts and to some breach-of-contract claims. Such damages restore the plaintiff to the same financial position they would have enjoyed absent the defendant's conduct.⁹ Reliance most often includes out-of-pocket costs,¹⁰ but may also include compensation for lost opportunities when appropriate.¹¹ In such cases, reliance damages may approach expectation

7. The law imposes several limitations on damages, which are discussed below in the section titled "Limitations on Damages."

8. See John R. Trentacosta, *Damages in Breach of Contract Cases*, 76 Mich. Bus. J. 1068, 1068 (1997) (describing expectation damages as damages that place the injured party in the same position as if the breaching party completely performed the contract); *Spring Creek Expl. & Prod. v. Hess Bakken Inv.*, 887 F.3d 1003, 1026 (10th Cir. 2018) (defining expectation damages as the amount of damages necessary to place the injured party in the same position it would have occupied had the breach not occurred). See also Restatement (Second) of Contracts § 344(a) (1981).

9. See E. Allan Farnsworth, *Legal Remedies for Breach of Contract*, 70 Colum. L. Rev. 1145, 1148 (1979) (the objective of reliance damages is to put the promisee, or nonbreaching party, back into the position it would have been had the promise not been made). See also Restatement (Second) of Contracts § 344(b) (1981). Reliance damages include expenditures made in preparation for performance and performance itself. Restatement (Second) of Contracts § 349 (1981).

10. Out-of-pocket costs are expenses incurred by a party in preparing to perform (or in performing) a contract in reliance on the terms of the agreement. This is distinct from the notion of out-of-pocket damages used in securities fraud damages, which relates to the difference between price paid and a but-for price that would have been paid. See the discussion in the section titled "Estimation of Economic Damages in Securities Cases" below.

11. Compensation for lost opportunities embodies the economic concept of opportunity cost, which expresses the relationship between scarcity and choice. Given an economic actor facing a

damages.¹² For a tort, the goal of reliance damages is to place the plaintiff in a position economically equivalent to their position absent the harmful act.¹³ For a breach of contract, measuring damages as the amount of compensation needed to return the plaintiff to the position they would have been in had the contract had not been made in the first place will result in refunding the part of the plaintiff's reliance investment that cannot be recovered in other ways. Thus, reliance damages may be appropriate where the plaintiff made an investment relying on the defendant's performance.

Example: Agent contracts with Owner for Agent to sell Owner's farm. The asking price is \$1,000,000, and the agreed fee is 6%. Agent incurs costs of \$1,000 in listing the property. A potential buyer offers the asking price, but Owner withdraws the listing. Agent calculates (expectation) damages as \$60,000, the agreed fee for selling the property. Owner calculates (reliance) damages as \$1,000, the amount that Agent spent to advertise the property.

3. *Restitution:* Plaintiff compensated by the amount of the defendant's gain from the unlawful conduct, also called compensation for unjust enrichment, disgorgement of ill-gotten gains, or compensation for unbar-gained-for benefits.

Restitution damages are awarded to prevent the defendant's unjust enrichment from the unlawful conduct. The goal of restitution damages is to restore the defendant to the economic position they would have been in had they not engaged in the wrongful act, and typically includes disgorgement of defendant's

choice between mutually exclusive alternatives, the opportunity cost of the alternative selected (e.g., entering into a contract with vendor A) is the value of the best alternative *not* chosen (e.g., entering into a contract with vendor B, C, or D). *See, e.g.,* N. Gregory Mankiw, *Principles of Microeconomics* 6 (8th ed. 2016) ("The opportunity cost of an item is what you give up to get that item." (emphasis omitted)).

12. In some situations, reliance damages can exceed expectation damages, but the court may limit damages to the expectation measure. *See, e.g.,* *Fairholme Funds, Inc. v. Fed. Hous. Fin. Agency*, No. 1:13-cv-1053-RCL, 2022 WL 11110584, at *4 (D.D.C. Oct. 19, 2022) (Plaintiff claimed reliance damages "many multiples higher" than the allowed measure of expectation damages. The court stated, "In contract cases, expectation damages are preferred, with reliance damages considered as an alternative or proxy if expectation damages are not readily ascertainable. . . . [P]laintiffs . . . cannot recover reliance damages so far in excess of ascertainable expectation damages that they would necessarily place those plaintiffs in a better position than they would have been in had the contract been performed.").

13. *See, e.g.,* *East River Steamship Corp. v. Transamerica Delaval Inc.*, 476 U.S. 858, 873 n.9 (1986) ("tort damages generally compensate the plaintiff for loss and return him to the position he occupied before the injury").

ill-gotten gains.¹⁴ In practice, restitution is often the same, from the perspective of quantification, as reliance damages. If the only loss to the plaintiff from the defendant's harmful act arises from an expenditure that the plaintiff made that cannot otherwise be recovered, the plaintiff receives compensation equal to the amount of that expenditure.¹⁵

4. *Statutory*: Plaintiff's compensation is an amount established by statute, either as a set amount per occurrence of wrongdoing or determined using a statutory formula. For example, this measure of damages is often found in cases involving violations of state labor codes and in copyright infringement.
5. *Liquidated*: Plaintiff compensated by an amount specified in a legal agreement or contract between the parties.
6. *Punitive*: Compensation to reward the plaintiff for detecting and prosecuting the wrongdoing or to deter similar wrongdoing in the future.

A plaintiff cannot normally seek punitive damages in a claim for breach of contract but may seek them in addition to compensatory damages in connection with a tort claim.¹⁶ Although punitive damages are rarely the subject of expert testimony, economists have advanced the concept that punitive damages compensate a plaintiff who brings a case for a wrongdoing that is hard to detect or hard to prosecute.¹⁷

Basic Issues Arising in Damages Estimation

Losses Caused

The analysis of losses caused is typically a key part of the analysis of damages. Analyzing damages requires isolating the portion, if any, of the plaintiff's losses that can be attributed to the harmful act from the portion that can be attributed to other factors.

14. Note the distinction between restitution and reliance damages. The objective of restitution damages is to put the promisor, or breaching party, back in the position in which it would have been had the promise not been made. In contrast, reliance damages seek to put the promisee, or nonbreaching party, back in the position in which it would have been if the promise had not been made. See E. Allan Farnsworth, *Legal Remedies for Breach of Contract*, 70 Colum. L. Rev. 1145, 1148 (1979). Both measures seek to restore the status quo ante. See also Restatement (Third) of Restitution and Unjust Enrichment (2011).

15. See Restatement (Second) of Contracts § 344(c) (1981).

16. Compensatory damages are damages "sufficient in amount to indemnify [or compensate] the injured person for the loss suffered." *Damages*, Black's Law Dictionary (11th ed. 2019).

17. See Steven Shavell, *Foundations of Economic Analysis of Law* 244 (2004).

Example: Worker who smokes is the victim of a disease caused either by exposure to xerxium or by smoking. Worker makes leather jackets tanned with xerxium. The disease precludes Worker from earning wages. Worker sues the producer of the xerxium, Xerxium Mine, and calculates damages as all lost wages. Defendant Xerxium Mine, in contrast, attributes most of the losses to smoking and calculates damages as only a fraction of lost wages.

Frequently, the defendant will calculate damages on the premise that the harmful act had no causal relationship to the plaintiff's losses—that is, the plaintiff's losses would have occurred irrespective of the harmful act. The defendant's but-for scenario will thus describe a situation in which the losses happen anyway. This is equivalent to arguing that the harmful act occurred but the plaintiff suffered no incremental losses from it.

Example: Contractors conspired to rig bids in a construction deal. State seeks damages for subsequent higher prices. Contractors' damages estimate is zero because they assert that the only effect of the bid rigging was to determine the winner of the contract and that prices were not affected.

In other situations, unexpected events occurring after the harmful event (known as subsequent unexpected events) can increase or decrease the plaintiff's actual loss relative to what might have been expected at the time of the harmful event.

Example: Housepainter uses faulty paint, which begins to peel a month after the paint job. Owner measures damages as the cost of repainting. Painter disputes this measure on the ground that a hurricane that occurred three months after the paint job would have ruined a proper paint job anyway.

A plaintiff may argue that a harmful act has caused significant losses for many years. The defendant may respond that most of the losses that occurred from the injury are the result of causes other than the harmful act. Thus, the defendant may argue that the injury was caused by multiple factors, only one of which was the result of the harmful act, or that the plaintiff's injury was caused by subsequent events.

Example: Real Estate Agent is wrongfully denied affiliation with Broker. Agent's damages study projects past earnings into the future at the rate of growth of the previous three years. Broker's study projects that earnings would have declined even without the breach because of a downturn in the real estate market.

Comment: The difference between a damages study based on extrapolation from the past, here used by Agent, and a study based on actual data after the harmful act, here used by Broker, is one of the most common sources of disagreement in damages. This is a factual dispute that hinges on Broker demonstrating that there is a relationship between real estate market conditions and the earnings of agents. The example also illustrates how subsequent unexpected events can affect damages calculations.

Hypothesizing Legitimate Conduct of the Defendant in Analyzing the Plaintiff's Economic Position But For the Harmful Event

One party's damages analysis may hypothesize the absence of any act of the defendant that influenced the plaintiff, whereas the other party's damages analysis may hypothesize an alternative, legal act. This type of disagreement is particularly common in antitrust and intellectual property disputes. Although disagreement over the alternative scenario in a damages study is generally a legal question, opposing experts may have been given different legal guidance and therefore made different economic assumptions, resulting in major differences in their damages estimates.

Example: Defendant Copier Service's long-term contracts with customers are found to be unlawful because they create a barrier to entry that maintains Copier Service's monopoly power. Plaintiff Rival's damages study hypothesizes no contracts between Copier Service and its customers, so Rival would face no contractual barrier to bidding those customers away from Copier Service. Copier Service's damages study assumes medium-term contracts with its customers and argues that these would not have been found to be unlawful. Under Copier Service's assumption, Rival would have been much less successful in bidding away Copier Service's customers, and damages are correspondingly lower.

Comment: Assessment of damages will depend greatly on the substantive law governing the injury. The proper characterization of Copier Service's alternative conduct usually is an economic issue. However, the expert must also have legal guidance as to the proper legal framework for damages. Counsel for the plaintiff may instruct the plaintiff's damages expert to use a legal framework different from that used by counsel for the defendant.

Considering All the Differences in the Plaintiff's Situation in the But-For Scenario Versus Assuming That Many Aspects Would Be the Same as in Actuality

The analysis of some types of harmful events requires consideration of effects that involve changes in the economic environment caused by the harmful event, such as price erosion.¹⁸ For a business, the main elements of the economic environment that may be affected by the harmful event include the prices charged by rivals, the demand facing the seller, and the prices of inputs. For example, misappropriation of intellectual property may cause lower prices because products produced with the misappropriated intellectual property compete with products sold by the owner of the intellectual property.¹⁹

In contrast, some types of harmful events do not change the plaintiff's economic environment. The theft of a small amount of the plaintiff's products would not change the market price of those products, nor would an injury to a worker change the general level of wages in the labor market. A damages study need not analyze changes in broader markets when the harmful act plainly has minuscule effects in those markets.

In situations where the plaintiff claims price erosion, the plaintiff may assert that absent the defendant's wrongdoing, a higher price could have been charged and therefore that the defendant's harmful act has eroded the market price. The defendant may reply that the higher price would lower the quantity sold. The parties may then dispute how much the quantity would fall as a result of higher prices.

Example: Valve Maker infringes Rival's patent. Rival calculates lost profits as the profits Rival would have made, including a price-erosion effect. The amount of price erosion is the difference between the higher price that Rival would have been able to charge absent

18. See, e.g., *Beijing Choice Elec. Tech. Co. v. Contec Med. Sys. USA Inc.*, No. 18 C 0825, 2020 WL 1701861, at *9 (N.D. Ill. Apr. 8, 2020) ("To prove lost profits damages, a patentee must reconstruct the market that 'would have developed absent the infringing product,' and the alleged infringer's market share may be a relevant data point in this reconstruction. For instance, if an alleged infringer's market share increases after it introduces the product accused of infringement, that may shed light on what the patentee's market share would have been had there been no infringement. Or, if an alleged infringer's market share does not change significantly after it introduces the accused product, that may indicate that lost profits damages are not appropriate because consumers do not care whether the product uses the patented features at issue" (citations omitted)).

19. See, e.g., *Power Integrations, Inc. v. Fairchild Semiconductor Int'l, Inc.*, 711 F.3d 1348, 1382–83 (Fed. Cir. 2013) ("Lost revenue caused by a reduction in the market price of a patented good due to infringement is a legitimate element of compensatory damages. Indeed, an infringer's activities do more than divert sales to the infringer. They also depress the price [of the patented product].").

Reference Guide on Estimation of Economic Damages

Valve Maker's presence in the market and the actual price. The price-erosion effect is that price difference multiplied by the combined sales volume of Valve Maker and Rival. Defendant Valve Maker counters that the volume would have been lower had the price been higher, and measures damages using the lower volume.

In more complicated situations, the damages analysis may need to focus on how an entire industry would be affected by the absence of the defendant's wrongdoing. For example, one federal appeals court held that a damages analysis for exclusionary conduct must consider that absent the defendant's conduct, firms other than the plaintiff may have entered the market. Competition from such firms would have reduced prices, and as a result the plaintiff's profits would have been lower than those posited in the plaintiff's damages analysis.²⁰

Example: Printer Maker has used unlawful means to exclude rival suppliers of computer printer ink cartridges. Rival calculates damages on the assumption that they would have been the only additional seller in the market absent the exclusionary conduct and that Rival would have been able to sell its cartridges at the same price actually charged by Printer Maker. Printer Maker counters that other sellers would have entered the market and driven the price down, and so Rival has overstated their damages.

Comment: Increased competition lowers prices in all but the most unusual situations. Again, determination of the number of entrants that may have been attracted to the market absent the exclusionary conduct, and analysis of their effect on prices, requires a full economic analysis of the industry.

A clear statement of the plaintiff's situation but for the harmful event is helpful in avoiding double counting that can arise if a damages study confuses or combines reliance and expectation damages.

Example: Marketer is the victim of defective products made by Manufacturer; Marketer's business fails as a result. Marketer's damages

20. See *Cave Consulting Grp., Inc. v. OptumInsight, Inc.*, No. 15-cv-03424-JCS, 2020 WL 127612, at *7 (N.D. Cal. Jan. 10, 2020) (no evidence provided that would provide the jury with any basis to disentangle "favorable aspects of an anticompetitive market such as an unnatural price differential between [plaintiff] and [its] competitors and limited competition from third parties because of the difficulty of entering the market."). See also *Sun Microsystems Inc. v. Hynix Semiconductor Inc.*, 608 F. Supp. 2d 1166 (N.D. Cal. 2009) (holding that a before-and-after damages analysis requires "some showing that the market conditions in the two periods were similar but for the impact of the violation"); *Dolphin Tours, Inc. v. Pacifico Creative Serv., Inc.*, 773 F.2d 1506, 1512 (9th Cir. 1985).

study adds together the out-of-pocket costs of creating the business and the projected profits of the business had there been no defects. Manufacturer's damages study measures the difference between the profits Marketer would have made absent the defects and the profits Marketer actually made.

Comment: Marketer has mistakenly added together damages from the reliance and expectation measures of damages. Under the reliance measure, Marketer is entitled to be put back to where they would have been had they not started the business in the first place. Damages would be total outlays less the revenues actually received. Under the expectation measure, Marketer is entitled to the extra profits they would have received had there been no product defects. Out-of-pocket expenses of starting the business would have no effect on expectation damages because they would be present in both the actual and but-for worlds and thus would offset each other.

Valuation Issues in the Analysis of Economic Damages

As discussed in the previous section, the analysis of economic damages compares a plaintiff's economic position in the but-for world—that is, absent any past and future effects of the alleged harmful act on the plaintiff's economic position—to that plaintiff's economic position in the actual world, and quantifies the economic value of that difference as of a specific date (the valuation date).²¹ Because an analysis of economic damages is, by definition, a valuation exercise, it typically requires that economic experts resolve issues arising from the application of valuation approaches to specific case circumstances. This section introduces valuation issues often addressed by economic experts.²²

21. As noted in the section titled “The Standard General Approach to Quantification of Economic Damages” above, in some situations the damages analysis aims to quantify the defendant's gain instead of the plaintiff's loss. In those situations, the relevant comparison is between the defendant's economic position in the actual world and the defendant's economic position in the but-for world—i.e., absent any past and future effects of the alleged harmful act on the defendant's economic position. The economic issues raised in this section similarly apply when analyzing the defendant's gain from the alleged harmful act.

22. In the section titled “Damages Issues in Selected Types of Cases” below, we introduce the analysis of economic damages in various case types, namely, consumer product liability, securities, antitrust, and loss of personal income. There, we do not specifically address business valuation disputes. However, the methodologies discussed in this section are also relevant to the analysis of economic damages in the context of business valuation disputes.

Issues Arising When the Potential Impact of the Alleged Harmful Act Is Analyzed Directly on a Particular Date

Issues Arising in Connection with the Use of the Market Price of the Product or Asset at Issue

Because a market price is simultaneously a price that the buying party was willing to pay at the time of the transaction and a price that the selling party was then willing to receive in exchange for the asset or product at issue, a market price provides an objective measure of economic value as of a particular point in time. However, as discussed below, the economic value represented by a market price reflects the specific circumstances under which the transaction occurred. Thus, there is often disagreement among experts as to whether and how the market price of the product or asset at issue can be used to analyze damages. This section summarizes some of the key issues that can generate disagreement.

The market price of the product or asset at issue in litigation is a frequent input to the analysis of damages on a particular date. A simple example of such a situation would be where the defendant's negligence caused total destruction of the plaintiff's cargo of wheat, worth \$17 million at the then-current market price of wheat. In this simple example, a damages expert may calculate damages as just that amount, \$17 million.

Market prices are often used to analyze the plaintiff's economic position in the but-for world, the actual world, or both. For example,

- In the simple example above, involving a destroyed cargo of wheat, the market price of wheat at the time of the defendant's negligence may be used to value the plaintiff's economic position but for the alleged harmful act (i.e., the \$17 million value of the plaintiff's cargo of wheat had it not been destroyed).
- In a consumer fraud case involving a product falsely represented to have certain desirable characteristics, the market price of the product may be used to measure the plaintiff's actual economic position at the time of purchase (i.e., how much the plaintiff paid for the product).
- In a defamation case involving a publicly traded company plaintiff, the change in the company's stock price around the time of the defendant's defamatory act may serve as an initial input to the analysis of the difference in the plaintiff's economic position between the but-for world (e.g., using the stock price shortly before the defamatory act) and the actual world (e.g., using the stock price shortly after the defamatory act).

However, disagreement often arises among experts as to whether market prices (or changes in market prices over certain periods) serve as an adequate input to analyzing the impact of the alleged harmful act on the plaintiff's economic position.

First, when using market prices to value the plaintiff's economic position in the but-for world, disagreements may arise as to whether (and, if so, by how much) the market price that the expert relied on for their analysis represents a value that was itself impacted by the alleged harmful act. If the value represented by the market price reflects the impact of the alleged harmful act, such impact must be removed from the market price in order to properly value the plaintiff's economic position in the but-for world.

For example, if the destroyed cargo of wheat mentioned above was large enough that its destruction significantly constrained the supply of wheat, thereby increasing the market price of wheat, then the market price of wheat immediately following the destruction of the cargo of wheat will overstate the plaintiff's economic position but for the alleged harmful act and, thus, will overstate damages. In that case, disagreement may arise among the experts as to the extent to which the market price of wheat was affected by the defendant's negligence. Moreover, disagreement may arise with respect to what statistical or economic methodologies should be used to quantify the necessary adjustment to the market price in order to account for that impact.

Second, when market prices are used to analyze the plaintiff's economic position in the actual world, disputes may arise as to whether (and, if so, by how much) the market price fully reflects the impact of the alleged harmful act. If the market price does not fully reflect the impact of the alleged harmful act, then it needs to be adjusted using a reliable methodology to properly value the plaintiff's economic position in the actual world.

For example, suppose that a manufacturer of wood windows with publicly traded common stock treats its windows with a defective preservative, causing the windows to rot. The window manufacturer sues the preservative manufacturer for damages from lost sales and from the cost of replacing the defective windows. The window manufacturer's expert may be tempted to use the window manufacturer's stock price following the disclosure of the alleged harmful act as a measure of the manufacturer's economic position in the actual world. A potential problem with using the market price of the plaintiff's stock after the alleged harmful act is that the stock market may anticipate recovery in the form of a damages award, and this will attenuate at least some of the decline in price following the alleged harmful act.²³ In the extreme, if stock traders expect that

23. Note that this understatement of damages arises when the publicly traded company stands to recover a damages award as the plaintiff in a matter. However, changes in the market price of company stock have a different role in situations, such as a securities matter, where the public company is the defendant. Damages may be overstated by an unknown amount if the release of

the plaintiff will receive exactly full compensation, the plaintiff's market value is unlikely to change at all when knowledge of the wrongdoing—including the fact that a damages award will be made—hits the stock market. Thus, in this example, the use of the observed market price of the plaintiff company's stock at the time of the injury understates the actual amount of harm by an unknown amount, so the expert should consider using additional valuation techniques. Disputes may arise among the experts as to which valuation techniques should be used to quantify the harm and how they should be applied.

Third, when market prices are used to analyze the plaintiff's economic position, disputes may arise as to whether (and, if so, by how much) market prices reflect not just the impact of the alleged harmful act, but also the impact of other factors. Any impact of factors other than the alleged harmful act must be removed from the estimate of economic damages in order to isolate the harm caused by the alleged harmful act.

For example, consider a securities fraud matter where a mining company defendant is alleged to have overstated the size of its mineral reserves and where the company's stock price declined by 30% following its revelation of the true size of the mineral reserves. Suppose that, on the day the company revealed the true size of its reserves, it also announced that a natural disaster had caused its largest mine to collapse. To quantify the losses, if any, caused by the market learning of the company's true mineral reserves, it is necessary to disaggregate the impact of that disclosure from the impact of the disclosure of the mine collapse. A dispute may arise as to how the change in stock price should be adjusted to remove the impact of the disclosure of the mine collapse and isolate the impact of the disclosure of the company's true reserves.

Issues Arising in Connection with the Use of the Market Price of Ostensibly Similar Products or Assets

In many cases, experts cannot take the market price of the product or asset at issue and apply it directly to analyze the plaintiff's economic position in the but-for world or in the actual world. For example, there may not be a market for the product or asset at issue from which to obtain a market price (e.g., a company may not be publicly traded). However, experts may still be able to use the market prices of ostensibly similar products or assets—often labeled comparables—to analyze the economic value of the product or asset at issue.

previously fraudulently concealed adverse information causes a reduction in the value of the company both because of the adverse information and because the market anticipates that the company will pay a large damages award to investors who overpaid for their shares during the period when the information was concealed.

Identifying products or assets that are ostensibly similar to the allegedly affected product or asset

A common area of disagreement when relying on the market price of comparables to analyze damages is whether the identified comparables are economically similar to the allegedly affected product or asset. For example, in matters involving real estate, experts often identify comparables from the universe of nearby properties with similar characteristics (e.g., property size, condition, proximity to amenities, zoning restrictions). If the identified comparables are not similar to the product or asset at issue along economically relevant dimensions, the comparables' market prices may not serve as a reliable measure of the economic value of the allegedly affected product or asset (in the but-for world or in the actual world) and may lead the economic expert to significantly misestimate economic damages.

There may also be a dispute as to whether the period when the identified comparables were traded (and thus when their market price was determined) is too distant from the damages valuation date. Temporal distance between the damages valuation date and the period when the selected comparables were traded may cause the market prices of the selected comparables to reflect macroeconomic and business conditions that are significantly different from those in place as of the damages valuation date. In that case, the market prices of the comparable products or assets may not reliably measure the economic value of the product or asset at issue. For example, in a matter involving a sale of a private oil company that took place at a time when oil prices were at historic lows, evaluating the fairness of the sale price by comparing it to the prices at which similar companies were sold during an earlier period (when oil prices were significantly higher) could lead the expert to overstate the value of the company as of the sale date.

Adjusting the market price of ostensibly similar products or assets

Even when experts agree on a list of comparables to use in the damages analysis, disputes may arise as to whether (and, if so, how) the value of the allegedly affected product or asset implied by the comparables' market prices needs to be further adjusted to adequately measure the economic value of the product or asset at issue.

Accounting for differences between the ostensibly similar products or assets and the allegedly affected product or asset. Despite experts' best efforts, circumstances are often such that the best available comparables remain different from the product or asset at issue in economically significant ways. In such circumstances, additional adjustments to account for those differences may

be required to ensure that the economic value of the allegedly affected product or asset is not misestimated. For example, in a matter involving a business valuation, the business at issue may be much smaller than any of the identified comparable businesses, rendering value comparisons inappropriate. Therefore, an expert may propose to restate the value of comparable businesses using valuation ratios—a ratio of some measure of value, such as stock price, to some measure of economic output, such as earnings—and multiply the comparables' valuation ratios by the measure of economic output for the smaller business to estimate its value, thereby adjusting for size.

However, disputes often arise over whether any adjustments made to the value of the comparables appropriately capture all significant economic differences between the comparables and the product or asset at issue. In the business valuation example, a dispute may arise as to whether the adjustment based on valuation ratios fully accounts for differences between the company at issue and the comparable companies, such as differences in profitability, growth prospects, or riskiness.

Example: Oil Company deprives Gas Station Operator of the benefits of Operator's business. Oil Company's damages study starts by calculating the ratio of gas station sale value to gasoline sales for five nearby gas station businesses that have sold recently. The average ratio is \$0.26 per gallon of sales per year. The Operator sells 1.6 million gallons per year, so the business was worth $\$0.26 \times 1,600,000 = \$416,000$, according to the Oil Company's expert. The expert for the Operator argues that the sales used by the Oil Company occurred before a major business relocated nearby. Thus, the gas station sale value to gasoline sales should be increased to \$0.30 to reflect the new growth rate as a result of the expected increase in business. The Operator's expert calculates the business to be worth $\$0.30 \times 1,600,000 = \$480,000$.

Accounting for the impact of the harmful act. In some cases where experts rely on comparables to analyze damages, the alleged harmful act did not cause a total loss of the value of the product or asset at issue, but rather caused only a reduction in its value. In those cases, damages experts may adapt the valuation implied by the comparables to measure the loss caused by the alleged harmful act—that is, the difference between the plaintiff's economic position in the but-for world and in the actual world. For example, in a business valuation case, an expert may propose to use valuation ratios to analyze damages, as illustrated by the numerical example below, although disputes may arise as to their appropriateness.

Example: Oil Company breaches an earlier agreement with Gas Station Operator and opens another station near Operator's station. As a result, Operator's gasoline sales are reduced by 700,000 gallons per year. Oil Company's damages study applies an average valuation ratio (based on recent sales of gas station businesses) of \$0.26 per gallon of sales per year to the reduction in sales: $\$0.26 \times 700,000 = \$182,000$. In contrast, Operator's damages study uses a statistical analysis (also based on recent sales of gas station businesses) that finds the impact of sales on gas station value depends on the total sales volume of the gas station, such that, given the Operator's level of sales absent the breach, each additional (or marginal) gallon of *subtracted* sales reduces value by \$0.47. As a result, the Operator's expert calculates damages of $\$0.47 \times 700,000 = \$329,000$.

Comment: Because fixed costs associated with running a gas station (e.g., rent) are diluted by larger sales amounts, the average valuation of gasoline sales will be less than the marginal valuation. Thus, a damages model that accounts for the level of sales absent the breach is the conceptually correct approach.

Issues Arising in Connection with the Use of Models to Simulate the But-For Price

In certain cases, experts cannot adjust the market price of the asset or product at issue—or of ostensibly similar assets or products—to reflect the impact of the alleged harmful act. In these cases, some experts have used statistical and economic models to simulate market prices in the but-for world.

It is well established in economics that market prices are determined by supply and demand. To estimate market prices in the but-for world, experts have proposed models that seek to represent the price-formation process, or the outcome of that process, in the relevant market when supply and demand for the asset or product at issue exclude the effects of the alleged wrongdoing. Experts rely on assumptions that simplify some of the complexities of real markets and focus their analysis on the specific impact of the harmful act.

Experts also rely on a wide variety of data to estimate the relevant variables and parameters of their models and represent real markets to a reasonable degree of accuracy. These data can include market data such as prices and quantities sold of the asset or product at issue, or the prices and quantities sold of related assets or products (such as substitute and complementary products). Experts can also rely on nonmarket data, such as accounting data or data generated via surveys.

Disagreements occur with respect to the assumptions and data used in these models. This section summarizes certain issues that arise when experts rely on statistical and economic models to simulate or approximate but-for prices.

Realistic modeling of preferences, incentives, and constraints of buyers and sellers

Experts use economic and statistical models to simulate real markets or market outcomes by focusing on the analysis of certain key elements and relationships of the market and by making assumptions about the influence of other less relevant characteristics. For a model to be useful, it needs to provide a sufficiently realistic representation of the relevant market. This usually involves defining the key characteristics of supply and demand of the asset or product at issue. Disputes may arise over which assumptions about demand and supply more realistically reflect the relevant market in the but-for world.

A valid model must provide a sufficiently realistic representation of the preferences of buyers. Experts usually achieve this by relying on methods of demand estimation commonly used by economists and marketing academics. These methods are broadly classified in two categories. The first category, known as the revealed preference method, relies on data from the choices made and prices paid by buyers in the real world to infer the underlying preferences and restrictions of buyers. The second category, known as the stated preference method, relies on data from surveys of relevant subjects that are considered representative of the population of buyers of the asset or product at issue.

When data from surveys are used, disputes may arise about whether such data accurately represent respondents' preferences—respondents may behave differently when taking a survey compared to how they would behave in the real market. Disputes may arise about how realistically a survey represents the environment in which buyers make purchase decisions in the real world, or about how accurately the sample of survey respondents represents the relevant population of buyers. Refer to the *Reference Guide on Survey Research*, in this manual, for a detailed treatment of these and other issues that arise when surveys are conducted.

A common question that arises when experts rely on a model to represent demand for an asset or product is whether the model appropriately accounts for variation in the preferences of different groups or types of buyers. For example, in an intellectual property dispute, an expert could use an economic model to estimate the price of a brand-name drug covered by a patent in a but-for world where the patent was not enforceable and generic drug manufacturers were allowed to compete. An overly simplistic model of demand could lead to a prediction that the entry of generic drug manufacturers into the market would result in a decrease in the price of the brand-name drug. However, a more realistic demand model

that takes into account the preferences of different types of consumers could lead to a finding that the market price of the brand-name drug would increase as the smaller segment of consumers who are brand-conscious would be willing to pay more for the brand-name drug.

A valid model must also provide a sufficiently realistic representation of the preferences and incentives of sellers. In many cases, experts rely on simplifying assumptions to represent the characteristics of supply. Some experts have assumed that the supply quantity is fixed at the quantity that was sold in the actual world. Other experts rely on economic frameworks to account for the changes in the economic position of sellers. These frameworks may include simplifying assumptions about the general relationship between the quantity offered and the price offered in the market or may include sophisticated models that simulate the behavior of individual sellers. Disputes commonly arise about whether the assumptions made by an expert regarding supply reflect the true positions and incentives of the suppliers in the but-for world.

Defining a valid model of supply generally requires consideration of key characteristics of the market that may influence the prices that consumers pay. For example, in a dispute involving the alleged mislabeling of a prescription drug's potential side effects, an expert must consider that the prices that consumers pay for prescription drugs may be influenced by insurance companies that can negotiate prices with the manufacturer and that can adjust consumer prices based on copays and deductibles.

It may also be necessary to define the characteristics of key competitors, distributors, retailers, and other relevant market participants. For example, a model that attempts to measure the impact on ticket prices of an alleged anti-competitive agreement between two bus lines should take into account available alternative means of transportation, such as cars, trains, or possibly airplanes. Disputes may arise as to the number, type, and characteristics of relevant alternatives consumers may have.

Modeling the impact of the alleged misconduct on demand and supply

To be helpful in the estimation of damages, a model of but-for prices must adequately reflect supply and demand absent the alleged misconduct while excluding the influence of unrelated factors. In general, the more complex the allegations are, or the more complex the facts surrounding the allegations are, the more difficult it will be for an economic model to reliably estimate market conditions absent the alleged misconduct.

Complex allegations may require more flexible models to represent the but-for world adequately. In general, models that allow more flexibility and that

provide the expert with more control over how to represent demand and supply in the but-for world are more difficult to estimate, and require larger amounts of data. For example, consider a dispute between a large buyer of insurance and an insurance company in which the allegations involve whether the insurer properly invoked a complex set of conditions to cancel a portfolio of policies and avoid paying for them. The damages model would require significant flexibility to perform the valuation of the portfolio in a but-for world where the defendant insurer could invoke some, but not all, of the cancellation conditions that it did in the actual world. Disputes commonly arise about whether an expert model adequately reflects complex allegations.

A model used by an expert should be able to account for the impact of confounding factors unrelated to the allegations but that may result in the same type of harm alleged. For example, in a dispute about potential contamination of groundwater from an industrial plant, an expert could estimate a statistical model—known as a hedonic model—to predict home prices based on certain characteristics of a home (e.g., number of bedrooms, number of bathrooms, etc.). The expert could attempt to use sale price data of homes before and after the alleged contamination event to estimate the impact of the alleged contamination on home values. However, if a zoning change affecting the properties at issue was enacted around the same time as the alleged contamination event, the expert's model would need to distinguish any decrease in the price of homes from the alleged contamination from any decrease (or increase) due to the zoning change. Disputes commonly arise about whether an expert model adequately controls for the impact of confounding factors.

Surveys provide the expert with some control over how to represent the but-for world via the information conveyed to survey respondents. However, disputes may arise about the specific information that respondents are assumed to have in the but-for world. For example, an expert could propose a survey to analyze how consumers would react to a label disclosing the use of genetically modified corn on a package of cereal labeled “100% natural corn.” Experts may disagree about the wording, size, and placement of such a label, all of which can affect the damages estimate arising from the survey.

Accounting for Market Frictions

When relying on market data to analyze economic damages as of a specific date, it may be necessary to consider how market frictions may have impacted market prices—whether it be the price of the allegedly affected product or asset or the price of ostensibly similar products or assets.

Perfectly competitive markets have what economists term a frictionless market structure. These markets have (1) a large number of buyers and sellers

of a single, homogeneous product; (2) fully informed participants; and (3) the feature that participants can easily enter or exit from the market. A friction is anything that prevents the market from being perfectly competitive. Economists have identified various types of market frictions that can impact market outcomes, including market power (e.g., oligopolies), adverse selection, and taxes.²⁴

For example, markets for businesses and properties have frictions that may make transaction values depart from the usual concept of the price negotiated by a willing seller and a willing buyer. In the case of a forced sale, and thus a less willing seller, the transaction price may understate the value. Adverse selection, which occurs when one party knows more about a property or business than the other, may cause severe failures in some markets.²⁵ Sales prices tend to be lower when equipment with hidden defects cannot be distinguished from equipment in unusually good condition. This is because buyers are only willing to pay a lower price that reflects the possibility of hidden defects in the equipment and because owners of equipment in good condition may choose not to offer it at that lower price.

Example: Negligence of Tire Maker causes the total loss of a Boeing 737 airplane. Tire Maker's damages analysis uses the prices of 737s of similar age in the used airplane market to set a value of \$23 million on the ruined airplane. However, Airline offers the testimony of an economist expert who explains that only a small fraction of 737s are ever put up for sale in the used airplane market. Rather, airlines choose to sell only defective airplanes because they continue to fly nondefective 737s. The expert then adjusts for the adverse selection of inferior airplanes in the used airplane market and places a value of \$42 million on the airplane.

Comment: Airline expert's adjustment is merited in principle, although it is challenging to carry out and is likely to be the subject of expert disagreement.

In financial markets, differences in information available to different market participants or limited asset liquidity can lead to market prices that differ, sometimes significantly so, from the prices that would have prevailed in perfectly competitive financial markets. For example, the sale of a large block of shares of

24. A comprehensive treatment of economic frictions is outside the scope of this reference guide.

25. See, e.g., George A. Akerlof, *The Market for "Lemons": Quality Uncertainty and the Market Mechanism*, 84 Q. J. Econ. 488 (1970), <https://doi.org/10.2307/1879431>.

a company's common stock may happen at a price that is much lower than recently prevailing market prices because potential purchasers of that block of shares are concerned that the seller might have negative, material nonpublic information about the value of the shares.

A major source of friction in property and business markets is the capital gains tax. Because capital gains are taxed only at realization, subtracting the amount of unrealized capital gains taxes from the value of a business or property would generally understate the value of the business or property to the existing owners if they have no plans to sell, except in the very distant future.

Issues Arising in Connection with the Use of Repair or Abatement Costs

In some cases, economic damages can be calculated as the costs that the plaintiffs incurred or would incur to restore their economic position from the actual world to the but-for world in which the alleged harmful act did not occur. These costs could include repair costs (e.g., the cost of the parts and labor used to repair a defective product), replacement costs (e.g., the cost of a third party hired to perform a task that the defendant was contracted to do but did not), or the costs of reducing or abating any harm caused by the alleged misconduct (e.g., the cleanup costs following an environmental contamination incident).

Damages experts often disagree on how to calculate these costs. First, experts may disagree on whether any costs allegedly incurred are attributable to the alleged misconduct. For example, if a service hired by the plaintiff to repair an allegedly defective product also performed general maintenance, the total cost paid may overestimate damages. Second, experts may disagree on the costs that are necessary to repair or abate the consequences of the alleged misconduct. For example, in a case where the plaintiff alleges that they will need to install expensive air filtration devices to reduce foul odors from a defective air conditioning system, experts may disagree on whether such costs are necessary if cheaper alternatives (e.g., more frequent maintenance) are available. Third, experts may disagree about whether the potential costs of repair match the economic value of the loss experienced by the plaintiff. For example, consider a builder who in the process of selling a house learned that a contractor used cheaper materials than promised. Assume that the cost of removing the cheaper materials and replacing them with the materials originally specified would be \$100,000; however, the builder was able to sell the home by offering a discount of only \$50,000. In this case, the replacement costs would overstate the economic loss suffered by the builder.

Issues Arising When the Potential Impact of the Alleged Harmful Act Spans Multiple Dates and Damages Are Analyzed Indirectly on a Single Date

Having discussed various issues that arise when experts analyze damages by assessing the impact of the alleged harmful act on a specific date directly, we now turn to issues arising in situations where economic experts analyze damages on a particular date indirectly. Specifically, we turn to situations where experts first assess the direct economic impact of the alleged harmful act (i.e., the flow of economic income or loss at a specific point in time that can be causally linked to the defendant's alleged misconduct) over multiple dates (e.g., the lost profits from operating a facility that was expected to produce widgets for a long period of time but was destroyed by a defendant's misconduct) and then value the cumulative direct impact over multiple dates as of a single valuation date.

Estimating the Period-by-Period Direct Impact of the Alleged Harmful Act

In situations where experts assess the direct economic impact of the alleged harmful act over multiple dates, it is necessary to estimate flows of economic income or loss to the plaintiff in past and future periods that resulted (or were expected to result) from the alleged harmful act. In doing so, experts face a number of considerations.

Many of those considerations, such as how the actions of plaintiffs and defendants would have differed had the alleged harmful act not occurred, or whether all economic consequences of the alleged harmful act have been considered, have been introduced more broadly in the section titled “Valuation Issues in the Analysis of Economic Damages” above. This section further explores these considerations in the specific context of assessing the period-by-period direct economic impact of the alleged harmful act.

Disputes about how the defendant's actions would have differed had the alleged harmful act not occurred

When analyzing damages, experts often rely on the plaintiff's allegations (e.g., as stated in a complaint or statement of claim) as the basis for identifying the alternative actions that the plaintiff alleges the defendant should have undertaken instead of the alleged harmful act. However, in some cases, the plaintiff's

allegations do not specify fully what the defendant could and should have done instead of the alleged harmful act, or the allegations are squarely contradicted by case facts. For example, consider a derivative lawsuit where a company's shareholders sue the CEO for using the firm's funds in wasteful company acquisitions that are expected to reduce the company's quarterly profits for periods lasting well into the future. The plaintiff's allegations may leave unspecified what the CEO should have done with the funds instead of the allegedly wasteful acquisitions or the allegations may assume that certain investment opportunities were available that the record demonstrates were not.

Depending on the circumstances, the ambiguity remaining in the allegations may be significant enough that it causes experts on opposite sides of the litigation to reach substantially different estimates of damages. For example, in the case of the CEO alleged to have engaged in wasteful corporate acquisitions, the expert retained by the CEO defendant may assume that the funds used to finance the acquisitions would have been used to fund internal projects that were expected to be as unprofitable as the wasteful acquisitions. On the other hand, the expert retained by the investor plaintiffs may assume that the funds would have been distributed to the shareholders as quarterly dividends instead. Thus, when assessing opposing experts' damages analyses, a critical issue may be how each expert modeled what the defendant's actions would have been had the alleged harmful act not occurred.

When the plaintiff's allegations are consistent with any of several alternative actions that the defendant might have taken had the alleged harmful act not occurred, there is a risk that expert analyses become tainted by hindsight. With the benefit of hindsight—often, after years have passed since the alleged harmful act occurred—the parties may instruct their experts to assume that the defendant would have taken particular actions (among various possible alternatives that are consistent with the plaintiff's allegations) that lead to a more favorable damages number. However, the defendant's actions, had the alleged harmful act not occurred, would have been based on the defendant's knowledge at the time of the alleged harmful act, and not on whatever knowledge only later became available, including as a result of litigation. In the example above involving wasteful corporate acquisitions, depending on what the CEO contemporaneously knew, had the alleged harmful act not occurred, the CEO's decision could have been either to pay out the funds as dividends (as the shareholders' expert assumed) or to reinvest the funds into internal projects (as the CEO's expert assumed).

Disputes about how the plaintiff's actions would have differed had the alleged harmful act not occurred

Even when a defendant's actions, had the alleged harmful act not occurred, are fully specified, there may be disagreements about what the plaintiff would have done in the hypothetical world where the alleged harmful act did not occur. Such

disagreements may also lead to significantly different damages numbers. Take the numerical example below, where the plaintiff in a real estate matter argued that undeveloped land was taken from him by the defendant's harmful act and that damages should include the value of the undeveloped land, as well as the value of the stream of monthly rental income for years to come that the plaintiff would have earned had the plaintiff been able to develop the land.

Example: Property Owner sues County for the value of undeveloped property condemned for a rapid-transit extension. Property Owner's damages claim is \$18 million, which is the appraisal value of a hypothetical condominium development on the property less the anticipated cost of building the development. The County's expert, an appraiser, argues that the market value of the property is \$2 million, based on comparable undeveloped land nearby.

Comment: In principle, if the real estate market is perfectly competitive, the current market value of undeveloped land and the market value of the same land with proper development, less the cost of that development, should be the same, because buyers would bid for the developed properties based on the value of the undeveloped land. Thus, Property Owner may have understated the development costs. But the value of nearby properties used as comparables may understate the value of the condemned property—they may be available for sale because they lack certain features that would make them more desirable to develop, such as a view. On the other hand, the Property Owner's valuation does not reflect the probability that the Property Owner may not succeed in building the condominium.

Moreover, as was the case with respect to modeling the defendant's actions had the alleged harmful act not occurred, there is a risk that expert analyses may be tainted by hindsight when making assumptions about what actions the plaintiff would have taken, had the alleged harmful act not occurred.

Disputes about whether all economic consequences of the alleged harmful act are being accounted for

Another area where disputes may arise when analyzing the direct economic impact of the alleged harmful act over multiple periods is whether the experts' damages analyses have fully considered all the reasonably foreseeable economic consequences of the alleged harmful act. Failure to fully consider all reasonably foreseeable economic consequences of the alleged harmful act may lead experts to estimate damages incorrectly, possibly significantly so.

Reference Guide on Estimation of Economic Damages

For example, where the injury takes the form of lost sales volume, the plaintiff usually has avoided the cost of production for the lost sales. Thus, an expert would overstate damages by not including the avoided costs of production as a reduction in the estimated direct economic impact of the alleged harmful act. Calculation of these avoided costs is a common area of disagreement about damages. Conceptually, avoided cost is the difference between the cost that would have been incurred at the higher volume of sales but for the alleged harmful act and the cost actually incurred at the lower volume of sales achieved. The avoided-cost calculation is done for each period. The following are some of the issues that arise in calculating avoided cost:

- For a firm operating at capacity, expansion of sales is cheaper in the longer run than in the short run; however, if there is unused capacity, expansion of sales may be cheaper in the short run.
- The costs that can be avoided if sales fall abruptly are less in the short run than in the longer run.
- Avoided costs may include marketing, selling, and administrative costs as well as the cost of manufacturing.
- Some costs are fixed, at least in the shorter run, and are not avoided as a result of the reduced volume of sales caused by the harmful act.

Sometimes putting costs into just two categories is useful: those that vary with sales (variable costs) and those that do not vary with sales (fixed costs). This breakdown is approximate, however, and does not do justice to important aspects of avoided costs. In particular, costs that are fixed in the short run may be variable in the longer run. Disputes frequently arise over whether particular costs are fixed or variable. One side may argue that most costs are fixed and were not avoided by losing sales volume, whereas the other side may argue that many costs are variable.

Certain accounting concepts relate to the calculation of avoided cost. Profit-and-loss statements frequently report the cost of goods sold.²⁶ Costs in this category are frequently, but not uniformly, avoided when sales volume is lower. But costs in other categories, called operating costs or overhead costs, may also be avoided, especially in the longer run. One approach to the measurement of avoided cost is based on an examination of all of a firm's cost categories. The expert determines how much of each category of cost was avoided.

An alternative approach uses regression analysis or some other statistical method to determine how costs vary with sales as a general matter within the firm or across similar firms. The results of such an analysis can sometimes be used to measure the costs avoided by the decline in sales volume caused by the harmful act.

26. See, e.g., *United States v. Arnous*, 122 F.3d 321, 323–24 (6th Cir. 1997) (finding that the district court erred when it relied on government's theory of loss because the theory ignored the cost of goods sold).

Disputes about the use of expected outcomes to estimate the impact of the alleged harmful act

In most situations where the expert's damages analysis includes an evaluation of the impact of the alleged harmful act on future flows of economic income or loss, it is necessary to account for the uncertainty that surrounds the actual amount of those flows under different, yet-to-be-determined economic circumstances. For example, in a matter involving the valuation of a business, it is typically necessary to analyze how the future profits of the business may differ under different states of the world (e.g., in an economic recession versus in an economic boom, or if the business's new product becomes popular versus if it does not).

A fundamental economic principle in the analysis of uncertainty is that the value of future flows of economic income or loss depends on the expected outcome of those flows.²⁷ The expected outcome of an uncertain future flow of economic income or loss is conceptually simple to calculate. First, it is necessary to determine the specific outcome for the economic flow under the various possible scenarios and the probability that each scenario will occur. Then, the expected outcome is calculated as the weighted average of the outcomes for the economic flow across the various possible scenarios, weighting each scenario by the probability that it will occur. For example, in a simple situation where a company faces a one-time future profit of \$1 million with probability 40% and a profit of \$16 million with probability 60%, the company's expected profit is \$10 million (\$1 million times 40% plus \$16 million times 60%).²⁸

Application of the expected-value approach involves a careful study of the various risk factors that are expected to impact the ultimate outcome for the flow of economic income or loss. For example, in a business valuation matter involving a commercial real estate developer, it may be necessary to consider how the company's profitability would differ depending on risk factors that are likely to include future sales prices of commercial real estate, construction costs

27. As discussed in the section titled "Disagreements About the Discount Rate to Value the Impact of the Alleged Harmful Act in Periods After the Valuation Date" below, another important issue in the analysis of damages when there are future flows of economic income or loss is the appropriate discount rate to be used to transform expected future flows into their present value.

28. Sometimes the alternatives and interactions between the possible outcomes become so complex that more sophisticated analytical methods may be required. In such cases, experts often generate hundreds to millions of possible outcomes using probabilistic simulation techniques (e.g., Monte Carlo). These techniques usually start from a model of the relation between the outcome variable of interest (e.g., a company's profits, or the payoffs from a financial derivative) and the risk factors that affect that variable (typically based on findings from the peer-reviewed academic literature or statistical analyses of historical data). Then, the value that the outcome variable of interest would take under different future realizations of the relevant risk factors is simulated. Because those realizations are not known with certainty, they are simulated based on random draws from the assumed or estimated statistical distribution of the risk factors. Those random draws are then used as an input to the model to determine the simulated value of the outcome variable of interest.

(e.g., labor, steel, or lumber), local zoning restrictions, and availability of bank financing. Disputes often arise among experts over which risk factors must be considered in analyzing expected values and with respect to how those factors are likely to impact the flows of economic income or loss under different situations. Economic experts often rely on peer-reviewed academic literature or on statistical analyses based on historical data to determine the relevant risk factors and how they are expected to impact the ultimate outcome.

Disputes about the economic situation in future periods

When it is necessary to estimate the direct period-by-period impact of the alleged harmful act in future periods, disputes often arise over the basis for the assumption that the future will look a certain way. For example, in matters involving the valuation of startup companies with no track record of earlier profitability, a common source of disagreement is the likelihood that the company at issue will reach profitability and, if it does, how profitable it will be. An expert who values a startup company with no track record of earlier profitability under the assumption that the company will reach profitability is likely to be scrutinized on the basis for that assumption.

Example: Plaintiff Xterm is a failed startup. Defendant VenFund has breached a venture-capital financing agreement. Xterm's damages study projects the profits it expected to make under its business plan. VenFund's damages estimate, which is much lower, is based on the value of the startup as revealed by sales of Xterm's equity made just before the breach.

Comment: Both sides confront factual issues in validating their damages estimates. Xterm needs to show that the expected profits according to its business plan were supported by relevant information available to it as of the time of the breach. VenFund needs to show that the sale of equity places a reasonable value on the firm (e.g., it did not take place in a "fire sale" and it incorporated the same information that was available as of the date of breach). This dispute can also be characterized as whether the plaintiff is entitled to expectation damages or reliance damages. Certain jurisdictions may limit damages for firms with no track record of profitability.²⁹

29. See, e.g., *Schonfeld v. Hilliard*, 218 F.3d 164, 172 (2d Cir. 2000) ("Although lost profits need not be proven with 'mathematical precision,' they must be 'capable of measurement based upon known reliable factors without undue speculation.' Therefore, evidence of lost profits from a new business venture receives greater scrutiny because there is no track record upon which to base an estimate. Projections of future profits based upon 'a multitude of assumptions' that require 'speculation and conjecture' and few known factors do not provide the requisite certainty." (citations omitted)).

*Disputes about the consideration of non-cash effects
of the alleged harmful act*

In some situations, a careful assessment of the plaintiff's economic situation in the actual world and in the but-for world reveals that the direct economic impact of the alleged harmful act on a period-by-period basis may include the loss of a flow of economic income that does not directly involve the loss of actual cash.

For example, in some firms, employee stock options are a significant part of total compensation. Employee stock options grant their holders the right to purchase shares of company stock at a fixed price. Stock options are often used by early-stage businesses because the options do not require the business to pay out any cash at the time they are granted. At the same time, the options are valuable compensation for employees because they potentially allow them to benefit from the company's future growth. Specifically, at a future date, the options may be exercised, and the employee option holder will pay only the previously agreed exercise price (typically, the price per share at the time the options are received) as opposed to the price per share at the time the options are exercised. If the company continues to grow successfully into the future, such that the shares' market price vastly exceeds the exercise price, option holders will pay a price for new shares that is a fraction of the shares' market price.

In a lost-sales matter where a plaintiff company's employees are compensated using stock options, the parties may dispute whether the value of options should be included in the costs avoided by the plaintiff as a result of lost-sales volume. The defendant's expert might argue that stock options should be included, because their issuance is costly to the shareholders. The defendant might place a value on newly issued options and amortize this value over the period from issuance to vesting. The plaintiff, in contrast, might exclude options costs because the options cost the firm no cash payout at the time the options are granted. However, compensating employees using stock options imposes real economic costs on the firm's shareholders, in the form of actual value outlays when these options are exercised or in the form of expected future value outlays at the time the options are granted. Those costs should be considered.

Example: Firm A pays its sales manager \$2,000 for every machine sold at \$100,000, as well as options to purchase 1,600 shares in a year at the existing price of \$10 per share. Firm A asserts that it lost \$10 million in sales (100 machines) as a result of Firm B's disparagement of Firm A. In its damages analysis, Plaintiff Firm A states that the lost sales represent lost profits of \$5.8 million: \$10 million less \$4 million in avoided production costs and \$200,000 in avoided sales commissions. Defendant Firm B calculates that each stock option is worth \$5 today based on an analysis

using accepted financial models to value the options. Thus, Firm B asserts that damages are \$5 million: \$10 million less \$4 million in avoided production costs and \$1 million in sales commissions (\$200,000 plus $\$5 \times 100 \times 1,600$).

Valuing the Period-by-Period Impact of the Alleged Harmful Act as of a Single Valuation Date

This section discusses issues that arise when determining the appropriate rates for the purposes of discounting and capitalization, as well as the appropriate valuation date. Once an expert generates estimates of the direct economic impact of the alleged harmful act in each relevant period, it is then necessary to convert those estimates into a single measure of damages as of a specific date—the damages valuation date. As noted above, experts do so by applying the fundamental economic principle that the value of flows of economic income or loss at different points in time can be translated into an equivalent value as of a particular date through discounting or capitalization using appropriate rates.

Discounting is the act of translating a future economic value to its equivalent economic value as of an earlier point in time. For example, discounting at an appropriate rate can be used to translate receiving \$105 a year from now into its economic value today and to compare that to receiving \$100 today. If the appropriate discount rate is 10%, then today's value of receiving \$105 in a year is approximately \$95—calculated as \$105 divided by $(1 + 10\%)$ —and receiving \$100 today is worth more than receiving \$105 in a year. Capitalization is the reverse of discounting—that is, it is the act of translating a past economic value into its equivalent value as of a later point in time. For example, capitalizing at an appropriate rate can be used to compare receiving \$100 today to having received \$95 a year ago (and having reinvested that amount). If the appropriate capitalization rate is 10%, then today's value of \$95 received a year ago is approximately \$105—calculated as \$95 multiplied by $(1 + 10\%)$ —and \$95 received a year ago is worth more than \$100 received today.

Disagreements about the discount rate to value the impact of the alleged harmful act in periods after the valuation date

As a matter of economics, the appropriate discount rate to convert the economic value of future flows of economic income or loss (e.g., \$100 of business profits in one year) into their economic value as of an earlier date depends on two factors: the time value of money and the risk premium. The time value of money relates to how individuals and companies trade off sure dollars in the future for sure

dollars as of an earlier date, and it is typically measured using a risk-free rate. The risk premium relates to how individuals and companies trade off uncertain dollars for certain dollars. As the name suggests, the risk premium is typically expressed as an increment to the time value of money, such that the discount rate can be calculated as the sum of the time value of money (i.e., the risk-free rate) and the risk premium.

Both factors are important in the determination of discount rates and can have a substantial impact on damages estimates. This section discusses key issues faced by experts when estimating discount rates that adequately measure the time value of money and the risk premium.

Estimating the time value of money

As noted above, the time value of money relates to how individuals and companies trade off dollars in the future for dollars as of an earlier date. The value of money has a temporal dimension for various reasons. First, inflation erodes the value of future money by reducing the basket of goods and services that can be purchased with the same amount of dollars. Second, individuals and companies can reinvest today's dollars in order to obtain a larger number of dollars in the future. Thus, the time value of money on a given date depends on inflation expectations and on available investment opportunities. As those change over time, so does the time value of money. Discount rates used in damages analyses that do not adequately account for the time value of money as of the valuation date may generate unreliable damages estimates.

To estimate the time value of money, experts typically rely on interest rates derived from the prices of safe government debt (in whatever currency damages are being sought and measured). When damages are being measured in U.S. dollars, experts typically use interest rates derived from the prices of U.S. Treasury bills, notes, and bonds of various maturities (ranging from a few days to as many as thirty years). U.S. government debt is typically regarded as risk-free, in the sense that the investor is guaranteed the promised return on their investment if the security is held to its maturity.³⁰

Interest rates derived from longer-term debt tend to differ from interest rates derived from shorter-term debt: Long-term interest rates are typically higher than short-term interest rates in normal economic conditions. Thus, the relevant interest rate to account for the time value of money depends on the horizon of the flows being analyzed. For example, lost profits thirty years into the future should be valued using discount rates that measure the time value of money based on interest rates with a similar horizon.

30. In truth, U.S. government debt is not entirely risk-free, because there is a risk (remote as it may be) that the U.S. government may default.

Estimating the risk premium

When determining the appropriate discount rate to value a flow of economic income or loss, the key source of disagreement among experts tends to be the estimation of the risk premium. Disagreements over this topic also tend to be difficult for the layperson to assess because the academic literature that studies risk premiums is vast and tends to be highly technical. Therefore, particular attention needs to be given to the basic principles surrounding the estimation of risk premiums in order to evaluate experts' positions and their bases.

The risk premium associated with a particular flow of economic income or loss is the compensation investors require for bearing the risks associated with that flow. The risks associated with a particular flow of economic income or loss are typically split into two types: systematic risks and idiosyncratic risks. Systematic risks relate to broader market conditions, that is, risks arising from factors that impact both the flow of economic income or loss at issue and the economy more broadly. Systematic risks affecting a firm include economic downturns, inflation, and other risks that an investor cannot avoid by holding a diversified investment portfolio. In contrast, idiosyncratic risks are risks arising from factors that impact the flow of economic income or loss at issue but do not impact the economy more broadly. Idiosyncratic risks may include whether a venture will succeed, a firm's ability to obtain financing, whether a competitor will develop a similar product, and risks related to the pricing of the product or competitive products, such as the price of inputs.

A basic principle of financial economics is that in order to make risky investments, investors require compensation for risks associated with those investments. Thus, whenever the uncertainty surrounding a flow of economic income or loss is related to overall market conditions, it is necessary to account for that uncertainty in the estimation of the discount rate.

In ideal competitive financial markets, investors demand compensation only for systematic risks, because those are the risks that investors cannot eliminate by holding a well-diversified portfolio of assets. Thus, experts often assume that no risk premium is associated with idiosyncratic risks.

A common approach for determining the risk premium associated with a particular flow of economic income or loss, although not the appropriate one under all circumstances where the calculation of a risk premium is warranted, is part of the Capital Asset Pricing Model (CAPM). The CAPM is a standard model in financial economics to analyze the relation between the risk from investing in a particular asset and the expected rate of return that investors demand for that asset (i.e., its discount rate).³¹ Under the CAPM, the expected return for a given asset

31. See, e.g., Aswath Damodaran, *Damodaran on Valuation: Security Analysis for Investment and Corporate Finance* 31–35 (2d ed. 2006); Richard A. Brealey, Stewart C. Myers & Franklin Allen, *Principles of Corporate Finance* 205–08 (13th ed. 2020).

$(E[R_i])$ is equal to the risk-free rate (R_f) (which compensates investors for the time value of money) plus a risk premium for that specific asset (which compensates investors for taking on the risk from investing in the asset). The risk premium for the asset is equal to the risk premium for the overall market ($E[R_m] - R_f$) multiplied by the asset's *beta*, which is explained below. Mathematically, the CAPM equation for the expected return (or discount rate) on an asset is

$$E[R_i] = R_f + \beta_i \times (E[R_m] - R_f)$$

A key part of applying CAPM to the valuation of a particular asset is to determine the asset's beta (β_i). Beta measures the sensitivity of the asset's returns to changes in returns on the overall market. Assets whose returns are more sensitive to the returns of the overall market tend to decline more when the overall market declines. Because investors require compensation for such declines, assets with higher betas carry higher risk premiums (and, thus, have higher discount rates) than assets with lower betas. To illustrate, for a company whose stock has a beta of 1.5, if the index of value for a representative and broad set of firms³² decreases by 10% over a year, then the value of the company's stock tends to decrease by 15% over that year (1.5 times 10%). Under CAPM, the risk premium for that stock can be calculated as the 1.5 beta multiplied by the historical average risk premium for the overall stock market.³³ The calculation may be presented in the following format:

1. Beta: $\beta_i = 1.5$
2. Market risk premium: $E[R_m] - R_f = 6.0\%$
3. Risk premium (line 1 times line 2): 9.0%

In this example, if the expert estimates the risk-free rate as 2.00%, for example, based on 20-year treasury rates as of the valuation date, then the estimated discount rate will be 11.00% (2.00% plus 9.00%).

Disagreements about the capitalization rate to value the impact of the alleged harmful act in periods before the valuation date

When the direct economic impact of the alleged harmful act is a flow of economic income or loss that occurred (or would have occurred in the but-for world) before the valuation date, it is necessary to determine a capitalization rate that can be used to value the past flow of economic income or loss as of the later valuation date. Such determination often requires careful consideration of the

32. *E.g.*, the S&P 500 index.

33. Experts may disagree on the appropriate methodology to estimate the market risk premium.

specific circumstances faced by the plaintiff that was impacted by the alleged harmful act at the time the direct economic impact occurred.

In some situations, it is natural to see past flows as income that could have been reinvested, and thus, it is necessary to consider the rate of return that investment would have generated. For example, in a matter where a brokerage firm is alleged to have overcharged its client investors for stock transactions over a period of years, investors may claim that the amount of the overcharge in each transaction would have been reinvested into the same stocks and generated an additional return by the valuation date. In other situations, it is natural to see the past flow as a loss that would have to be financed (e.g., from a bank), and it is necessary to consider what rate of return would have been required in order to finance that loss. For example, in a patent infringement case where the patentee's profits were adversely impacted by the infringing company's conduct, the patentee may claim that its lost profits are economically equivalent to an unsecured loan (albeit an involuntary one) to the infringer, and therefore the infringer's borrowing rate should be used to capitalize past lost profits.

The appropriate capitalization rate to value past flows of economic income or loss is not always a matter of expert analysis. Sometimes, it is set by statute or legal precedent (a topic covered in the section titled "Prejudgment Interest" below), and all an expert needs to do, once the direct economic impact of the alleged harmful act in past periods has been estimated, is to capitalize those estimates through the valuation date.

Disagreements about what valuation date to use

An important decision in many analyses of economic damages is the valuation date, that is, the date as of which the value of the direct economic impact of the alleged harmful act over multiple periods will be determined. Sometimes, the appropriate valuation date is set by law. For example, in a breach of contract matter, the proper valuation date is typically the date of the alleged breach. However, when the valuation date is not set by law, expert disputes may arise over the valuation date, given its potential impact on damages.

There are at least two reasons why the valuation date used in a damages analysis can have a material impact on damages. First, the appropriate rates for discounting and capitalization purposes change significantly over time. For example, all else being equal, the appropriate discount rate to value a business's expected future profits will be higher in periods when future inflation is expected to be high. Thus, if there are significant changes in inflation expectations, the damages valuation date can have a significant impact on the damages estimate. Second, the experts' assessment of the direct economic impact of the alleged harmful act across multiple periods depends on the parties' knowledge as of the valuation date, and that knowledge may change over time as the parties'

economic circumstances evolve. For example, in a business valuation case, the value of the business at issue may be very different at a date when a company has no direct competitors versus a date—potentially just a few months later—after competitor firms have entered the market, significantly eroding the profitability of the business at issue.

Other Issues Arising in General in Damages Measurement

Data Validity

Validation of any dataset is critical. The expert needs to have a firm basis for relying on the chosen data. Opposing parties frequently try to impeach damages estimates by challenging the reliability of the data or an expert's validation of the data. This section discusses some key issues that experts consider when evaluating data validity.

Criteria for Determining the Validity of Data

The validity of data is ultimately a matter of judgment. Experts often need to use data that are not mathematically precise because the only relevant available data may be known to contain some errors. Experts generally have an obligation to use data that are as accurate as possible, meaning that the expert has used every practical means to eliminate erroneous information. Experts should also perform cross-checks with other data, to the extent possible, to demonstrate completeness and reliability. Where data are inherently inaccurate because of random influences, validity requires absence of bias or adjustment for bias. Validation of data turns in part on commonsense indicators of accuracy and bias. The following is a list, in rough order of presumptive validity, of data sources often used in damages measurement:

1. Official government publications and databases, such as from the Census Bureau, the Bureau of Labor Statistics, and the Bureau of Economic Analysis
2. Filings with the Securities and Exchange Commission, including a company's audited financial statements
3. A company's accounting and sales records maintained in the normal course of business
4. A company's operating reports prepared for management in the normal course of business
5. Reports issued by securities analysts covering a company

Reference Guide on Estimation of Economic Damages

6. A survey designed by the damages expert with assistance from survey professionals, conforming to established standards of survey design and execution
7. A marketing–research study conforming to established standards for these studies
8. Industry reports and other materials prepared by unaffiliated organizations and consultants
9. Newspaper articles
10. A company’s study of damages from the harmful event, prepared in the normal course of business
11. A company’s study of damages, prepared for litigation

Other factors can alter this presumptive order of validity. When audited financial statements are alleged to be fraudulent, they (or some portions therein) may lose their presumption of validity. The most fully researched articles in the best newspapers have a higher presumption of validity. Some private industry reports are highly reliable. Rules of evidence may also affect when and how these various data sources can be used in expert reports and at trial. However, when an expert’s preferred analysis would rely on data from an opposing party and those data are unavailable, then courts may make allowances for this lack of availability if the expert has made every effort to demonstrate that the data used in the expert’s actual analysis are reasonable.

Quantitative Methods for Validation

One important aspect of validation is to verify that the data are complete. If a separate summary document is available that shows the number of records in the database together with summary statistics such as total amounts paid, completeness is easy to establish. Other methods for establishing completeness include examining serial numbers for records and finding other sources of information about transactions that should be in the data and verifying the presence of all or a sample of them.

Another validation method is to examine the accuracy of a sample of observations in a dataset by comparing the sampled observations to corresponding source documents to ensure the values match. Choosing which specific observations to sample can be done in alternative ways. For example, if the dataset consists of purchasing records, then the expert may examine all of the records for a sample of customers, or the expert may examine all of the records for a sample of transactions of certain types.

Another important aspect of validation is to test the internal integrity of the data. For example, sales proceeds should reflect underlying quantities sold and unit prices. The expert can compare sales proceeds to the product of quantities

and prices. Similarly, an expert may analyze the distribution of values for a particular data field to identify observations with values outside the expected range. For example, a negative value in a field representing a unit price would not make logical sense.

Handling of Missing Data

In dealing with missing data, it is critical to ascertain why the data are missing and to attempt to isolate the extent of the missing data. If only a small fraction of data is missing and the pattern appears to be random, then potentially the issue of the missing data can be disregarded and inferences can be drawn using only the available data.

However, missing data are seldom random. For example, suppose that only 1% of transactions are missing, but the transactions that are missing are large ones accounting for a third of all volume. Validation by summarizing across different characteristics will usually identify missing data that are not random. Such errors might occur if all the missing transactions were submitted in a different format that the program for reading the data does not handle. For example, a manufacturer might record sales to Walmart separately from all other customers.

Identifying and adding the missing data to the database is the best correction for missing data, but this is often not possible. In this case, the expert needs to address the problem in another way. The simplest method is to “gross up” damages to reflect the missing data. For example, if 10% of the transactions are randomly missing, then the expert may correct for the missing transactions by dividing calculated damages by 0.9. This method implicitly assumes that the percentage of missing transactions is known and that the missing and non-missing transactions reflect the same damages on average.

A related approach is to rely on partial, detailed data to measure damages as a fraction of another variable, such as sales. With this approach, other reliable and complete company records such as audited financials may be used to identify the company’s total revenues, and damages are then calculated as the fraction of total sales as calculated above. This approach implicitly assumes that the relationship between the missing variable (i.e., damages) and the related, observable variable (e.g., sales) is stable and that most of the variation in outcomes for the missing variable can be explained by the variation in outcomes for the observable variable. The expert may choose to patch together incomplete data from one source and infer complete, reliable data using other approaches. Such approaches can include using a survey of customers or workers to measure damages per dollar of sales or per dollar of earnings and then applying those ratios to reliable data on total sales or total earnings.

Prejudgment Interest

The law may specify how to calculate interest for losses prior to a verdict on liability, generally termed prejudgment interest.³⁴ The law may exclude prejudgment interest, specify prejudgment interest to be a statutory rate, or exclude compounding.³⁵ Table 1 illustrates these alternatives. With simple uncompounded interest, losses from five years before trial earn five times the specified annual interest rate, so compensation for a \$100 loss from five years ago is \$135 at a 7% annual interest rate. With compound interest, the plaintiff earns interest on past interest. Compensation at 7% interest compounded annually is about \$140 for a loss of \$100 five years before trial. The difference between simple and compound interest becomes much larger if the time from loss to trial is greater or if the interest rate is higher. Because interest is often reinvested to earn further interest, economic analysis generally supports the use of compound interest.

Table 1. Calculations of Prejudgment Interest (in Dollars)

Years of Before Trial	Loss Without Interest	Loss with Compound Interest at 7%	Loss with Simple Uncompounded Interest at 7%
10	\$100	\$197	\$170
9	\$100	\$184	\$163
8	\$100	\$172	\$156
7	\$100	\$161	\$149
6	\$100	\$150	\$142
5	\$100	\$140	\$135
4	\$100	\$131	\$128
3	\$100	\$123	\$121
2	\$100	\$114	\$114
1	\$100	\$107	\$107
0	\$100	\$100	\$100
Total	\$1,100	\$1,578	\$1,485

34. See generally Michael S. Knoll, *A Primer on Prejudgment Interest*, 75 Tex. L. Rev. 293 (1996) (discussing prejudgment interest extensively). See, e.g., *Ford v. Rigidply Rafters, Inc.*, 984 F. Supp. 386, 391–92 (D. Md. 1997) (specifying a method of calculating prejudgment interest in an employment discrimination case to ensure plaintiff is fairly compensated rather than given a windfall); *Arcon/Pac. Ltd. v. Coit*, No. C-81-4264-VRW, 1997 WL 578673, at *1–*2 (N.D. Cal. Sep. 8, 1997) (reviewing supplemental interest calculations and applying California state law to determine the appropriate amount of prejudgment interest to be awarded); *Prestige Cas. Co. v. Michigan Mut. Ins. Co.*, 969 F. Supp. 1029, 1032–34 (E.D. Mich. 1997) (analyzing Michigan state law to determine the appropriate prejudgment interest award).

35. When compounding interest, it is important to use a rate that reflects the periodicity at which interest is compounded (e.g., one should use an annual rate if interest is compounded annually).

Where the law does not prescribe the form of interest for past losses, experts will normally apply a reasonable interest rate to bring those losses forward. The parties may disagree on whether the interest rate should be measured before or after tax. The before-tax interest rate is the normally quoted rate. To calculate the corresponding after-tax rate, one subtracts the amount of income tax the recipient would have to pay on the interest. Thus, the after-tax rate depends on the tax situation of the plaintiff. As an example, if the before-tax interest rate is 9% and the tax rate is 30%, then one would subtract 2.7% (9% times 30%) from the before-tax interest rate of 9% to arrive at an after-tax interest rate of 6.3%.

Even where damages are calculated on a pretax basis, economic considerations suggest that the prejudgment interest rate should be on an after-tax basis: Had a taxpaying plaintiff actually received the lost earnings in the past and invested the earnings at the assumed rate, income tax would have been due on the interest. The plaintiff's accumulated value would be the amount calculated by compounding past losses at the after-tax interest rate.

Where there is economic disparity between the parties, there may be a disagreement about whose interest rate should be used—the borrowing rate of the defendant or the lending rate of the plaintiff or some other rate. There may also be disagreements about adjustment for risk.³⁶

Accounting for Income Taxes

A damages award compensates the plaintiff for lost economic value. In principle, the calculation of compensation should measure the plaintiff's loss after taxes and then calculate the magnitude of the pretax award needed to compensate the plaintiff fully, once taxation of the award is considered. In practice, the tax rates applied to the original loss and to the compensation are frequently the same. When the rates are the same, the two tax adjustments are a wash. In that case, the appropriate pretax compensation is simply the pretax loss, and the damages calculation may be simplified by the omission of tax considerations.

In some damages analyses, explicit consideration of taxes is essential, and disagreements between the parties may arise about these tax issues. If the plaintiff's lost income would have been taxed as a capital gain (at a preferential rate), but the damages award will be taxed as ordinary income, the plaintiff can be expected to include an explicit calculation of the extra compensation needed to

36. See generally James M. Patell, Roman L. Weil & Mark A. Wolfson, *Accumulating Damages in Litigation: The Roles of Uncertainty and Interest Rates*, 11 J. Legal Stud. 341 (1982), <https://doi.org/10.1086/467705> (extensive discussion of interest rates in damages calculations).

make up for the loss of the tax advantage. Sometimes tax considerations are paramount in damages calculations.³⁷

Example: Trustee wrongfully sells Beneficiary's property at full market value. Beneficiary would have owned the property until death and deferred the capital gains tax.

Comment: Damages are the difference between the actual capital gains tax and the present value of the future capital gains tax that would have been paid but for the wrongful sale.

In some cases, the law requires different tax treatment of the claimed loss and compensatory awards. Again, the tax adjustments do not offset each other, and consideration of taxes may be a source of dispute.

Example: Driver injures Victim in a truck accident. A state law provides that awards for personal injury are not taxable, even though the income lost as a result of the injury would have been taxable. Victim calculates damages as lost pretax earnings, but Driver calculates damages as lost earnings after tax.³⁸ Driver argues that the nontaxable award would exceed actual economic loss if it were not adjusted for the taxation of the lost income.

Comment: Under the principle that damages are to restore the plaintiff to the economic equivalent of the plaintiff's position absent the harmful act, it may be recognized that the income to be replaced by the award would have been taxed.³⁹ However, the law in a particular jurisdiction may not allow a jury instruction on the taxability of an award.⁴⁰

37. See generally John H. Derrick, Annotation, *Damages for Breach of Contract as Affected by Income Tax Considerations*, 50 A.L.R. 4th 452 (1986) (discussing a variety of state and federal cases in which courts ruled on the propriety of tax considerations in damage calculations; courts have often been reluctant to award difference in taxes as damages because it is calling for too much speculation).

38. See generally Brian C. Brush & Charles H. Breedon, *A Taxonomy for the Treatment of Taxes in Cases Involving Lost Earnings*, 6 J. Legal Econ. 1 (1996) (discussing four general approaches for treating tax consequences in cases involving lost future earnings or earning capacity based on the economic objective and the tax treatment of the lump sum award).

39. See, e.g., *Myers v. Griffin-Alexander Drilling Co.*, 910 F.2d 1252 (5th Cir. 1990) (holding loss of past earnings between the time of the accident and the trial could not be based on pretax earnings).

40. See generally John E. Theuman, Annotation, *Propriety of Taking Income Tax into Consideration in Fixing Damages in Personal Injury or Death Action*, 16 A.L.R. 4th 589 (1982) (discussing a variety of state and federal cases in which the propriety of jury instructions regarding tax consequences is at issue). See, e.g., *Bussell v. DeWalt Prods. Corp.*, 519 A.2d 1379 (N.J. 1987) (holding that trial court hearing a personal injury case must instruct jury, upon request, that personal injury damages are not subject to state and federal income taxes); *Gorham v. Farmington Motor Inn, Inc.*, 271 A.2d 94 (Conn. 1970) (holding court did not err in refusing to instruct jury that personal injury damages were tax-free).

- Example:* Worker is wrongfully deprived of tax-free fringe benefits by Employer. Under applicable law, the award is taxable. Worker's damages estimate is grossed up by a factor so that the amount of the award, after tax, is sufficient to replace the lost tax-free value.
- Comment:* Again, to achieve the goal of restoring the plaintiff to a position economically equivalent absent the harmful act, an adjustment of this type is appropriate. The adjustment is often called grossing up damages.⁴¹ To accomplish grossing up, divide the lost tax-free value by one minus the tax rate. For example, if the loss is \$100,000 of tax-free income, and the income tax rate is 25%, the award should be \$100,000 divided by 0.75, or \$133,333.

Damages with Multiple Challenged Acts: Disaggregation

Plaintiffs sometimes challenge a number of defendants' acts and offer an estimate of the combined effect of those acts. If the court determines that only some of the challenged acts are illegal, the damages analysis needs to be adjusted to consider only those acts. Ideally, the damages testimony would equip the factfinder to determine damages for any combination of the challenged acts, but that may be tedious. If there are, say, ten challenged acts, it would take more than 1,000 separate studies to determine damages for every possible combination of findings about the unlawfulness of the acts.

There have been several cases where the jury has found partially for the plaintiff, but the jury lacked assistance from the damages experts on how the damages should be calculated for the combination of acts the jury found to be unlawful. Although some of these juries have attempted to resolve these issues, appeals courts have sometimes rejected damages found by juries without supporting expert testimony.⁴²

One solution to this problem is to make the determination of the illegal acts before damages testimony is heard, termed bifurcation of liability and damages.

41. See Cecil D. Quillen, Jr., *Income, Cash, and Lost Profits Damages Awards in Patent Infringement Cases*, 2 Fed. Cir. Bar J. 201, 207 (1992) (discussing the importance of taking tax consequences and cash flows into account when estimating damages).

42. See, e.g., *Litton Sys., Inc. v. Honeywell Inc.*, Case No. CV 90-4823 MRP (Ex), 1996 U.S. Dist. LEXIS 14662, at *13 (C.D. Cal. July 24, 1996) (granting new trial on damages only "[b]ecause there is no rational basis on which the jury could have reduced Litton's 'lump sum' damage estimate to account for Litton's losses attributable to conduct excluded from the jury's consideration"); *Image Tech. Servs., Inc. v. Eastman Kodak Co.*, 125 F.3d 1195, 1224 (9th Cir. 1997), cert. denied, 523 U.S. 1094 (1998) (plaintiffs "must segregate damages attributable to lawful competition from damages attributable to Kodak's monopolizing conduct").

The damages experts can adjust their testimony to consider only the acts found to be illegal.

In some situations, damages are the sum of separate damages for the various illegal acts. For example, there may be one injury in New York and another in Oregon. Then the damages testimony may consider the acts separately, and disaggregation is not challenging.

When the challenged acts have effects that interact, it is not possible to consider damages separately and add up damages for each individual act. This is an area of great confusion. When the harmful acts substitute for each other, the sum of damages attributable to each separately is *less* than their combined effect. As an example, suppose that the defendant has used exclusionary contracts and anticompetitive acquisitions to ruin the plaintiff's business. However, the plaintiff's business could not survive if either the contracts or the acquisitions were found to be legal. Damages for the combination of acts are the value of the business, which would have thrived absent both the contracts and the acquisitions. Now consider damages if only the contracts but not the acquisitions are illegal. In the but-for analysis, the acquisitions are hypothesized to occur because they are not illegal, but not the contracts. But the plaintiff's business cannot function in that but-for situation because the acquisitions alone were sufficient to ruin the business. Hence, damages—the difference in value of the plaintiff's business in the but-for and actual situations—are zero. The same would be true for a separate damages measurement for the acquisitions, with the contracts taken to be legal but not the acquisitions. Thus, the sum of damages for the individual acts is zero, but the damages if both acts are illegal are the value of the business.

When the effects of the challenged conduct are complementary, the sum of damages for each type of conduct by itself will be *more* than damages for all types of conduct together. For example, suppose a party claims that a contract is exclusionary based on the combined effect of the contract's duration and its liquidated damages clause that includes an improper penalty provision. The actual amount of the penalty would cause little exclusion if the duration were brief, but substantial exclusion if the duration were long. Similarly, the actual duration of the contract would cause little exclusion if the penalty were small but substantial exclusion if the penalty were large. A damages analysis for the penalty provision in isolation compares but-for—without the penalty provision but with long duration—to actual, where both the penalty provision and long duration are in effect, and finds that damages are large. Similarly, a damages estimate for the duration in isolation gives large damages. The sum of the two estimates is nearly double the damages from the combined use of both provisions.

A request that the damages expert disaggregate damages among each of the individual challenged acts is therefore complex and will not necessarily lead to individual estimates that will add up to the estimate based on all of the challenged acts. In principle, a separate damages analysis—with its own carefully

specified but-for scenario and analysis—needs to be done for every possible combination of illegal acts.⁴³

Example: Hospital challenges Glove Maker for illegally obtaining market power through the use of long-term contracts and the use of a discount program that gives discounts to consortiums of hospitals if they purchase exclusively from Glove Maker. The jury finds that Glove Maker has attempted to monopolize the market with its discount programs but that the long-term contracts were legal because of efficiencies. Hospital states that its damages are the same as in the case in which both acts were unlawful because either act was sufficient to achieve the observed level of market power. Glove Maker argues that damages are zero because the lawful long-term contracts would have been enough to allow it to dominate the market.

Comment: The appropriate damages analysis is based on a careful new comparison of the market with and without the discount program. The but-for analysis should include the presence of the long-term contracts because they were found to be legal.

Disputes About Whether the Plaintiff Is Entitled to All the Damages

When the plaintiff is in some sense a conduit to other parties, the defendant may argue that the plaintiff is entitled to only those damages that it would have retained in the but-for scenario. In the following example, a regulated utility is arguably a conduit to the ratepayers:

Example: Generator Maker overcharges Utility. Generator Maker argues that the overcharge would have been part of Utility's rate base, and so Utility's regulator had set higher prices because of the overcharge. Utility, therefore, did not lose anything from the overcharge. Instead, the ratepayers paid the overcharge. Utility argues that it stands in for all the ratepayers and that the damages

43. Order Denying Motion for Class Certification, *Reitman v. Champion Petfoods United States, Inc.*, No. 18-cv-1736-DOC-JPRx, 2019 U.S. Dist. LEXIS 221941 (C.D. Cal. Oct. 30, 2019). In denying class certification the court found that “the [Plaintiffs’ damages] model does not test whether the corrective statements have a different impact on consumers in particular combinations. Therefore, if any theory of liability is disposed of, the survey does not provide a reliable way to determine the difference in value based on the remaining theories of liability because the expert did not test the impact of particular combinations of statements. For these reasons, Plaintiffs have not ‘show[n] that such damages can be determined without excessive difficulty and attributed to their theory of liability.’” *Id.* at *32 (citing *JustFilm, Inc. v. Buono*, 847 F.3d 1108, 1121 (9th Cir. 2017)).

award will accrue to the ratepayers by the same principle—the regulator will set lower rates because the award will count as revenue for rate-making purposes.

Comment: In addition to the legal issue of whether Utility does stand in for ratepayers, there are two factual issues: Was the overcharge actually passed on to ratepayers? Will the award be passed on to ratepayers?

Similar issues can arise in the context of employment law.

Example: Plaintiff Sales Representative sues for wrongful denial of a commission. Sales Representative has subcontracted with another individual to do the actual selling and pays a portion of any commission to that individual as compensation. The subcontractor is not a party to the suit. Defendant Manufacturer argues that damages should be Sales Representative's lost profit measured as the commission less costs, including the payout to the subcontractor. Sales Representative argues that they are entitled to the entire commission.

Comment: Given that the subcontractor is not a plaintiff, and Sales Representative avoided the subcontractor's commission, the literal application of standard principles for damages measurement would appear to call for the lost-profit measure. The subcontractor, however, may be able to claim their share of the damages award. In that case, damages would equal the entire lost commission, so that, after paying off the subcontractor, Sales Representative receives exactly what they would have received absent the breach.

Limitations on Damages

Uncertainty and Speculation in Damages Estimates

Generally, a plaintiff may not recover damages beyond an amount proven with reasonable certainty.⁴⁴ This rule permits damages estimates that are not mathematically certain but excludes those that are speculative.⁴⁵ Failure to prove damages to a reasonable certainty is a common defense.⁴⁶

44. See, e.g., Restatement (Second) of Contracts § 352 (1981) ("Damages are not recoverable for loss beyond an amount that the evidence permits to be established with reasonable certainty.").

45. Restatement (Second) of Contracts § 352 cmt. a states, in pertinent part: "Damages need not be calculable with mathematical accuracy and are often at best approximate."

46. See, e.g., *Cole v. Homier Distrib. Co.*, 599 F.3d 856, 866 (8th Cir. 2010) (expert testimony on lost profits excluded under *Daubert* standard because it "failed to rise above the level of speculation."). See also *Webb v. Braswell*, 930 So. 2d 387 (Miss. 2006). In *Webb*, the plaintiff's expert

However, defining what constitutes reasonable certainty or speculation in a damages analysis may be difficult. The exclusion of damages on grounds of excessive uncertainty regarding the amount of damages may result in an award of zero damages—even when it is likely that the plaintiff suffered significant damages, though the actual amount is quite uncertain.

Traditionally, damages are calculated without reference to uncertainty about outcomes in the but-for scenario. Outcomes are taken as actually occurring if they are the expected outcome and as not occurring if they are not expected to occur. This approach may overcompensate some plaintiffs and undercompensate others. For example, suppose that a drug company was deprived of the opportunity to bring to market a drug that had a 90% chance of receiving Food and Drug Administration (FDA) approval, at a profit of \$2 billion, and a 10% chance of not receiving FDA approval, with losses of \$1 billion. The court may treat 90% as near enough to certainty and ignore the 10% risk of failure and award damages of \$2 billion.

By contrast, economists quantify losses from uncertain outcomes in terms of expected values, where the value in each outcome is weighted by its probability. Under that approach, economic losses in the above example would be calculated as the foregone \$2 billion potential profit assuming FDA approval times 90% plus the \$1 billion potential loss times 10%, or $(0.9) \times (\$2 \text{ billion}) + (0.1) \times (-\$1 \text{ billion}) = \$1.7 \text{ billion}$. Thus, the plaintiff would be overcompensated by \$300 million under the traditional approach that ignored the small probability of failure.

Now suppose the drug has only a 40% chance of FDA approval with the same economic payoffs. Although the court may decide to award the plaintiff no damages on grounds of uncertainty and speculation, the economic loss would be calculated as $(0.4) \times (\$2 \text{ billion}) + (0.6) \times (-\$1 \text{ billion}) = \$200 \text{ million}$. This issue can arise in any situation involving businesses or products whose future profitability is highly uncertain due to an unproven track record of profitability.

Damages That Are Too Remote

A second limitation on damages is that a plaintiff may not recover damages that are too remote. In tort cases, this restriction is expressed in terms of proximate cause,⁴⁷ which often is equivalent to reasonable foreseeability. In contract cases,

sought to testify as to future damages resulting from unplanted crops, without establishing that the crops would have been profitable. The court excluded the testimony based on Mississippi's adoption of the *Daubert* standard, stating that “damages for breach of contract must be proven with reasonable certainty and not based merely on speculation and conjecture.” *Id.* at 397.

47. See William L. Prosser, *Palsgraf Revisited*, 52 Mich. L. Rev. 1 (1953); Osborne M. Reynolds, Jr., *Limits on Negligence Liability: Palsgraf at 50*, 32 Okla. L. Rev. 63 (1979).

the limitation is similarly embodied in the idea of reasonable foreseeability—a party may not recover damages that were not reasonably foreseeable by the parties at the time of the agreement.⁴⁸ Generally, a party is liable for what are known as direct or general damages—those damages that arise naturally from the breach itself. A defendant may also be liable for consequential or special damages—damages apart from those arising naturally from the breach—if such damages were reasonably foreseeable at the time of the agreement.⁴⁹

Mitigation of Losses

A third limitation on damages is that a party may not recover for losses it could have avoided; this limitation is often expressed by stating that the injured party has a duty to mitigate, or lessen, its damages. The economic justification for the mitigation rule is that the injured party should not cause economic waste by needlessly increasing its losses.⁵⁰

For example, in a dispute about mitigation, a defendant may propose that any damages estimate should include an offset for earnings the plaintiff should have achieved, under proper mitigation, rather than actual earnings. As another example, the defendant might presume that the plaintiff could mitigate by locating another source of supply in the event of a breach of a supply agreement. Damages are limited to the difference between the contract price and the current market price in that situation.

For personal injuries, the issue of mitigation often arises because the defendant believes that the plaintiff's failure to work after the injury is a withdrawal from the labor force or retirement rather than the result of the injury.⁵¹ For commercial torts, mitigation issues can be more subtle. Where the plaintiff believes that the harmful act destroyed a company, the defendant may argue that the company could have been put back together and earned profit, possibly in a different line of business.⁵² The defendant will then treat the hypothetical profits as an offset to damages.⁵³

Alternatively, where the plaintiff continues to operate the business after the harmful act and includes subsequent losses in damages, the defendant may argue that the proper mitigation was to shut down after the harmful act.⁵⁴

48. See E. Allan Farnsworth, *Legal Remedies for Breach of Contract*, 70 Colum. L. Rev. 1145, 1199–1210.

49. *Id.*

50. See *id.* at 1183–84.

51. See William T. Paulk, *Mitigation Through Employment in Personal Injury Cases: The Application of the "Reasonable" Standard and the Wealth Effects of Remedies*, 58 Ala. L. Rev. 647–64 (2007).

52. See *Seahorse Marine Supplies Inc. v. Puerto Rico Sun Oil Co.*, 295 F.3d 68, 84–85 (1st Cir. 2002).

53. *Id.* at 84.

54. *Id.* at 85. See also *In re First New England Dental Ctrs., Inc.*, 291 B.R. 229, 240 (D. Mass. 2003).

Example: Franchisee Soil Tester starts up a business based on Franchiser's proprietary technology, which Franchiser represents as meeting government standards. During the startup phase, Franchiser notifies Soil Tester that the technology has failed. Soil Tester continues to develop the business but sues Franchiser for profits it would have made from successful technology. Franchiser calculates much lower damages on the theory that Soil Tester should have mitigated by terminating the startup.

Disagreements about mitigation may be hidden within the frameworks of the plaintiff's and the defendant's damages studies.

Example: Defendant Board Maker has breached an agreement to supply circuit boards. Plaintiff Computer Maker's damages study is based on the loss of profits on the computers to be made from the circuit boards. Board Maker's damages study is based on the difference between the contract price for the boards and the market price at the time of the breach.

Comment: There is an implicit disagreement about Computer Maker's duty to mitigate by locating alternative sources for the boards not supplied by the defendant. The Uniform Commercial Code spells out the principles for resolving these legal issues under the contracts it governs.⁵⁵

Damages That May Exceed the Cost of Avoidance

An important consideration in capping damages may be the costs of steps that the plaintiff could have taken that would have eliminated damages. This argument is closely related to mitigation but has an important difference: The defendant may argue that the plaintiff's failure to undertake a costly step that would have avoided losses was reasonable, but that the failure to take that step shows that the plaintiff knew that damages were much smaller than its later damages claim.

55. See, e.g., *Aircraft Guar. Corp. v. Strato-Lift, Inc.*, 991 F. Supp. 735, 738–39 (E.D. Pa. 1998) (Mem.) (finding that according to the Uniform Commercial Code, plaintiff-buyer had a duty to mitigate if the duty was reasonable in light of all the facts and circumstances, but that failure to mitigate does not preclude recovery); *S.J. Groves & Sons Co. v. Warner Co.*, 576 F.2d 524 (3d Cir. 1978) (holding that the duty to mitigate is a tool to lessen plaintiff's recovery and is a question of fact); *Thomas Creek Lumber & Log Co. v. United States*, 36 Fed. Cl. 220 (1996) (finding that under federal common law, the U.S. government had a duty to mitigate in breach-of-contract cases).

Example: Insurance Company suffered a business interruption because a fire made its offices unusable for a period of time. Insurance Company's damages claim for \$10 million includes not only the lost business until the offices were usable but also damages for permanent loss of business from customers who found other sources during the period the offices were unusable. Defendant argues that the plaintiff's failure to relocate to temporary quarters shows that their losses were less than the \$350,000 cost of that relocation.

Comment: Defendant's argument has the unstated premise that Insurance Company could have carried on its business and avoided any of its later losses by relocating. Insurance Company will likely argue that a decision not to relocate was commercially appropriate because relocation would not have avoided much of the lost business.

The Effect of a Liquidated Damages Clause

In addition to legally imposed limitations on damages, the parties themselves may have agreed to impose limits on damages, should a dispute arise. Such clauses are common in many types of agreements. Once litigation has begun, the parties may dispute whether these provisions are legally enforceable. The law may limit enforcement of liquidated damages provisions to those that bear a reasonable relation to the actual damages. In particular, the defendant may attack the amount of liquidated damages as an unenforceable penalty. The parties may disagree on whether the harmful event falls within the class intended by the contract provision.

Changes in economic conditions may be an important source of disagreement about the reasonableness of a liquidated damages provision. One party may seek to overturn a liquidated damages provision on the grounds that new conditions make it unreasonable.

Example: Scrap Iron Supplier breaches supply agreement and pays only the specified liquidated damages. Buyer seeks to set aside the liquidated damages provision because the price of scrap iron has risen, and the liquidated damages are a small fraction of actual damages under the expectation principle.

Comment: There may be conflict between the date for judging the reasonableness of a liquidated damages provision and the date for measuring expectation damages, as in this example. Generally, the date for evaluating the reasonableness of liquidated damages is the date the contract is made. In contrast, the date for measuring

expectation damages is the date of the breach. The conflict may be resolved by the substantive law of the jurisdiction.

Damages in Class Actions

Class Certification

The U.S. Supreme Court's decision in *Comcast Corp. v. Behrend* states that “rigorous analysis” is required to establish if the model proposed by plaintiffs in a class action is capable of measuring damages on a class-wide basis.⁵⁶ Consistent with this requirement, courts commonly analyze damages models as part of their decision whether to certify a class.⁵⁷

A key question often analyzed by courts is whether the proposed method of measuring class-wide damages isolates the impact of the theory of harm alleged. In *Comcast*, the Supreme Court found that the lower court erred in certifying a class of cable television subscribers because the plaintiffs had failed to show that the proposed damages model adequately translated the legal theory of the harmful event into an analysis of the economic impact of that event. Specifically, the plaintiffs proposed a damages model that estimated the combined impact of four proposed theories of antitrust impact but failed to estimate damages specific to each theory. Because the lower court eventually dismissed all but one of the plaintiffs' theories of harm and the plaintiffs' expert acknowledged that his model did not isolate damages resulting from any one of the plaintiff's theories of harm, the Supreme Court found that the proposed damages model was inadequate in that it was unable to isolate the harm resulting from the single surviving theory.⁵⁸

Since *Comcast*, many courts have emphasized the importance of having a damages model that ties directly to the theory of harm. For example, in *Reitman v. Champion*, a matter involving alleged misrepresentations on the packaging of dog food, the court denied class certification because the plaintiffs' damages

56. 569 U.S. 27, 35 (2013).

57. See, e.g., Memorandum of Law & Order, *Johnson v. Evangelical Lutheran Church in Am.*, No. 11–00023 (MJD/LIB), 2013 U.S. Dist. LEXIS 41944 (D. Minn. Mar. 26, 2013) (court evaluated if Board of Pensions of the Evangelical Lutheran Church in America breached its fiduciary duties by reducing annuity payments and rejected class certification on the basis that the board actions helped rather than harmed the majority of putative class members); Memorandum Opinion and Order, *Indiana Pub. Requirement Sys. v. AAC Holdings, Inc.*, No. 3:19-cv-00407, 2023 U.S. Dist. LEXIS 31022 (M.D. Tenn. Feb. 24, 2023) (The court evaluated whether plaintiff had put forth a reliable method to estimate damages consistent with the alleged misrepresentations. The court rejected plaintiff's damages model with respect to plaintiff's materialization-of-the-risk theory because it did not factor in the risk on which the theory was based. The court accepted plaintiff's damages model otherwise.).

58. *Comcast*, 569 U.S. at 38.

methodology tested the effects of statements created by plaintiffs to correct the alleged misrepresentations, and not the effects of the alleged misrepresentations on consumers.⁵⁹ Similarly, in *Freitas v. Cricket Wireless*, a case involving the sale of 4G-capable phones in markets where the defendant did not actually provide 4G coverage, the court denied class certification because plaintiffs simply measured the price difference between various 3G and 4G phones, but failed to account for other differences in the phones, such as the brand and features of the phones.⁶⁰

Another question that courts commonly analyze in connection with the requirements for class certification is whether the damages model proposed by the plaintiffs results in the need for individualized inquiry.⁶¹ Courts have usually accepted damages models that offer a common or formulaic method to estimate damages even if those models result in individualized damages calculations.⁶² However, class certification may be rejected in cases where computing individual damages is deemed overly complex or fact-specific.⁶³

A third common question is whether the proposed damages methodology is sufficiently developed for the court to assess if the model is capable of measuring class-wide damages. Courts have rejected models that fail to explain how important variables will be accounted for,⁶⁴ that do not plausibly explain how the consequences of the allegations will be isolated,⁶⁵ or that are “vague, indefinite, and unspecific.”⁶⁶ At the same time, some courts have accepted damages models that have not been implemented but merely proposed at an adequate level of detail.⁶⁷

59. The court also indicated that “if any theory of liability is disposed of, [the plaintiffs’ damages model] does not provide a reliable way to determine the difference in value based on the remaining theories of liability because the expert did not test the impact of particular combinations of statements.” See Order Denying Motion for Class Certification, *Reitman v. Champion Petfoods USA, Inc.*, No. 18-cv-1736-DOC-JPRx, 2019 U.S. Dist. LEXIS 221941 (C.D. Cal. Oct. 30, 2019).

60. *Freitas v. Cricket Wireless, LLC*, No. C 19-07270 WHA, 2022 WL 3018061, at *6 (N.D. Cal. July 29, 2022).

61. See, e.g., *Ludlow v. BP, P.L.C.*, 800 F.3d 674 (5th Cir. 2015).

62. See, e.g., *In re Whirlpool Corp.*, 722 F.3d 838 (6th Cir. 2013); *Leyva v. Medline Indus., Inc.*, 716 F.3d 510 (9th Cir. 2013).

63. In *Behrend v. Comcast Corp.*, the court reiterated that class-certification damages should not require “labyrinthine individual calculations.” 655 F.3d 182, 206 (3d Cir. 2011). See also *Brown v. Electrolux Home Prods., Inc.*, 817 F.3d 1225 (11th Cir. 2016) (stating “individual damages defeat predominance if computing them ‘will be so complex, fact-specific, and difficult that the burden on the court system would be simply intolerable.’”) (citation omitted).

64. *Bruton v. Gerber Prods. Co.*, No. 12-cv-02412-LHK, 2018 U.S. Dist. LEXIS 30814, at *34 (N.D. Cal. Feb. 13, 2018).

65. *Ang v. Bimbo Bakeries USA, Inc.*, No. 13-cv-01196-HSG, 2018 U.S. Dist. LEXIS 149395, at *2 (N.D. Cal. Aug. 31, 2018).

66. See also *Ohio Pub. Emps. Ret. Sys. v. Fed. Home Loan Mortg. Corp.*, No. 4:08CV0160, 2018 WL 3861840 (N.D. Ohio Aug. 14, 2018).

67. See, e.g., *In re Scotts EZ Seed Litig.*, 304 F.R.D. 397 (S.D.N.Y. 2015). See also *Goldemberg v. Johnson & Johnson Consumer Cos.*, 317 F.R.D. 374 (S.D.N.Y. 2016).

A court operating under the rule that class certification requires a fully developed damages quantification may need to grant discovery prior to class certification to support the class's damages analysis and the defendant's opposition.

Finally, as in other types of litigation, courts have evaluated damages models proposed in class actions with respect to their relevance and reliability. Many courts have rejected damages models proposed in class actions because they fail to meet the standard of relevance and reliability set by *Daubert*.⁶⁸

Class-Wide Damages

In many class actions, the damages expert measures and testifies to class-wide damages using methods discussed elsewhere in this reference guide. At a high level, the damages method offered by the expert may take any of a number of forms. Among other possibilities, it may involve a uniform damages amount per class member, or per instance of harm, multiplied by the total number of class members or instances of harm; it may involve a uniform damages amount per time period (e.g., workweek) multiplied by the number of at-issue time periods; it may involve a uniform damages percentage (e.g., an overpayment percentage) that is applied to total sales; or it may involve the application of a common method (e.g., a formula) to calculate differing damages amounts for different class members based on various inputs.

In class actions involving securities, damages experts are usually required to estimate per-share damages. Class-wide damages are typically calculated in a subsequent claims process where individual shareholders submit claims, along with evidence of their trades in the securities at issue.⁶⁹

Finally, courts do not typically require class-wide damages to be measured with certainty. As the Supreme Court stated, "Calculations need not be exact."⁷⁰ While mere speculation or guess is not sufficient, courts have held that it is enough if class-wide damages are demonstrated "as a matter of just and reasonable inference."⁷¹

68. See, e.g., *IBEW Local 90 Pension Fund v. Deutsche Bank AG*, No. 11 Civ. 4209 KBF, 2013 WL 5815472 (S.D.N.Y. Oct. 29, 2013); *In re Blood Reagents Antitrust Litig.*, 783 F.3d 183 (3d Cir. 2015). Note, however, that there is disagreement across district courts about whether the *Daubert* standard should be applied to evidence presented at the class-certification stage. See, e.g., *Cox v. Zurn Pex, Plumbing Prods. Liab. Litig.*, 644 F.3d 604 (8th Cir. 2011); *Sali v. Corona Reg'l Med. Ctr.*, 909 F.3d 996, 1005–06 (9th Cir. 2018).

69. See, e.g., *Order Regarding Plaintiffs' Motions for Prejudgment Interest, Approval of Notice of Verdict and Claims Administration Procedure, and Unsealing Documents* (Dkt. Nos. 745, 748, 752), *Hsingching Hsu v. Puma Biotechnology, Inc.*, No. SACV 15–00865 AG (SHKx), 2019 U.S. Dist. LEXIS 154278 (C.D. Cal. Sep. 9, 2019).

70. *Comcast Corp. v. Behrend*, 569 U.S. 27, 35 (2013).

71. See, e.g., *Behrend v. Comcast Corp.*, 655 F.3d 182, 203–04 (3d Cir. 2011) (quoting *Story Parchment Co. v. Paterson Parchment Paper Co.*, 282 U.S. 555, 563 (1931)). See also *In re MyFord Touch Consumer Litig.*, 291 F. Supp. 3d 936 (N.D. Cal. 2018).

Damages of Individual Class Members

Damages experts sometimes have a role in the process of disbursing funds from a verdict or settlement to individual class members. For example, an expert can develop software that measures individual damages based on evidence supplied by individuals through a claims-processing facility. In *Millsap v. McDonnell Douglas*, more than 1,000 class members—persons affected by the defendant’s challenged layoffs—completed sworn questionnaires describing their post-layoff experiences.⁷² McDonnell Douglas supplied additional information from its employee records. The class’s damages expert used standard methods for valuing claims for lost earnings to calculate estimates for each class member. Because the settlement reflected a compromise among the parties on a number of disputes about the law and about the facts underlying the layoffs, the total cash from the settlement was less than the sum of these estimates, and class members received a fraction of the amount indicated by the damages model.

Damages as a Basis to Evaluate the Fairness of a Proposed Settlement

Class-wide damages measures have a key role in resolving class-action cases, because courts refer to them in determining the fairness of proposed settlements. The court’s careful review of the benefits proposed for the class is essential because the interests of the class’s counsel may not be aligned with those of the class members with respect to settlement.

Example: Lender required excessive escrow deposits for property taxes from a class of mortgage borrowers, although the excess was repaid at the end of each year. Under the terms of the proposed settlement negotiated between Lender’s lawyers and those for the class, the excess is to be refunded to the class members immediately, with 30% of that amount paid to class counsel as fees.

Comment: This settlement is unreasonable and leaves the class worse off than they were under the excessive escrows. The loss to the class from placing funds in an escrow is the foregone interest on the amount in the escrow, which would likely be no more than 10% of the excess amount of the escrow. By granting 30% of the refund as fees to class counsel, the class members are at least 20% worse off than they would be if the excess were repaid with a delay.

72. No. 94-cv-633-H(M), 2003 WL 21277124 (N.D. Okla. May 28, 2003).

Damages Issues in Selected Types of Cases

Estimation of Economic Damages in Consumer Product Liability and Misrepresentation Cases

Consider consumer class actions in which a product is alleged to have a particular defect that the plaintiff claims should have been disclosed to consumers, or in which a product is alleged to have been misrepresented to consumers before they purchased it. In these types of cases, a common damages claim is that consumers would not have bought the product, or would have paid less for it, had they known about the alleged defect or had the product not been misrepresented.⁷³ The following sections discuss issues that often appear in the calculation of damages associated with these claims.

Defining the Plaintiff's Economic Position in the Actual and But-For Worlds

As explained earlier in this reference guide, the role of the damages expert is to translate the plaintiff's theory of harm into an objective model for damages. In the case of overpayment damages in a product liability or misrepresentation case, the plaintiff's actual economic position is usually defined as the price paid for the allegedly defective product at a then-current market price without the benefit of appropriate disclosures from the manufacturer.⁷⁴ Plaintiffs commonly offer invoices, sales receipts, or other retail sales data as evidence of purchase and of the prices paid. Disputes may arise if the plaintiff cannot offer direct evidence of the quantity of products purchased or the price paid for them (for example, if the manufacturer has data only on sales to distributors), or if the price paid was different across buyers due to individual discounts or negotiations.

The plaintiff's position in the but-for world is generally more complicated to define. In cases where specific statements made by the product manufacturer allegedly misrepresent the product (for example, by including incorrect information on

73. See, e.g., *In re MyFord Touch Consumer Litig.*, No. 13-cv-3072-EMC (N.D. Cal. Oct. 13, 2015); First Amended Class Action Complaint for Damages, *Zakaria v. Gerber Prods. Co.*, No. 2:15-cv-0200-JAK (Ex), 2015 WL 1085581 (C.D. Cal. Feb. 27, 2015). Other common damages claims are that the manufacturer profited unfairly from the sale of the defective product and that the plaintiffs suffered economic losses in their attempt to repair the defect. Issues arising from these claims can be analyzed using the frameworks provided in the preceding sections.

74. See, e.g., *Hendricks v. Starkist Co.*, No. 13-cv-00729-HSG, 2016 U.S. Dist. LEXIS 134872 (N.D. Cal. Sep. 29, 2016); *Elkies v. Johnson & Johnson Servs.*, No. 2:17-cv-07320-GW-JEMx, 2020 U.S. Dist. LEXIS 256341 (C.D. Cal. June 22, 2020).

the product label), a standard approach is to assume that in the but-for world such misrepresentations would have not occurred (for example, assuming that the label would not include the allegedly misleading information).⁷⁵ Cases in which the plaintiff alleges that the manufacturer omitted relevant information that would have been material for consumers can be more challenging for the damages expert because the characteristics of the disclosure (e.g., wording, size) in the hypothetical but-for world can have significant implications for how consumers react to it and the market price they pay.⁷⁶ Moreover, if the alleged defect only manifests in some products with a given probability,⁷⁷ the specific way in which information about that probability is conveyed to consumers can also have implications for how they react to it and the market price they pay.⁷⁸

Determining the But-For Price

In some cases, the market price of the product, adjusted to reflect the effect of the allegations, may be an appropriate estimate of the but-for price. For example, if the manufacturer of the product later added a warning to the product that corrected the alleged omissions in a way that is consistent with plaintiffs' allegations, the market price of the product in the period after the warning was added may be an appropriate measure of the price of the product in the but-for world. In this case, damages experts must account for other factors beyond the addition of the warning that may have affected the price of the product over the same period in order to isolate the effect of the alleged misconduct. For example, changes in supply or demand conditions after a warning label was added to a product may lead to changes in the price of the product that are unrelated to the alleged misconduct.

Damages experts may also rely on data from ostensibly similar products or assets to account for the effect of confounding factors. Empirical methods such as regression analysis can use information from similar products to account for confounding factors such as market-wide trends, geographic variation, and

75. See, e.g., *Jones v. ConAgra Foods Inc.*, No. C 12–01633 CRB, 2014 U.S. Dist. LEXIS 81292 (N.D. Cal. June 13, 2014); *Larsen v. Vizio, Inc.*, No. 8:14-cv-01865-CJC-JCG (C.D. Cal. May 5, 2015).

76. For example, a warning label with negative language about the product could lead to a very different outcome compared to neutral language. See, e.g., Christopher M. Heaps & Tracy B. Henley, *Language Matters: Wording Considerations in Hazard Perception and Warning Comprehension*, 133 J. Psych. 341 (1999), <https://doi.org/10.1080/00223989909599747>.

77. See, e.g., *In re Takata Airbag Prod. Liab. Litig.*, 1:14-cv-24009-FAM (1787) (S.D. Fla. Apr. 24, 2021).

78. Daniel Kahneman & Amos Tversky, *Prospect Theory: An Analysis of Decision Under Risk*, 47 *Econometrica* 263 (1979), <https://doi.org/10.2307/1914185>.

variation in product features, among others.⁷⁹ For these types of analyses, experts need to demonstrate that the benchmarks used are sufficiently similar to the product at issue and that the model adequately captures the most important features of a product.⁸⁰ Experts also need to show that the prices of benchmark products are affected by similar factors as the price of the product at issue, other than the alleged misconduct (i.e., the prices have “parallel trends”).⁸¹

Some damages experts in product liability and misrepresentation class actions have not relied on observed market prices but instead have relied on stated preference models, which use surveys to try to assess the impact of the alleged omissions or misrepresentations on consumer demand.⁸² Some plaintiff experts have relied directly on the results from stated preference models to estimate per-unit overpayment damages, while other experts have combined estimates of impact on consumer demand with models or assumptions about the supply side of the market to generate estimates of but-for prices.

Conjoint Analysis and Supply-Side Considerations

A stated preference model commonly used by experts for plaintiffs is based on a methodology called conjoint analysis.⁸³ Conjoint analysis is a survey-based methodology used to analyze consumer preferences for products and product features.⁸⁴ Conjoint analysis assumes that the subjective value consumers perceive from a product is the sum of the benefits they derive from individual product features or attributes.⁸⁵ In a “choice-based” conjoint analysis (the type most often

84. Vithala R. Rao, *Applied Conjoint Analysis* (2014).

85. For example, an expert could assume that the subjective value that a consumer obtains from buying a TV is equal to the value they derive from the TV having a 55-inch screen, plus the value of having an LED screen, plus the value of having smart features, minus the value sacrificed by paying the TV’s price.

used in litigation), the researcher uses a survey to ask consumers to choose which product they prefer among hypothetical products that vary across product attributes. The researcher then analyzes respondents' choices using statistical methods to generate an estimate of the monetary value that a consumer places on different attributes (also known as willingness to pay).⁸⁶ A conjoint analysis used in a product liability case will include one or more attributes that relate to the plaintiffs' allegations. For example, if the plaintiffs claim that the frame-refresh rate of a TV was overstated, the conjoint survey could include some hypothetical product options with the frame-refresh rate advertised to consumers, and other options with the (allegedly lower) correct frame-refresh rate. Based on respondents' answers (and the assumptions underlying the conjoint analysis methodology), an expert may be able to estimate the price that a consumer would be willing to pay for a TV with the advertised frame-refresh rate over a TV with the lower refresh rate.

An expert relying on a conjoint analysis should demonstrate that it provides a sufficiently realistic representation of the preferences of the buyers of the product. This may involve demonstrating that the model includes an appropriate set of attributes that define the demand for the product, that respondents are able to choose not to buy any of the options shown to them (known as the no-purchase option), that the predictions generated by the model are reliable, and that the calculation of respondents' willingness to pay is consistent with the assumptions underlying the conjoint methodology.⁸⁷ When implemented correctly and using a representative sample of respondents, an expert could, for example, rely on conjoint analysis to estimate the demand for TVs with and without the misrepresentation at issue.⁸⁸

As explained in the section titled "Issues Arising in Connection with the Use of Models to Simulate the But-For Price" above, because market prices are determined by the interaction of demand and supply, consumer-survey-based methods like conjoint analysis by themselves are insufficient to estimate the market price of the product at issue in the but-for world. Experts using conjoint analysis have relied on at least two different assumptions to attempt to account for supply-side factors. Some experts have assumed that the quantity supplied in the but-for world is the same as the quantity supplied in the actual world.⁸⁹ The but-for price obtained with this method will be the price necessary to sell the

historical quantity of product in the but-for world, in which some consumers would potentially have lower willingness to pay for the but-for product. From an economic perspective, the assumption of a constant or “fixed” quantity supplied results in an estimate of damages based solely on a downward shift in demand that the plaintiffs contend would occur in the but-for world, measured at the quantity sold in the actual world.⁹⁰ Other experts have assumed that the quantity sold in the but-for world may be different from the quantity sold in the actual world.⁹¹ For example, some experts have estimated a but-for price based on a market simulation in which supply-side factors include hypothetical sellers that, along with the defendant, maximize their individual profits taking into account their competitors’ reactions.⁹² The validity of the estimates from this method depends on how accurately the assumptions and characteristics of the market simulation reflect the characteristics of the actual market.

Estimation of Economic Damages in Securities Cases

Consider the typical securities case,⁹³ with a plaintiff investor (often, on behalf of a class of investors) who claims to have suffered damages from misrepresentations (false or misleading statements or omissions) made by a defendant (or group of defendants) in connection with the purchase of a company’s stock.⁹⁴ In such cases, the plaintiff claims to have suffered investment losses upon the revelation to the market of the false or misleading nature of the misrepresentations through one or more “corrective” disclosures or events. This section introduces key economic issues and areas of disagreement among experts in the analysis of damages in such cases.⁹⁵

90. For this reason, the but-for price calculated using this assumption may not be a market price that would result from the interaction of supply and demand in the relevant market.

91. See, e.g., *Earl v. Boeing Co.*, 611 F. Supp. 3d 345 (E.D. Tex. 2020).

92. See, e.g., Greg M. Allenby et al., *Valuation of Patented Product Features*, 57 J.L. & Econ. 629, 630 (2014), <https://doi.org/10.1086/677071>.

93. Statutes under which plaintiffs in securities cases may seek to recover damages include, but are not limited to, the Securities Exchange Act of 1934 § 10(b) (and Rule 10b-5 promulgated thereunder) (“Rule 10b-5” cases) and the Securities Act of 1933 § 11 or § 12(a)(2) (“Section 11” or “Section 12” cases).

94. The concepts discussed herein also apply in securities cases where securities other than common stock (e.g., options and bonds) are at issue.

95. As a threshold matter, given the nature of the plaintiff’s claims, analysis of damages in securities cases requires that experts have extensive training in financial economics, the discipline within economics that studies security prices and their determinants. Such training is often obtained through doctoral degrees in economics, finance, or accounting, followed by additional experience (in an academic or professional setting) in the analysis of the determinants of security prices and values. Depending on the circumstances, additional training may further bolster the

Inflation and Losses Caused

The economic issues that arise in the analysis of damages in securities cases relate to the concepts of inflation and losses caused. This section introduces these two concepts and how they relate to the measurement of damages in securities cases.

The concept of stock price inflation arises, for example, when analyzing damages in Rule 10b-5 cases, where the “out-of-pocket” measure of damages (calculated as the difference between inflation at the time of purchase and inflation at the time of sale)⁹⁶ limits the amount of per-share damages that plaintiffs can recover.⁹⁷ Inflation at a given point in time is the difference between (1) the actual price at which the stock then traded and (2) the but-for price that would have existed in the absence of the misrepresentations (also known as the “true” value).⁹⁸

The actual stock price is easily ascertained based on the plaintiff’s trading records or market data. However, estimation of the but-for price—and thus, inflation—requires two analytical steps. The first step is a careful delineation of the information that the plaintiff claims the defendants could and should have revealed instead of or in addition to the misrepresentations prior to the plaintiff’s purchase (the “but-for disclosure” or “truthful substitute”). This delineation is based on the plaintiff’s allegations and typically not on economic analysis. However, this delineation is critical because the second step, which is based on economic analysis, is the application of tools and techniques from financial economics to estimate the stock’s but-for price given the but-for disclosure.

The concept of losses caused arises, for example, when analyzing damages in Rule 10b-5, Section 11, and Section 12(a)(2) cases, where the plaintiff’s recoverable

expert’s qualification to analyze issues at hand (e.g., accounting training may be helpful in securities cases where the misrepresentations relate to a company’s accounting disclosures and practices).

This section focuses on the analysis of damages on a per-share basis. Total damages for a plaintiff are calculated by combining damages per share and the plaintiff’s trading records (with the number of shares bought and sold by the plaintiff on relevant dates). In securities class actions, total damages are typically not covered in expert reports submitted to the court, as class members’ trading records only become available after damages claims are filed, typically after a settlement occurs or if a verdict for plaintiffs is reached.

96. See, e.g., *Robbins v. Koger Props., Inc.*, 116 F.3d 1441, 1447 n.5 (11th Cir. 1997).

97. Per-share recoverable damages in Rule 10b-5 cases are the lesser of (1) “out-of-pocket” damages, (2) the losses caused by the alleged misrepresentations (discussed further below), and (3) a cap prescribed by the Private Securities Litigation Reform Act of 1995 (the “90-day bounce-back” provision).

98. See, e.g., *Ludlow v. BP, P.L.C.*, 800 F.3d 674, 682 (5th Cir. 2015) (“At the same time, the ‘out-of-pocket measure,’ sometimes called the ‘price inflation’ metric, is often used. Under this theory, ‘a purchaser of securities may recover against a defendant . . . only the “difference between the price paid and the [true] value of the security . . . at the time of the initial purchase by the defrauded buyer.”’”).

damages are limited to the losses, if any, caused by the misrepresentations.⁹⁹ In the context of damages, losses caused refers to stock price declines, if any, that occurred in the actual world and are attributable to the arrival of information (corrective information) into the market that is causally linked to the misrepresentations.

Quantification of the losses, if any, caused by the misrepresentations requires, as a first step, identification of instances when new corrective information was revealed to the market. The next step is to use tools and techniques from financial economics to measure, for each of those instances, the impact, if any, of such information on stock price. Such measurement is typically conducted using tools and techniques from financial economics. For example, an event study model, discussed below, can be used to estimate the impact that market or industry factors—which are typically not causally linked to the misrepresentations—had on the stock price. In addition, any effect of company-specific information that is not corrective information (confounding information) must be separated from any effect of company-specific information that is. In sum, any losses that resulted from “changed economic circumstances, changed investor expectations, new industry-specific or firm-specific facts, conditions, or other events,”¹⁰⁰ and thus would have occurred even in the absence of corrective information, must be isolated and removed in determining the amount of any stock price declines that are attributable to the misrepresentations.

99. In the context of Rule 10b-5 cases, in *Dura Pharms., Inc., v. Broudo*, 544 U.S. 336, 342–44 (2005), the Supreme Court referred to losses caused as a limitation on out-of-pocket damages: “If the purchaser sells later after the truth makes its way into the marketplace, an initially inflated purchase price might mean a later loss. But that is far from inevitably so. When the purchaser subsequently resells such shares, even at a lower price, that lower price may reflect, not the earlier misrepresentation, but changed economic circumstances, changed investor expectations, new industry-specific or firm-specific facts, conditions, or other events, which taken separately or together account for some or all of that lower price. . . . Indeed, the Restatement of Torts, in setting forth the judicial consensus, says that person who ‘misrepresents the financial condition of a corporation in order to sell its stock’ becomes liable to a relying purchaser ‘for the loss’ the purchaser sustains ‘when the facts . . . become generally known’ and ‘as a result’ share value ‘depreciate[s].’” In the context of Section 11 and Section 12(a)(2), defendants can remove from the damages amount prescribed by statute (*statutory damages*) the portion that did not result from the misrepresentations. See 15 U.S.C. § 77(k) regarding Section 11 (“[I]f the defendant proves that any portion or all of such [statutory damages] represents other than the depreciation in value of such security resulting from [the alleged material misrepresentations], such portion of or all such damages shall not be recoverable”) and 15 U.S.C. § 77l regarding Section 12 (“if the [defendants prove] that any portion or all of [statutory damages] represents other than the depreciation in value of the subject security resulting from [the alleged material misrepresentations], then such portion or amount . . . shall not be recoverable.”).

100. *Dura*, 544 U.S. at 343.

Key Areas of Disagreement in the Economic Analysis of Inflation and Losses Caused

Event study model

Damages analyses in securities cases almost invariably involve an event study model, which is a widely used and generally accepted methodology to analyze changes in stock prices following the revelation of information to the market.¹⁰¹ Using an event study model to analyze changes in stock price following the release of allegedly corrective information is a common step in the analysis of losses caused.¹⁰²

An event study model can be used to estimate the portion of a stock's return (the percentage change in stock price, including dividends) over some period (the event window) that can be attributed to market and industry factors. The remaining portion, often labeled the residual or abnormal return, may be attributed to company-specific information (i.e., information that affects the company but not the overall market or its industry peers),¹⁰³ including any corrective information disclosed over the event window. An event study model can be used to test whether a residual return is statistically unusual relative to the typical level of stock-price volatility (i.e., "statistically significant").¹⁰⁴ Economists interpret residual returns that are statistically significant as evidence that company-specific information caused a stock-price change. Residual returns that are not statistically significant are interpreted as having no cause that can be distinguished from randomness.

There are several common areas of disagreement among experts when using an event study model. Each of these areas illustrates the importance of carefully

101. See, e.g., A. Craig MacKinlay, *Event Studies in Economics and Finance*, 35 J. Econ. Literature 13 (1997), <http://www.jstor.org/stable/2729691>.

102. An event study model can also be used to analyze changes in stock price following allegedly false or misleading statements, which may be relevant for the analysis of inflation.

103. Note that company-specific information does not necessarily coincide with information disclosed by the company. Sometimes, company disclosures may convey information that moves the overall market and the stock prices of its industry peers. See, e.g., George Foster, *Intra-Industry Information Transfers Associated with Earnings Releases*, 3 J. Acct. & Econ. 201 (1981), [https://doi.org/10.1016/0165-4101\(81\)90003-3](https://doi.org/10.1016/0165-4101(81)90003-3); Andrew J. Patton & Michela Verardo, *Does Beta Move with News? Firm-Specific Information Flows and Learning About Profitability*, 25 Rev. Fin. Stud. 2789–2839 (2012), <https://doi.org/10.1093/rfs/hhs073>. And sometimes, third-party disclosures may convey company-specific information (e.g., a short-seller report analyzing a company's prospects, as discussed in Alexander Ljungqvist & Wenlan Qian, *How Constraining Are Limits to Arbitrage?*, 29 Rev. Fin. Stud. 1975, 2012–14 (2016), <https://doi.org/10.1093/rfs/hhw028>).

104. The most commonly used threshold for the assessment of statistical significance in event studies is the 5% level. As discussed in David H. Kaye & Hal S. Stern, *Reference Guide on Statistics and Research Methods*, in this manual, "In practice, statistical analysts typically use levels of 5% and 1%. The 5% level is the most common in social science, and an analyst who speaks of significant results without specifying the threshold probably is using this figure."

tailoring the event study model in a particular case to the facts and circumstances of that case. Absent such tailoring, experts may reach erroneous conclusions.

First, experts may disagree on whether the event study model adequately captures the effect of market and industry factors. There may be disagreement about whether appropriate market and industry factors¹⁰⁵ have been selected,¹⁰⁶ or about whether the model adequately captures the sensitivity of company stock returns to market and industry factors.¹⁰⁷ A model that overstates or understates the effect of market or industry factors will incorrectly estimate the residual return and thus may lead to an incorrect finding of statistical significance (or lack thereof).¹⁰⁸

Second, experts may disagree on whether a model adequately estimates the typical level of stock-price volatility used to assess the statistical significance of residual returns.¹⁰⁹ The typical level of volatility may vary significantly over time for a given company stock, as circumstances change.¹¹⁰ A model that overstates or understates volatility may lead to an incorrect finding of statistical significance (or lack thereof).¹¹¹

Third, experts may disagree on the appropriate event window to analyze residual returns following a particular information release. In an efficient market, a company's stock price will at all times quickly and fully reflect all publicly

105. Market and industry factors are usually modeled using the returns on market-wide and industry indices, respectively. In choosing an appropriate industry index, experts typically balance between an index with more constituent company stocks (less prone to the effect of outlier returns but also potentially less comparable to the stock of interest) and an index with fewer constituents (more comparable to the stock of interest but also more prone to the effect of outlier returns).

106. See, e.g., Exhibit 138 to Defendants' Motion for Summary Judgment, *Strathclyde Pension Fund v. Bank OZK*, No. 4:18-cv-793-DPM, ECF No. 158–9, (E. D. Ark. Feb. 5, 2022).

107. See, for example, the discussion of the dispute about whether a model adequately captured the sensitivity to industry factors in *Smilovits v. First Solar Inc.*, No. CV12-0555-PHX-DGC, 2019 WL 7282026, at 11–12 (D. Ariz. Dec. 27, 2019).

Academic literature in financial economics shows that the sensitivity of company stock returns to market and industry factors varies depending on the circumstances. See, e.g., Patton & Verardo, *supra* note 103, at 2789.

108. The statistical significance of residual returns is assessed using a t-statistic, which is calculated as the ratio of the residual return to the estimate of typical volatility. Thus a misestimated residual return will lead to a misestimated t-statistic.

109. See, e.g., Defendants' Motion for Partial Summary Judgment, *Evanston Police Pension Fund v. McKesson Corp.*, No. 3:18-cv-6525-CRB, ECF No. 166, (N.D. Cal. June 7, 2021).

110. See, e.g., Robert Engle, *GARCH 101: The Use of ARCH/GARCH Models in Applied Econometrics*, 15 J. Econ. Persps. 157, 158 (2001), <https://doi.org/10.1257/jep.15.4.157> (“Even a cursory look at financial data suggests that some time periods are riskier than others; that is, the expected value of the magnitude of error terms at some times is greater than at others.”).

111. Misestimated volatility will cause a misestimated t-statistic, which is used to assess statistical significance, as discussed *supra* note 108.

available information.¹¹² Thus, if the stock trades in an efficient market, experts will typically analyze stock-price changes over short event windows (such as the trading day that immediately follows the release). However, under certain circumstances, experts may choose to apply different event windows. For example, in the presence of multiple pieces of information disclosed at different times during the same trading day, event windows shorter than a trading day may be helpful in analyzing the effect of a particular piece of information.

Analysis of “confounding” information

Because an event study model estimates a single residual return for a particular event window, it does not disaggregate the impact of separate pieces of company-specific information arriving within the same event window. This feature of event study models limits its usefulness in securities cases when the arrival of corrective information coincides with the arrival of confounding information.

To value the effect of corrective information when there is confounding information, experts may need to apply available tools and techniques from financial economics (other than an event study model) that can be used to value specific pieces of information (e.g., discounted cash-flow models, valuation based on multiples, earnings response models).¹¹³ To evaluate whether a specific application of such tools and techniques is economically sound, it is necessary to scrutinize the underlying assumptions and determine if they are sufficiently tethered to the allegations, facts, and circumstances of the case. Without such scrutiny, it is not possible to determine a priori whether a particular method or group of methods will be capable of estimating losses caused by misrepresentations consistent with the plaintiff’s theory of liability in the case.

Measuring inflation at the time of purchase

Because inflation at each point in time (e.g., at the time of the plaintiff’s purchase) cannot be observed from market prices (indeed, it is based on a counterfactual, or

112. This is known as the semi-strong form of market efficiency. See Stephen A. Ross, Randolph Westerfield & Bradford D. Jordan, *Corporate Finance* 346 (6th ed. 2002) (“[S]emistrong-form efficiency requires not only that the market be efficient with respect to historical price information, but that all of the information available to the public be reflected in price.”).

113. See, e.g., Richard A. Brealey, Stewart C. Myers & Franklin Allen, *Principles of Corporate Finance* (11th ed. 2014).

The concept of market efficiency, discussed above, is relevant to the analysis of information that may have impacted the stock price. In an efficient market, only new information can impact the stock price and no price declines can be attributed to the repetition of information that is already publicly available.

but-for, disclosure), it must be estimated. Experts often disagree on how to measure inflation, including whether stock-price declines following the revelation of corrective information can be used to measure inflation earlier in time.

Stock-price declines following corrective information can measure inflation earlier in time only if (1) any price impact of confounding information has been removed, as discussed above, (2) the corrective information matches the but-for disclosure, and (3) the information environment (i.e., market, industry, and company conditions) earlier in time is such that if the company had made the but-for disclosure then, the stock price would have declined by the same amount as it did upon the release of corrective information in the actual world.¹¹⁴ In its *Goldman Sachs* ruling, the Supreme Court noted that the “inference—that the back-end price drop equals front-end inflation—starts to break down when there is a mismatch between the contents of the misrepresentation and the corrective disclosure.”¹¹⁵ If the facts and circumstances of the case do not support using stock-price declines following corrective information to measure inflation earlier in time, then additional analysis, including analysis based on valuation tools and techniques from financial economics, is typically required.¹¹⁶

Estimation of Economic Damages in Antitrust Cases

This section provides examples to illustrate the application of the principles for estimation of economic damages to antitrust cases. The scope of the discussion is limited; a full discussion of damages methods across the complete spectrum of antitrust offenses is beyond the scope of this reference guide.¹¹⁷

Threshold Issues

A model for economic damages arising from an antitrust violation must satisfy the causation requirement articulated in *Comcast*, by measuring the economic damages arising only from defendant conduct found to be unlawful.¹¹⁸

114. See, e.g., Bradford Cornell & R. Gregory Morgan, *Using Finance Theory to Measure Damages in Fraud on the Market Cases*, 37 UCLA L. Rev. 883, 889–97 (1990).

115. *Goldman Sachs Grp., Inc. v. Arkansas Tch. Ret. Sys.*, 594 U.S. 113, 123 (2021).

116. As is the case when valuing the effect of corrective information when there is confounding information, there is no a priori reason that a particular method or particular group of methods will be capable of estimating inflation consistent with the plaintiff’s theory of liability in a specific securities case.

117. For a comprehensive discussion of antitrust damages, see A.B.A., *Proving Antitrust Damages: Legal and Economic Issues* (2017), and Daniel L. Rubinfeld, *Antitrust Damages*, in *Research Handbook on the Economics of Antitrust Law* 378–93 (Einer Elhague ed., 2012).

118. In *Comcast*, the court held that the plaintiffs failed to present a valid methodology for measurement of class-wide damages because their damages model included the effects of conduct

Further, a model estimating damages arising from an antitrust violation must measure what courts have described as antitrust injury. Plaintiffs must show not only that they suffered economic injury, but additionally that the injury they sustained is “of the type the antitrust laws were intended to prevent and that flows from that which makes defendants’ acts unlawful.”¹¹⁹

In many instances, meeting this requirement can be straightforward. For example, any alleged overcharge that consumers pay due to a price-fixing cartel flows directly from the cartel’s subversion of price competition, which the antitrust laws seek to prevent. Hence, damages based on a reliable overcharge computation reflect antitrust injury.

However, not all harms constitute antitrust injury. For example, a firm may be harmed by two rivals that merge to form a single, more efficient competitor, but the harm that firm sustains—an erosion in its market position because it faces a new, more efficient competitor—is the result of increased competition rather than harm to competition.¹²⁰ An increase in competition is not something the antitrust laws seek to prevent—quite the opposite, in fact—and as such it is not antitrust injury.¹²¹

Quantifying Damages in an Antitrust Matter

The foundation of an antitrust damages model is a but-for world that reflects all relevant conditions in the actual world other than the anticompetitive conduct at issue, as explained in the section titled “The Standard General Approach to Quantification of Economic Damages” above.

Models used to compute antitrust damages generally fall into one of two categories, overcharge damages and lost-profit damages. As explained below, the choice of model depends on the nature of the plaintiff’s claim and the economic relationship between the plaintiff and defendant.

Overcharge Damages

An overcharge model attempts to measure damages sustained by one of the parties to a vertical buyer–seller relationship by deriving an estimate of what the price in the market would be if the conduct did not occur.

under multiple theories of liability, only one of which was found to be triable on a class-wide basis. See *Comcast Corp. v. Behrend*, 569 U.S. 27 (2013).

119. See *Brunswick Corp. v. Pueblo Bowl-O-Mat, Inc.*, 429 U.S. 477 (1977).

120. *Cargill, Inc. v. Monfort of Colorado, Inc.*, 479 U.S. 104 (1986).

121. See A.B.A., *supra* note 117, at 19–33. See also Jonathan M. Jacobson & Tracy Greer, *Twenty-One Years of Antitrust Injury: Down the Alley with Brunswick v. Pueblo Bowl-O-Mat*, 66 *Antitrust L.J.* 273 (1998).

For example, a plaintiff that purchased a product from a supplier engaged in anticompetitive conduct might compute overcharge damages as the difference between the supra-competitive price actually paid and the lower price that would have prevailed absent the conduct at issue (i.e., the but-for price), multiplied by the quantity actually purchased. Similarly, a supplier that sold a product to a buyer engaged in anticompetitive conduct (e.g., a monopsonistic conspiracy) may compute overcharge damages as the difference between the higher price it would have received absent the buyer's anticompetitive conduct and the artificially suppressed price actually received, multiplied by the quantity actually sold. Antitrust claims that lend themselves to an overcharge model of damages include horizontal price-fixing, bid-rigging, illegal-monopolization, and exclusionary-conduct claims when brought by a customer or supplier.

Damages experts generally rely on one of two approaches to estimate overcharge damages:

1. A before-and-after model, which compares price during the period in which the anticompetitive conduct is believed to have had an effect (the impact period) with price in a period before (or after) the anticompetitive conduct occurred (the control period).
2. A difference-in-differences model, which compares the change in price from the control period to the impact period with the change in price during the same periods in a reasonably comparable market.

Conceptually, both methods seek to identify price levels absent the impact of the challenged conduct and then estimate the competitive price level in the but-for world. Below is a hypothetical example of a price-fixing cartel to illustrate the application of these methods.

Before-and-after model of overcharge damages

Suppose that the plaintiffs allege harm due to supra-competitive prices charged by a cartel and estimate damages as follows: (1) estimate a regression model with observations on prices over a period of months or years prior to the date at which the cartel took effect,¹²² under the assumption that the model describes prices that would have prevailed but for the cartel; (2) use the estimated model to

122. Multiple regression is a statistical method that can be used to measure the relationship between multiple explanatory variables and a variable of interest (e.g., price), and thus distinguish between the effect of defendant's anticompetitive conduct and the effect of other economic factors. A detailed discussion of the use of regression analysis (including to estimate economic damages) is beyond the scope of this reference guide. See Daniel L. Rubinfeld & David Card, *Reference Guide on Multiple Regression and Advanced Statistical Models*, in this manual. See also A.B.A., *supra* note 117, at 123.

predict the prices that would have prevailed during the damages period but for the cartel; and (3) estimate overcharge damages as the difference between observed prices during the damages period and prices predicted by the regression model, multiplied by the quantity sold.¹²³

The validity of such an estimate depends on the validity of the underlying regression model, which must account for the impact on prices of economic factors, other than the challenged conduct, that influence demand and costs. A regression that omits such factors will generally yield an unreliable estimate of damages. The direction of the error depends on the nature of the omitted factors. Two examples illustrate the point:

Example: Negative news during the cartel period about the health effects of the product at issue causes demand to fall, and absent the cartel, the price of the product at issue would fall as a result. A regression model that fails to account for the price effect of the negative news would likely overstate but-for prices during the cartel period and understate damages as a result.

Example: The structure of the market changed due to a merger between rival manufacturers just before the cartel began operating. The price effects of the merger, if any, would persist in the but-for world, as the cartel did not cause the merger. A regression model that failed to separately account for the price effects of the merger would improperly attribute the effects of the merger to the cartel and overstate damages as a result.

A regression model that supports a before-and-after estimate of damages may also yield an unreliable estimate of but-for prices if the conduct at issue also affects the explanatory factors included in the regression. Examining the impact of the conduct at issue on explanatory factors in a regression used to estimate but-for prices is thus a critical step in evaluating a benchmark model of damages.

123. Note that this approach assumes that the impact of explanatory variables is identical during the control and cartel periods. Rather than forecasting but-for prices in the cartel period based on an earlier control period, a damages expert may instead rely on the so-called dummy variable method: (1) estimate a regression model with observations on price using a sample that includes the damages period in addition to the period beforehand; (2) include in the regression specification a dummy variable that measures the difference between prices in the control and cartel periods, holding all other factors constant; and (3) use the point estimate for the dummy variable as the basis for computing overcharge damages. The dummy variable method allows a more flexible specification in which the effects of explanatory variables can differ during the control and cartel periods. See Justin McCrary & Daniel L. Rubinfeld, *Measuring Benchmark Damages in Antitrust Litigation*, 3 J. Econ. Methods, no. 1, 2013, at 63–74, <https://doi.org/10.1515/jem-2013-0006>. See also John K. Wald, *Antitrust Damages in Financial Markets*, 16 J. Competition L. & Econ., no. 1, 2020, at 63–73, <https://doi.org/10.1093/joclec/nhaa003>, for an example of the application of this method in the NASDAQ odd-eighths litigation.

Example: Suppose that the price of the product at issue depends on the price of a particular input, and the regression model includes the price of that input. If cartel participants account for a substantial fraction of demand for the input, then in the but-for world, the price of the input will likely be lower.¹²⁴ Thus a regression that relies on the actual input price, which reflects the impact of the cartel, will likely yield a biased estimate of the but-for price of the product at issue.¹²⁵

Difference-in-differences model of overcharge damages

The preceding examples highlight the errors that may arise if a regression-based estimate of overcharge damages omits economic factors that affect price. The omitted factors discussed above—new information and changes in market structure—are observable. In such cases, correcting the bias may be as simple as including appropriate explanatory variables in the regression to measure the impact of the omitted factors on price.

Many cases, however, are not so simple. The omitted factors that affect prices may be unobservable, a variable that can serve as a proxy for unobserved factors may not be available, or the nature of the omitted factor is such that its impact cannot be separately identified using multiple regression. In such cases, damages experts may turn to a difference-in-differences regression model in order to account for the impact of omitted factors.

Rather than estimating the overcharge by examining price before and during the cartel period, a difference-in-differences model isolates the impact of the cartel through comparison to a second, comparable market unaffected by the conduct at issue. A difference-in-differences regression measures the impact of the cartel as the difference between (1) the change in prices in the market of interest, and (2) the change in prices over the same period in a second, comparable market unaffected by the conduct at issue.¹²⁶ The key assumption here that identifies the impact of the cartel—the so-called parallel trend assumption—is that prices in the two markets share a common, parallel

124. The cartel suppresses output of the final good and thus suppresses demand for the input in question. If cartel participants account for a substantial fraction of demand for the input, increased demand for the input in the but-for world means that the price of the input will likely increase as well.

125. For a more detailed discussion of this point, see Halbert White, Robert Marshall & Pauline Kennedy, *The Measurement of Economic Damages in Antitrust Civil Litigation*, 6 A.B.A. Econ. Comm. Newsl., no. 1, 2006, at 18.

126. See, e.g., Joshua D. Angrist & Jörn-Steffen Pischke, *Mostly Harmless Econometrics: An Empiricist's Companion* (2008).

trend, so that absent the cartel, change in prices in the two markets over time would be identical.¹²⁷

For example, suppose the plaintiffs claim that suppliers of a product in a particular geographic region operated a cartel. A damages expert might adopt as a comparator a second, separate geographic market for the same product in which the alleged conspirators do not operate, and use a difference-in-differences regression to account for the effects of unobserved factors and isolate the price effects of the cartel.¹²⁸

Lost-Profits Damages

A lost-profits model is frequently used to measure damages in matters in which the plaintiff and defendant are competitors rather than parties to a vertical, buyer–seller relationship, such as matters involving exclusionary conduct.

While overcharge damages require an estimate of but-for prices, a damages model that seeks to measure lost profits requires a more extensive counterfactual that specifies prices, unit sales (or market share), and costs in the but-for world.¹²⁹ Assuming that the plaintiff’s fixed costs would not change in the but-for world, lost-profit damages for a firm harmed by a rival’s anticompetitive conduct are given by the following formula¹³⁰:

$$D = (P_{\text{but-for}} - C_{\text{but-for}}) \times Q_{\text{but-for}} - (P_{\text{actual}} - C_{\text{actual}}) \times Q_{\text{actual}}$$

A model that estimates lost profits must carefully consider the effects of the conduct at issue on each element of the plaintiff’s profits in the but-for world.

Price Effects. Because conduct that partially or completely excludes a firm from a market reduces competition and allows the defendant to increase prices, prices in the but-for world will likely be lower than observed prices. Indeed, the prospect of increasing prices creates an incentive for firms to engage in exclusionary conduct.¹³¹ That said, in some circumstances plaintiffs may assert that in the but-for world, they would be able to charge higher prices, as the

127. Note that the regression specification should still include all observable factors that affect price and are independent of the cartel (i.e., do not vary as a result of the cartel), just as with the before-and-after model discussed above.

128. See, e.g., R. Forrest McCluer & Martha A. Starr, *Using Difference in Differences to Estimate Damages in Healthcare Antitrust: A Case Study of Marshfield Clinic*, 20 Int’l J. Econ. Bus. 447 (2013), <https://doi.org/10.1080/13571516.2013.800323>.

129. Some damages experts may specify damages using a model of but-for profit margins rather than modeling underlying prices and costs.

130. Costs shown here should be read as average cost per unit of output, not as variable cost.

131. Note, however, that some theories of liability, such as predatory pricing, imply higher prices in the but-for world.

challenged conduct prevented them from effectively competing and forced them to offer prices lower than those they otherwise would have offered.¹³²

Quantity Effects. Economic theory teaches that if prices increase, output declines. Thus, if the effect of the conduct at issue is to raise prices, lower prices in the but-for world will generally be accompanied by higher output. However, the critical question is not output for the market as a whole but whether the plaintiff's output would increase absent the challenged conduct.

Lower prices and higher output have offsetting effects on profits: All else being equal, lower prices reduce profits, but higher output increases profits. The net impact of these effects is an empirical question whose answer depends on the elasticity of demand for the products or services at issue. If demand is elastic, quantity effects will outweigh price effects, profits in the but-for world will increase, and all else being equal, the plaintiff's profits in the but-for world would be higher. If demand is inelastic, profits in the but-for world will decrease, and all else being equal, the plaintiff's profits in the but-for world would be lower.

Cost Effects. The impact of the challenged conduct on the plaintiff's costs is likewise an empirical question; the plaintiff's costs can increase or decrease as a result of the challenged conduct. In some cases, the conduct at issue may raise the plaintiff's costs. Indeed, the specific objective of exclusionary conduct is often raising a rival firm's costs. Additionally, rather than directly raising input costs, the conduct at issue may increase the plaintiff's costs by reducing the plaintiff's output and thereby depriving the plaintiff of the benefit of economies of scale. In such cases, the plaintiff's unit costs would decline as output increases in the but-for world.

On the other hand, the plaintiff's costs in the but-for world may be higher if the output increase contemplated in the damages model exceeds the plaintiff's actual capacity to produce, market, or distribute the products or services at issue and would require additional investment. In such cases, the plaintiff must establish that it had the wherewithal to increase its capacity in the but-for world, and estimated damages should reflect the costs of any incremental investments necessary to expand the plaintiff's capacity.

Models of lost profits frequently rely on the assumption that the period prior to the conduct at issue provides a reliable basis for predicting market conditions in the but-for world. As explained in the section titled "Considering All the Differences in the Plaintiff's Situation in the But-For Scenario Versus Assuming That Many Aspects Would Be the Same as in Actuality" above, this assumption requires careful scrutiny, as it may yield an unreliable estimate of damages. The purpose of the defendant's challenged conduct may have been to forestall

132. See, e.g., *ZF Meritor, LLC v. Eaton Corp.*, 696 F.3d 254 (3d Cir. 2012). ZF Meritor's lost-profits damages model relied on projections that assumed that the exclusionary loyalty discounts offered by defendant Eaton forced ZF Meritor to offer deep discounts that it otherwise would not have offered.

changes in competitive conditions (e.g., by deterring entry) and maintain the status quo, in which case market conditions in the period prior to the challenged conduct are not a reliable basis for predicting market conditions in the but-for world. Suppose, for example, that the market for a particular product was a duopoly, and that one firm (the defendant) entered an exclusive dealing agreement with a downstream purchaser that foreclosed the second firm (the plaintiff) and deterred the entry of new competitors. Then a damages model that assumes a duopoly in the but-for world would yield an unreliable conclusion, as it fails to account for the competitive impact of nascent competitors that would have entered the market but for the challenged conduct.

Estimation of Economic Damages from Loss of Personal Income

Many of the disputes that arise in estimating damages for lost personal income can be resolved by carefully applying the standard damages approach. Damages are the difference between the but-for and actual worlds, where the actual world reflects any mitigating factors. Estimating such damages can also involve issues that are unique, such as estimating losses over a person's lifetime, valuing fringe benefits, estimating lost income in wrongful death cases, or estimating compensation for shortened life expectancy. We discuss these issues below.

Estimation of Losses Over a Person's Lifetime

In nearly all cases involving lost income, the effects continue past trial and sometimes until the plaintiff's death. Therefore, quantifying damages for loss of personal income necessarily involves projecting the plaintiff's work history and retirement. Conceptually, the estimate of income for each year, either but-for or actual, is the expected income multiplied by the probability that the person will be working for that year. The probability that the person will be working for that year is the product of the probability that the person will survive the year, the probability that the person will be in the labor force, and the probability that the person will be employed, given that the person worked in the prior year.¹³³ We refer to this as the standard method for estimating personal losses.

In many cases, such as those involving wrongful termination, the projection that the plaintiff was working is the same for both the but-for world and the actual

133. Except for wrongful-death cases, the probability that the persons will be working is usually 1 for both the but-for and actual cases. In wrongful-death cases, the probability is still usually 1 in the but-for case but 0 in the actual case.

world. However, in wrongful death cases and some personal injury cases, these projections may differ,¹³⁴ and the expert will need to compute separate projections for the but-for and actual worlds before taking the difference between the two.

These projections may rely on data from government agencies, including the Bureau of Labor Statistics (BLS) and the Social Security Administration (SSA).¹³⁵ These data include tables on survival, workforce participation, and employment. The expert usually needs to manipulate this information in order to generate the conditional probabilities needed.

In order to simplify the calculations, the expert may use the person's expected lifespan and retirement age based on the person's age at trial using standard tables from the SSA and BLS. Then the expert need only sum the discounted losses for each year until the expected age at death. This method, often referred to as the life-expectancy method, will considerably simplify the calculations associated with estimating lost retirement benefits. However, the standard and the life-expectancy methods will usually generate the same estimate of losses only if the expert is assuming that the expected discounted income in each year is the same—that is, that the expected increase in income is offset by the discount rate (see section titled “Disagreements About the Discount Rate to Value the Impact of the Alleged Harmful Act in Periods After the Valuation Date” above).

Calculation of Fringe Benefits

Fringe benefits are often a component of lost pay and may include medical insurance and retirement benefits such as Social Security. Although sick days and vacation are also fringe benefits, they are included already in lost-pay calculations. An exception occurs if these days are accrued but not taken, where, for example, the employee lost the cash payout that would have occurred at a normal termination or lost the benefit of future days off with pay.

Medical insurance benefits

In the following discussion, we assume that the plaintiff no longer has the benefit of the employer-provided insurance as a result of the actions of the defendant. Such situations typically arise in wrongful-termination or wrongful-death cases.

134. This situation may arise in a personal injury case if the injured person is less likely to be able to work as a result of the accident. If so, then the person may have an increased likelihood of leaving the labor force for each age compared to the likelihood prior to the incident. Similarly, the injured person may be more likely to retire at an earlier age.

135. Data from additional providers may be available with a finer level of granularity than SSA or BLS data (e.g., with respect to location or occupation). However, the reliability of these data may be disputed because of questions about the methodology used to generate the tables.

Reference Guide on Estimation of Economic Damages

Calculating damages for lost medical insurance is straightforward if the plaintiff can purchase insurance under COBRA, or from their current employer, or on the open market. Then the value of the lost medical insurance is the employee's portion of the premium. If insurance coverage available to the plaintiff differs significantly between the but-for and the actual worlds, then the expert will need to project the impact of the difference in policy coverage.

If the plaintiff chooses not to purchase insurance even though the option is available, or the plaintiff is unable to purchase insurance,¹³⁶ then the plaintiff may argue that the value of insurance is the sum of their actual expenses less the premium in the but-for world. The defendant will likely respond that the plaintiff assumed the risk that the incurred medical expenses could exceed the plaintiff's portion of the premium, and therefore that the defendant's responsibility should be limited to the plaintiff's portion of the premium forgone. The plaintiff may counter that their pay was insufficient to afford the insurance.

Retirement benefits

For lost retirement benefits, the issues are similar to those involving lost medical benefits, but the calculations are more complex. There are basically two types of retirement plans: defined benefit plans and defined contribution plans. Defined benefit plans are those where the benefits paid out after retirement are guaranteed to be a definite amount upon retirement. In contrast, defined contribution plans are those where the employer makes a predefined contribution for the employee but the benefits paid out depend on the return earned on the money invested.

The expert can calculate both types of retirement plans on the basis of either the amounts paid in or the amounts paid out by the employer. If the expert uses the amount the employer paid for the benefits, which may be a function of the amount the plaintiff earned, then the calculation is analogous to computing the loss in plaintiff's earnings. The disadvantage of this approach is that the amounts paid in may not adequately predict the benefits paid out, particularly when the plan is a defined benefit plan. We discuss this topic below in connection with Social Security benefits, where the problem is particularly acute.

Defined benefit plan

To determine the present value of the benefits received under a defined benefit plan, the calculation is simplified if the expert uses the life-expectancy method

136. For example, a preexisting condition may make it difficult to purchase insurance on the open market or may limit the plaintiff's coverage to exclude a preexisting condition either permanently or for a period of time.

to calculate the plaintiff's losses. In this situation, the expert must determine the number of years that the plaintiff would have worked at the firm upon retirement, and the plaintiff's retirement age, expected lifespan, and salary at the firm over time. These factors must be consistent with the expert's assessment of the projected trajectory of the plaintiff's employment in both the but-for and the actual worlds.

However, if the expert instead uses probability tables for each year, then the calculation is more complex. For each year where the plaintiff may cease to be in the labor force for reasons other than death, the expert must determine the likelihood that the plaintiff is receiving benefits from the plan because of disability (if the plan permits) or retirement. Complicating this determination is that the payout from the plan may depend on the age at retirement. Thus, the calculation must incorporate the probability for each possible payout. Depending on the plan, defining possible outcomes can be extremely complex.

A common example of a defined benefit plan is Social Security.¹³⁷ Determining benefits from Social Security can be forbiddingly complex because the number of potential outcomes is so large. For example, a person can retire at almost any age, and disability payments are made if the person is unable to work. In addition, calculating the benefit at any age depends on the person's average salary over the most recent thirty-five years. If Social Security benefits are critical to the magnitude of damages, the expert may choose to simplify the calculation by relying on the life-expectancy method.

Defined contribution plan

For a defined contribution plan, the expert's task is to project the employer's contribution, the number of years that the employee would have worked at the firm, and the employee's age at retirement. Generally, this determination is straightforward because it is based on the same factors the expert would use to project the employee's salary in the but-for and actual worlds. The present value of the employer's contributions will be the expected payouts from the plan.

Wrongful Death

Generally, calculation of economic damages for wrongful death depends on whether the claimant is a relative of the decedent or is the estate. If the claimant is a relative of the decedent, economic damages are limited to the economic value that the relative would have received had the decedent lived. If the relative

137. Social Security is generally regarded as a defined benefit plan although it has some elements of a defined contribution plan.

Reference Guide on Estimation of Economic Damages

is a dependent, the recovery may be substantial, whereas if the decedent was a child or unmarried and childless and the only relatives are parents, the recovery may be small, because most parents receive little economic value from their children. In contrast, if the claimant is the estate, the recovery may include all of the lost economic value.

Where the claimant is a relative, damages from lost wages may be reduced to reflect the decedent's own consumption spending had the person continued living. Such expenses may be relatively small if the claimant is a spouse with children under the theory that much of the decedent's income would have been spent to support the dependents. If decedents have no children or if there is another earner in the family, offsets for the spending of decedents on themselves may be higher.

Shortened Life Expectancy

An important issue is whether a plaintiff may recover compensation for shortened life expectancy caused by an injury. This issue may arise, for example, in medical malpractice cases in which a doctor fails to diagnose and treat a condition or where a surgeon fails to remove a medical device used during surgery.

A related issue is whether dependents in a wrongful-death action may recover economic damages for support the decedent would have provided had the decedent lived—that is, whether such damages can be recovered over the remainder of the decedent's expected lifetime, had he lived. Quantifying such damages requires a projection of the decedent's life expectancy using the methods discussed above.

Acknowledgments

The authors would like to express their gratitude for the substantial contributions of Eduardo Hurtado and Neill Norman in the development of this reference guide.

Glossary of Terms

avoided cost. Cost that the plaintiff did not incur as a result of the harmful act.

Usually it is the cost that a business would have incurred in order to make the higher level of sales it would have enjoyed but for the harmful act.

before-and-after damages. A damages model based on the assumption that the period prior to the challenged conduct (or at some point after the challenged conduct) provides a reliable basis for conditions in the but-for world, absent the challenged conduct.

but-for analysis. Description of the plaintiff's economic situation but for the defendant's harmful act. Damages are generally measured as but-for value less actual value received by the plaintiff.

capitalization. Calculation of today's equivalent to a past dollar to reflect the time value of money and risk. If the capitalization rate is r , the capitalization factor applicable to one year in the past is:

$$\text{capitalization factor} = (1 + r).$$

The capitalization for two years is the capitalization factor squared; for three years, it is the capitalization factor cubed, and so on for longer periods.

compound interest. Interest calculation giving effect to interest earned on past interest, as opposed to simple interest, which does not. Simple interest at interest rate r over a number of periods t and on a principal amount P is computed as $P(1 + rt) - P$, while compound interest earned over the same period is computed as $P(1 + r)^t - P$. Thus, for example, given an interest rate of 20%, the compound interest earned on a lost dollar of income three years earlier is computed as $(1 + 0.20)^3 - 1 = \$0.73$, while simple interest is $(1 + 0.20 \times 3) - 1 = \0.60 .

difference-in-differences. A regression methodology that seeks to identify the impact of the challenged conduct by comparing the change in outcomes (e.g., prices or market share) over time between a group (the treatment group) exposed to the challenged conduct, and a second group (the control group) not exposed to the challenged conduct.

discount rate. Rate used to discount future cash flows.

discounting. Calculation of today's equivalent to a future dollar to reflect the time value of money and risk. If the discount rate is r , the discount factor applicable to one year in the future is:

$$\text{discount factor} = 1/(1 + r).$$

The discount for two years is the discount factor squared; for three years, it is the discount factor cubed, and so on for longer periods.

Reference Guide on Estimation of Economic Damages

earnings. Economic value received by the plaintiff. Earnings could be salary and benefits from a job, cash flows from a business, royalties from licensing intellectual property, or the proceeds from a one-time or recurring sale of property. Earnings are measured net of costs. Thus, lost earnings are lost receipts less costs avoided. Note that the term earnings can also be used to mean the accounting concept of net income, which is not a purely economic concept.

fixed cost. Cost that does not change with a change in the amount of products or services sold.

prejudgment interest. Interest on losses occurring before trial.

present value. Value today of money due in the past (with interest) or in the future (with discounting).

price erosion. Effect of the harmful act on the price charged by the plaintiff. When the harmful act is wrongful competition, as in intellectual property infringement, price erosion is one of the ways that the plaintiff's earnings have been harmed.

regression analysis. Statistical technique for inferring stable relationships among quantities. For example, regression analysis may be used to determine how costs typically vary when sales rise or fall.

variable cost. Component of a business's cost that would have been higher if the business had enjoyed higher sales. See also avoided cost.

Prologue to the *Reference Guide on Exposure Science and Exposure Assessment*, the *Reference Guide on Epidemiology*, and the *Reference Guide on Toxicology*

Courts are sometimes faced with cases that involve toxic substances that cause disease rather than traumatic injury. Those cases often raise difficult questions of factual causation for which scientific evidence is important or essential. The next three reference guides address the disciplines of exposure science and exposure assessment, epidemiology, and toxicology, each of which often plays an important role in such cases.

The discipline of exposure science and exposure assessment focuses on assessing what the dose of a particular substance might have been under a defined set of circumstances. Simply stated, “dose” refers to the amount of a toxic substance that has entered the body. Dose comprises both the magnitude of exposure and the duration of the exposure. Exposure scientists describe the conditions that determine the extent to which a toxic substance enters the body of a person exposed to that substance. For example, if a toxic substance is poorly absorbed through the digestive tract but passes easily into the bloodstream from the lungs, exposure science endeavors to explain the differences between swallowing or inhaling a given quantity of that substance.

The discipline of toxicology focuses on determining the “response” to a dose—that is, both whether an agent causes a specific type of adverse (toxic) effect and how much of a particular substance it takes to cause that effect. Because of the obvious ethical limitations of studying known or suspected toxic substances directly in humans, toxicology relies on a combination of experimental studies using animals (called *in vivo* studies) and human-derived cells and/or tissues (called *in vitro* studies). The experimental setting enables toxicologists to carefully control and define dose and exposure. Much of toxicology seeks to understand the mechanism by which a substance causes adverse biological effects.

The discipline of epidemiology is focused (in this context) on evaluating whether the exposure of a population of individuals to a particular substance is associated with a change (usually an increase) in the occurrence of a specific

disease. Epidemiology faces the same ethical constraints against human experimentation as does toxicology. As a result, except for randomized clinical trials of pharmaceutical agents with potential benefits thought to outweigh their potential risks, epidemiologic studies are observational rather than experimental. Observational epidemiologic studies cannot control exposure and dose as toxicological studies can. But epidemiologists, unlike toxicologists, are able to study groups of human beings rather than human tissues or nonhuman animals.

Each of these disciplines may be brought to bear on a particular scientific question concerning a suspected toxic substance, and they interrelate in important ways. Epidemiologists rely heavily on exposure science to help define the dose and duration of exposure to a substance that individuals in a study population received. Toxicologists also rely on careful assessment of dose. Toxicological information about a substance's mode or mechanism of action helps in assessing whether an observed epidemiologic association reveals a causal relationship between exposure and disease. Conversely, epidemiologic information about a substance's association with disease in human populations helps in assessing whether toxicological effects seen in animal or in vitro studies may validly be extrapolated to people.

Thus, these three reference guides, while independent, share many common elements. As much as possible, the authors have attempted to use common terms and definitions, although the reader should understand that usage may differ across disciplines. Not surprisingly, there will be some redundancy found among the three reference guides. But such redundancy is perhaps useful to highlight critically important elements that are necessary when assessing the scientific strengths and limitations of causal claims in litigation involving toxic substances and disease. The authors of these three reference guides encourage careful consideration and integration of the key scientific elements highlighted in all three guides: the *Reference Guide on Exposure Science and Exposure Assessment*, the *Reference Guide on Epidemiology*, and the *Reference Guide on Toxicology*.

Introduction to Exposure Science

Humans and other organisms regularly come into contact with a wide range of agents that directly or indirectly result in some form of adverse effect or harm. Generally referred to as stressors, these agents are typically chemical, physical, or biologic in nature but may also be psychosocial. Exposure science is a distinct discipline that studies individuals and populations and their behaviors related to contact with stressors, the nature and extent of such contact, and the fate of these stressors in the environment and in organisms over space and time. Though the origins of exposure science date to the ancient Greek physician Hippocrates, modern exposure science is rooted in the industrial-hygiene and radiation health-physics practices of the last century, and the importance of this field is increasingly recognized.¹

Exposure science has a complementary role with epidemiology² and toxicology,³ two disciplines devoted to understanding the inherent potential hazard of a given stressor. This is particularly important in the context of risk assessment, which is a formal process by which the nature and probability of adverse health effects in organisms exposed to a given stressor can be estimated. Given that a dose only results from exposure, exposure science is intrinsically linked with one of the fundamental tenets of human health risk assessment, the toxicological concept attributed to Paracelsus that “the dose makes the poison.” Characterization of exposure plays a key role in environmental epidemiology, as such studies are designed to ascertain whether or not there is an association between exposure to a particular stressor of interest and a health effect in humans. More generally, in order to evaluate whether individuals or populations exposed to a stressor are at risk of harm,⁴ or have actually been harmed, information on toxicity or hazard derived from epidemiological and toxicological studies is needed, as is information

1. In 2012, the National Research Council (NRC) published a seminal report on the field, *Exposure Science in the 21st Century: A Vision and a Strategy*. This report defines exposure science more formally as “the collection and analysis of quantitative and qualitative information needed to understand the nature of contact between receptors and physical, chemical, or biologic stressors.” Nat’l Rsch. Council, *Exposure Science in the 21st Century: A Vision and a Strategy* 20 (2012), <https://doi.org/10.17226/13507>. Following release of this report, the Exposure Science in the 21st Century Federal Working Group (ES21 FWG), consisting of twenty federal organizations, was established to create a common understanding of exposure science, expand partnerships, and drive research across the federal government. In the past decade, federal exposure science programs have rapidly expanded to address increasing demand for exposure data and methods, including programs within the National Exposure Research Laboratory and the National Center for Computational Toxicology of the U.S. Environmental Protection Agency (EPA).

4. See, e.g., *Rhodes v. E.I. du Pont de Nemours & Co.*, 253 F.R.D. 365 (S.D. W. Va. 2008) (suit for medical monitoring costs because exposure to perfluorooctanoic acid (PFOA) in drinking water allegedly caused an increased risk of developing certain diseases in the future); *In re Welding*

on the exposures incurred by those individuals or populations. This interrelationship is a central theme in a report by the National Academies of Sciences, Engineering, and Medicine (the National Academies) that examines how data being generated today across disciplines can be used in risk assessment applications.⁵

This reference guide emphasizes assessment of exposure to chemical stressors, which serves as a model for considerations of approaches to characterization (e.g., direct measurement, indirect estimation, exposure reconstruction) and quantification of exposure (see sections titled “Exposure Assessment Considerations for Chemical Stressors” and “Quantification of Exposure to Chemical Stressors”). However, some considerations specific to exposure of certain biological and physical stressors are discussed briefly (see “Exposure Assessment of Biologic and Physical Stressors”).

Key Concepts

Exposure science describes the environment, the behavior of stressors in the environment, the characteristics and activities of individuals and populations, and the processes that lead to human contact with and uptake of these stressors. For exposure to occur, the stressor and an individual (or population) need to come together in both space and time. The time of continuous contact between the stressor and individual (or population) is the exposure period. Exposure can be described in terms of intensity or magnitude (how much), frequency (how often) and duration (how long) of contact at an external boundary (those characterized by external exposure surfaces, such as the surface of the skin). For most stressors, both intensity or magnitude and route of exposure are critical characteristics in determining adverse effects. In addition, factors such as the frequency, duration, and timing of exposure (e.g., life-stage considerations, acute versus chronic exposure) are influential in determining adverse effects. These factors depend on the source of the stressor, its transport and fate, its persistence in the environment, and the activities of individuals that lead to contact with the stressor.

Exposure science also extends beyond the exposure event itself (i.e., the point of contact with a stressor) to study and describe the processes that affect the transport and transformation of a stressor, or agent, from its source to a dose at a target internal organ, tissue, or toxicity pathway associated with a disease process. Exposure scientists use a broad range of data and information (empirically derived and modeled) to describe conditions in the real world that could lead to human health risks, typically by conducting an exposure assessment. An exposure

Fume Prods. Liab. Litig., 245 F.R.D. 279 (N.D. Ohio 2007) (exposure to manganese fumes allegedly increased the risk of later developing brain damage).

5. Nat'l Acads. of Scis., Eng'g & Med., Using 21st Century Science to Improve Risk-Related Evaluations (2017) [hereinafter National Academies 2017 Report], <https://doi.org/10.17226/24635>.

assessment is a process of estimating or measuring the magnitude, frequency, and duration of exposure to a stressor, and the characteristics of the population exposed. These exposure assessments, which link exposure to health outcomes and help regulators evaluate various options to manage exposures effectively, can be for current, prospective, and retrospective exposures.⁶ Ideally, an exposure assessment describes the sources, routes, pathways, and uncertainty; describes contact with agents as they occur in the real world at various life stages; and provides data to understand and quantify health outcomes as they occur in various populations.⁷ A source-to-outcome framework, as illustrated in Figure 1, helps to visualize the information and processes important for exposure science, including the major types of experimental and computational approaches to exposure characterization commonly utilized in exposure assessment. Historically, exposure assessment may have ended with the description of the exposure itself (sometimes framed as the potential dose to the body, e.g., prior to crossing a relevant absorption barrier like the skin), but it is now common for practitioners to quantify stressors present in blood, urine, or various tissues of the body as a result of current or past exposure—referred to as biomarkers of exposure—and even to quantify certain biological responses of concern triggered by exposure, referred to as biomarkers of effect.

Practitioners

It is important to note that not all exposure assessments are sufficiently complex to require an exposure scientist or similar exposure expert. Indeed, some assessments are relatively simple, with epidemiologists or toxicologists likely capable of estimating exposure in relatively straightforward scenarios, such as consumption of a residue in food or ingestion of a medication. In more complex cases, such as when

Washington, DC: The National Academies Press. <https://doi.org/10.17226/24635>.

exposures result from a stressor moving from sources through one or more environmental media, or when historic exposure profiles must be constructed, it is unlikely that toxicologists or epidemiologists will be able to offer appropriate qualifications, because more advanced modeling and integration of various exposure data are needed to characterize exposures. Given the heterogeneity of exposure science, it should not be surprising that practitioners (exposure scientists as well as related experts) come from a wide range of academic backgrounds. These backgrounds may include environmental health sciences (including some specializing in exposure science), industrial hygiene, environmental and analytical chemistry, chemical and environmental engineering, geology and hydrogeology, toxicology (toxicokinetic applications in particular), epidemiology, and even behavioral sciences (pertaining to those aspects of human behavior that affect exposures). As noted in Figure 1, exposure scientists may address issues of exposure and dose from a source to a biologically effective dose, but these experts are not typically qualified to address health effects of such exposure, which is typically the domain of experts in epidemiology, toxicology, and medicine. Further details on the qualifications of experts are offered in the last section of this reference guide (section titled “Qualifications of Exposure Scientists or Other Exposure Assessors” below).

Relevance to Disease Causation and Risk Assessment

In the evaluation of disease causation for an individual, exposure science is applied to characterize the individual's contact with a stressor, either qualitatively or quantitatively, which is then linked to evidence of disease causation. Exposure assessment is also a major component of risk assessment. In this context, exposure assessments typically must identify and quantify the exposure of populations that are most highly exposed and populations that are most vulnerable, including all relevant exposure pathways (while ideally allowing the pathways to be identified and defined individually), and quantifying inherent uncertainty in the assessment itself.

Exposure Science and the Law

Exposure is the bridge between the presence of a stressor (or agent) in an environment and its ability to cause harm. Therefore, either contact or the plausibility of contact⁸ with a stressor by the individual or population in question must be established before a harmful level of exposure can be definitively determined to have occurred, which is a central challenge in legal cases. Exposure science evidence is particularly relevant in claims of toxic tort or product liability, in which exposure information is critical to effectively assess the liability of defendants in situations where plaintiffs are suing for damages to their health, or the health of their family members, or a group in a class-action claim. Legal actions to protect consumers are usually brought by agencies and groups, including nongovernmental organizations and affected industries, and less frequently by members of the public. Other areas where exposure science is necessary are in formulating a national environmental- or occupational-health-standard control strategy, in developing or updating state or local regulations to protect human health, and in setting safety standards used to protect our food supply or consumer products from contaminants. Not all legal questions concerning human exposures to potentially harmful substances require expert testimony. For example, when the magnitude of exposure is not relevant or is clearly evident (e.g., because a plaintiff

8. See, e.g., *Kitzmiller v. Jefferson*, No. 2:05-CV-22, 2006 WL 2473399 (N.D. W. Va. Aug. 25, 2006) (defendants offered expert testimony that plaintiff's use of liquid cleaning agents containing benzalkonium chloride failed to show that she was exposed to benzalkonium chloride in the air); *Hawkins v. Nicholson*, No. 02-1578, 2006 WL 954654, at *4 (Vet. App. Mar. 2, 2006) (noting that "a veteran who served on active duty in Vietnam between January 9, 1962, and May 7, 1975, is entitled to a rebuttable presumption of exposure to Agent Orange"); *In re Stand 'n Seal*, 623 F. Supp. 2d 1355 (N.D. Ga. 2009) (consumer use of spray-on product allegedly resulted in inhalation exposure to toxic substances, causing respiratory injuries).

was observed to take the prescribed amount of a prescription medicine or was observed being covered in a powder), expert testimony is not indicated. However, expert testimony may be needed in cases involving complex exposure scenarios or in which the magnitude of exposure itself is not a simple question of fact. Such expert testimony—in which a qualitative or quantitative estimate of the magnitude, duration, and frequency of the exposure—is critical to understanding the potential presence or absence of causality between the agent and the health effect, the latter of which typically is based on toxicological, clinical, or epidemiological evidence.

Understanding Human Exposure: Key Concepts

This section of the reference guide is descriptive rather than quantitative. It covers the various physical processes that lead to human exposures to stressors and introduces the terms that exposure scientists apply to those processes, as well as exposure-related characteristics of exposed individuals and populations. Given that exposure science overlaps with other disciplines, many of which use different terms for the same concepts, it is important to note that the definitions used in this reference guide reflect the field of exposure science.

Exposure vs. Dose

Exposure refers to the contact between an agent and the external boundary (exposure surface) of the body for a specific duration. In toxicology, this metric is sometimes also referred to as administered dose or external dose. In this reference guide the general term dose is used to refer to the amount of a stressor (e.g., a toxicant such as benzene) that, over a specified time period, enters the body after crossing an external exposure surface, such as the lungs. In certain contexts, dose may also be referred to as internal exposure, internal dose, or absorbed dose. However, the concept of dose is generally understood to represent the amount of the stressor that gets past the absorption barrier (e.g., lungs) and into circulation (e.g., into blood), a process referred to as uptake,⁹ while the amount of the contaminant that can interact with organs and tissues to cause biological

9. The capacity for a substance to be absorbed via uptake processes is a reflection of its bioavailability. Chemical properties, the physical state of the material to which an individual is exposed, the ability of the individual to physiologically absorb the chemical (e.g., nutritional status, gut flora activity), and even the exposure medium can all affect bioavailability.

effects can be referred to as a biologically effective dose or target dose depending on the context. Note that dose profiles are a function of time, and over time are dependent on factors described for exposure and pharmacokinetics/toxicokinetics (e.g., absorption into the body, distribution throughout the body, metabolism within the body, and elimination from the body).

Characteristics of the Exposed Individual or Population

The focus for human exposure science in the context of legal evidence is often the exposed individual, group, or population (sometimes referred to as the receptor or receptor population) and not the sources of the stressor, considering potential contact based on the individual or population's location and behaviors. In this context, understanding the characteristics of human receptors, their behaviors, and the relationship between these factors and exposure is crucial for what is known as a receptor-based approach. There is inherent variability in exposure that occurs because of factors related to human behavior and characteristics that help determine an individual's exposure to a stressor, such as location, occupation, activities within a location, socioeconomic status, consumer preferences, dietary habits, and other lifestyle choices. Such exposure factors include rates of ingestion (e.g., foods, water) or inhalation, factors affecting dermal exposure (e.g., skin surface area), activity factors (e.g., time spent in indoor environment, time spent exercising outdoors), or other factors (e.g., body weight, amount and frequency of consumer product use). Where appropriate, exposure assessors also consider characteristics that might increase exposure or predispose an individual, life stage,¹⁰ specific group, or population to greater health risk. These include factors associated with susceptibility, those in which there is an increased likelihood to be more affected by exposure to a stressor than the general population because of intrinsic factors, such as biological sex, life stage, and genetic polymorphisms. Other factors considered include those associated with vulnerability, such as economic, demographic, social, cultural, psychological, and physical states of the human receptor that influence patterns of exposure to environmental contaminants or alter the relationship between the exposure to environmental contaminants and the health effect of concern (e.g., built environment, access to health care, racism, discrimination). Behaviors relative to life stage can also be particularly influential determinants for exposure, especially for

10. An exposure assessor often needs to establish a dialogue with toxicologists/health scientists to consider whether a specific "window of susceptibility" during a given life stage is important to a particular risk assessment.

infants and toddlers and for a developing embryo/fetus during pregnancy. Note that in most cases, drivers for human activities are complex and cannot be predicted readily. Instead, human activities are often treated as variables described by population distributions based on available (e.g., observational or modeled) data.

Figure 2. Examples of exposure sources across a product life cycle.

Exposure Sources

Human chemical exposure sources can be broadly grouped into near-field sources that are close to the exposed individual, such as consumer product use or occupational exposures, and far-field sources wherein individuals are exposed to chemicals via environmental media following release or use far away. As shown in Figure 2 above, which provides a broad overview of major types of exposure sources across a product's life cycle, there are sources of intended exposure (e.g., dermal exposure to cosmetics or consumption of food additives) and unintended exposure (e.g., accidental releases or spills that reach environmental media such as air or water).

There are many chemicals for which intentional use will lead to human exposures, including substances added to food (and indeed food itself),¹¹

11. The natural constituents of food include not only substances that have nutritional value, but also hundreds of thousands of other natural chemicals. This includes a range of compounds generally considered beneficial for human health (e.g., phytonutrients such as flavonoids and

cosmetics, personal care products, fibers and the colorants added to them, and medical products of many types, including pharmaceuticals; many of these uses are carefully regulated under applicable federal and state laws. In addition to exposure to chemicals that are used to manufacture a product, additional chemical exposures can arise during typical use of a product, such as the anticipated generation of tobacco combustion products from use of cigarettes or of thermal transformation productions from use of electronic nicotine delivery systems. Direct contact with products obviously results in some level of exposure. Here direct contact may mean ingestion via swallowing or other mechanisms, such as inhalation or contact with the skin. There are also some exposures that result from intentional use but are not as well understood, including those related to insertion of some medical devices, such as exposure to silicone and metals from certain types of implants. Generally, however, anticipated exposures resulting from intentional use are more readily quantifiable than those associated with unintended exposures.

Unintended exposures include exposure to known chemicals as well as to unknown chemicals, such as those resulting from unanticipated releases, impurities, or environmental reactions that result in the formation of new substances. Many unintended exposures result from deliberate uses of certain chemicals that, although not intended to lead to human exposures, will inevitably do so. Some amount of a pesticide applied aurally may drift into a nearby residential area, components of food packaging materials may migrate into food, and many types of household products are not intended for direct human ingestion or contact, but exposures nonetheless occur indirectly. As with packaging components, materials used in certain medical devices can contain chemicals that may ultimately leach or volatilize from the material and result in exposure, including plasticizers like phthalates in intravenous tubing and catheters. Ultimately, many exposures to a broad range of environmental contaminants and agents used in occupational settings are unintended; these are often exposures that may not be entirely mitigated by engineering controls and protective equipment, but can also include accidental releases. Unintended exposures are generally more difficult to identify and quantify than are intended exposures; such scenarios require significant expertise to appropriately characterize exposure(s).

polyphenols) as well as those that are harmful, including both toxins (toxic compounds naturally produced by living organisms, such as the cyanogenic glycosides produced by a variety of plants consumed as food, including almonds, cassava, sorghum, and stone fruits), and toxic chemicals taken up from the environment (such as arsenic or lead).

Exposure Routes

An exposure route is the way that a contaminant enters an individual at the point of contact.¹² Inhalation of air containing a substance of interest (vapors as well as particulates) is one of the major routes of exposure.¹³ The internal exposure from inhalation is a function of not only the air concentration of the substance being breathed but also the breathing rate of the individual. The physical form of the substance in air will also influence what happens to the substance during inhalation. For example, chemicals that are in the vapor phase will remain in that physical state and will move to the lungs, where a certain fraction will pass through the lungs and enter systemic circulation. The extent to which different chemical substances pass through the lungs is dependent in large part upon their physical properties, particularly solubilities in both fatlike materials and water. Passage through cell membranes (of the cells lining the lungs) requires that substances have a degree of both fat solubility and water solubility. Certain fibrous materials (including but not limited to asbestos), particulate matter (including but not limited to combustion products), and dusts may also move through the airways and may reach the lungs, but to varying degrees. It is anticipated that at least some such materials will be trapped in the nose and excreted.

Generally, only very fine particles reach the lower lung area and are available for absorption systemically. Some particles may be deposited in the upper regions of the respiratory tract and then carried by certain physical processes to the pharynx and then be coughed up or swallowed. Thus, a variety of inhaled substances can enter the body through the gastrointestinal (GI) tract or the respiratory tract.¹⁴

Ingestion is another major route of exposure to substances in environmental media.¹⁵ Ingestion exposure can occur from intentional consumption of food,

15. See, e.g., *Foster v. Legal Sea Foods, Inc.*, No. CCB-03-2512, 2008 WL 2945561 (D. Md. 2008) (hepatitis A allegedly contracted from eating undercooked mussels); *Winnicki v. Bennigan's*, No. CIV.A. 01-3357 (JAG), 2006 WL 319298 (D.N.J. 2006) (alleged foodborne illness contracted from defendant's restaurant led to renal failure and death); *Palmer v. Asarco Inc.*, No. 03-CV-0498-CVE-PJC, 2007 WL 2254343 (N.D. Okla. 2007) (children allegedly ingested dust and soil contaminated with lead); *Rhodes v. E.I. du Pont de Nemours & Co.*, 253 F.R.D. 365 (S.D. W. Va. 2008) (suit for medical monitoring costs because exposure to perfluorooctanoic acid (PFOA) in drinking water allegedly caused an increased risk of developing certain diseases in the future).

water, other liquids, and certain other substances designed for consumption, such as medicines or supplements. Ingestion exposure can also occur from the intentional or inadvertent nondietary ingestion¹⁶ of soil, dust, or other substances, or of chemical residues on surfaces or objects that are contacted via hand-to-mouth or object-to-mouth activity (especially relevant for young children); this includes incidental ingestion of substances such as cosmetics, personal care products, and certain medications applied to the mouth or lips. They are swallowed, enter the GI tract, and to greater or lesser degrees are absorbed into the bloodstream at various locations along that tract. This is often referred to as the oral route of exposure.

Dermal exposure, the remaining major route of exposure for substances in products and the environment, reflects contact with the largest organ of the body, the skin.¹⁷ The skin is composed of two layers, with a thin outer layer of squamous keratinocytes (called the epidermis or the stratum corneum) that is highly hydrophobic and provides the protective barrier function of skin. Beneath the epidermis is a much thicker living layer of cells including blood vessels, nerves, hair follicles, and sweat glands. As with the GI tract and the lungs, substances are absorbed through the skin to greater or lesser degrees, depending on their physical and chemical characteristics. Other factors also influence dermal absorption, including the specific surface involved, as the skin is not uniform in thickness or in its composition of skin surface fluids, its temperature, and whether occlusion (e.g., trapping material between skin and clothing) has occurred. The uptake of chemicals through these two skin layers is governed by diffusion, and therefore regulated by Fick's law, which states that the rate of diffusion across a barrier will be directly proportional to the concentration gradient. Regardless of exposure route(s) of interest, it is important to note that, depending on the nature of the stressor present at an absorption boundary, in some cases harm can occur directly within the respiratory or GI tracts or on the skin before absorption occurs.¹⁸

Exposure Pathways

An exposure pathway reflects the course a stressor takes from the source to the point at which it reaches the human receptor of interest (e.g., individual, group,

16. Such nondietary ingestion occurs to some extent in all individuals. However, there are individuals for whom this can be more considerable, such as those with pica behavior or similar conditions.

17. See, e.g., *United States v. Chamness*, 435 F.3d 724 (7th Cir. 2006) (evidence that methamphetamine and the ingredients used in its manufacture are toxic to the eyes, mucous membranes, and skin supported sentencing enhancement for danger to human life).

18. Rodricks, *From Exposure to Dose*, *supra* note 14.

population).¹⁹ Exposure pathways analysis allows the identification of all the routes by which stressors from a given source may enter the body, because it identifies all relevant media of human contact into which the stressors migrate. To ensure thoroughness in the assessment, all conceivable pathways should be explicitly identified, with the understanding that ultimately some pathways will be found to contribute negligibly to the overall exposure. The simplest pathways are those described as direct exposure. For example, a substance, such as a non-caloric sweetener or an emulsifier, once added to food follows a simple and direct pathway to the people who ingest the food. The same can be said for pharmaceuticals, cosmetics, and other personal care products. Calculating exposure to such substances, as shown below in the section titled “Quantification of Exposure to Chemical Stressors,” is generally a straightforward process. Even in such cases, however, complexities can arise. For example, in the case of certain personal care products that are applied to the skin, there is a possibility of inhalation exposures to any substance in those products that can readily volatilize (move from a liquid to a gaseous state) at room temperatures. One physical characteristic of chemicals that exposure scientists need to understand is their capacity to volatilize. Not all chemicals are readily volatile, but inhalation routes can be significant for those that are volatile, regardless of their sources.²⁰

Indirect pathways of exposure can range from the relatively simple to the highly complex. Many packaging materials are polymeric chemicals—very large molecules synthesized by causing very small molecules to chemically bind to each other (or to other small molecules) to make very long chemical chains. These polymers (polyethylene, polyvinyl chloride, polycarbonates, and others) tend to be physically very stable and chemically quite inert (meaning they have very low toxicity potential). But it is generally not possible to synthesize polymers without very small amounts of the starting chemicals (those small molecules, usually called monomers) remaining in the polymers. The small molecules can often migrate from the polymer into materials with which the polymer

19. See, e.g., *SPPI-Somersville, Inc. v. TRC Cos.*, No. 07-5824 SI, 2009 WL 2612227, at *16 (N.D. Cal. 2009) (groundwater contamination claim was dismissed because there was no current pathway to exposure); *United States v. W.R. Grace Co.*, 504 F.3d 745 (9th Cir. 2007) (affirming exclusion of report, but not expert testimony based on the report, identifying which pathways of asbestos exposure were most associated with lung abnormalities); *Grace Christian Fellowship v. KJG Invs. Inc.*, 2009 WL 2460990, at *12 (E.D. Wis. 2009) (preliminary injunction was denied because the plaintiff did not establish that a complete pathway currently existed for toxicants to enter the building); Nat’l Exposure Rsch. Lab’y, U.S. Env’t Prot. Agency, Scientific and Ethical Approaches for Observational Exposure Studies, Doc. No. EPA 600/R-08/062 (2008), <https://perma.cc/QM3KTAY6>; U.S. Env’t Prot. Agency, *Exposure Factors Handbook* (2011), <https://perma.cc/D8AR-5FT5>.

20. Inhalation exposures to nonvolatile chemicals can occur if they are caused to move into the air as dusts. See Nat’l Rsch. Council, *Human Exposure Assessment for Airborne Pollutants: Advances and Opportunities* (1991), <https://doi.org/10.17226/1544>.

comes into contact. If those materials are foods or consumer products, people consuming those foods or otherwise using those products will be exposed.

Some amount of the pesticides applied to food crops may remain behind in treated foods and be consumed by people.²¹ This last pathway can become more complicated when treated crops are used as feed for animals that humans consume (meat and poultry and farm-raised fish) or from which humans obtain food (milk and eggs). Exposure scientists who study these subjects thus need to understand what paths pesticides follow when they are ingested by farm animals used as food. The same complex indirect pathways arise for some veterinary drugs used in animals from which humans obtain food.²² In the realm of environmental contamination, pathways can multiply, at which point the problem of exposure assessment can become even more complex, as exposure must be aggregated across relevant pathways. Example sources of environmental contamination include air emissions from manufacturing facilities and from numerous sources associated with the combustion of fuels and other organic materials.²³ Similar emissions that reach water supplies, including ground water used for drinking water or for agricultural applications, can result in human exposures through drinking water and food.²⁴ Contaminants of drinking water that are volatile can enter the air when water is used for bathing, showering, and cooking. In particular, contamination of air in homes and other buildings because of the presence of volatile chemical contaminants in the water beneath those structures, a process referred to as vapor intrusion, is of increasing concern.²⁵ Wastes from industrial processes and many kinds of consumer wastes can similarly result in releases to air and water.²⁶ In some cases, emissions to air can lead to the deposition of contaminants in soils and household dusts; this type of contamination is usually

21. Other pathways for pesticide exposure include spraying homes or fields. See, e.g., *Kerner v. Terminix Int'l, Co.*, No. 2:04-CV-735, 2008 WL 341363 (S.D. Ohio 2008) (pesticides allegedly misapplied inside home); *Brittingham v. Collins*, No. CIV. AMD 06-1952, 2008 WL 678013 (D. Md. associated with nonvolatile substances. Some such substances may remain in soils for very long periods; others may migrate from their sites of deposition and contaminate ground water, whereas others may degrade relatively quickly. All such issues regarding the movement of chemicals from their sources through the environment to reach human populations come under the heading of chemical fate and transport.²⁷ Transport concerns the processes that cause chemicals to follow certain pathways from their sources through the environment, and fate concerns their ultimate disposition—that is, the medium in which they finally reside and the length of time that they might reside there. Fate and transport scientists have models available to estimate the amount of chemical that will be present in that final environmental medium, often referred to as the exposure medium.²⁸ Some discussion of the nature of these models is offered below in the sections titled “Exposure Assessment Considerations for Chemical Stressors” and “Quantification of Exposure to Chemical Stressors.” One final feature of pathways analysis that should be noted concerns the fact that some chemicals degrade rapidly when they enter the environment, others slowly, and some not at all, or only exceedingly slowly.

The study of environmental persistence of different chemicals is a significant feature of exposure science; its goal is to understand the chemical nature of the degradation products and the duration of time the chemical and its degradation products persist in any given environmental medium. Most inorganic chemicals are highly persistent; metals that become contaminants may change their chemical forms in small ways (lead sulfide may convert to lead oxide), but the metal persists forever (although it may migrate from one medium to another). Most organic chemicals degrade in the environment as a result of their exposure to light, to microorganisms present in soils and sediments, and to other environmental substances. But many organic substances (e.g., polyfluorinated substances such as perfluorooctanoic acid (PFOA), polychlorinated biphenyls (PCBs), and chlorinated dioxins such as dichloro-diphenyl-trichloroethane (DDT)) are quite resistant to degradation and may persist for unexpectedly long periods (although even these ultimately degrade). Exposure assessors also need to be aware of the possibility that the degradation products of certain chemicals may be as toxic, or even more toxic, than the chemicals themselves. The once widely used solvents trichloroethylene and perchloroethylene (tetrachloroethylene) are commonly found in ground water. Under certain conditions, these compounds degrade by processes that lead to the replacement of some chlorine atoms by hydrogen atoms. One product of such degradation is the more hazardous chemical vinyl

27. The common phrase used by exposure scientists is “fate and transport.” In fact, transport takes place and has to be understood before fate is known.

28. In the context of exposure science, the term “final” refers to the medium through which people become exposed. A chemical may in fact continue to move to other media after that human exposure has occurred.

chloride (vinyl chloride monomer or chloroethene), the presence of which in drinking water should not be ignored in an assessment.

A description of pathways is the critical step in characterizing exposure and, especially for environmental contaminants, must be done with thoroughness. Are all conceivable pathways accounted for? Have some pathways been eliminated from consideration, and if so, why? Are any environmental degradation products of concern? Only with adequate description can adequate quantification (see section titled “Quantification of Exposure to Chemical Stressors” below) be accomplished.

Introduction to Exposure Assessment

The primary objective of an exposure assessment is to estimate exposure to the stressor(s) of concern to the human receptor. The completion of an exposure assessment provides the information needed (the amount or concentration and duration of exposure) by epidemiologists and toxicologists, who will have information on the adverse health effects of the chemicals involved and on the relationships between those effects and the resulting dose.²⁹ It is important to note that exposure assessment, and underlying exposure data, can directly contribute to sources of error in epidemiological studies, as discussed in the section titled “Sources of Error in Epidemiologic Studies” of the *Reference Guide on Epidemiology*, in this manual.³⁰ Examples of such sources of error are included in that reference guide and include issues such as methods for imputation of measurements below a method limit of detection (see also “Data for Exposure Assessment: Measurements and Models” below).

As discussed in the next section, exposure assessments can be directed at exposures that occurred in the past, those that are currently occurring, or those that will occur in the future should certain actions be taken (e.g., the entry of a new product into the consumer market or the installation of new air pollution controls). Some aspects of exposure assessment may vary, based on application. Note that various regulatory programs publish their own guidance documents.³¹ As a field, exposure science has moved beyond the classical, source-oriented

29. See Steve C. Gold et al., *Reference Guide on Epidemiology*, and David L. Eaton et al., *Reference Guide on Toxicology*, in this manual. See also, e.g., *White v. Dow Chem. Co.*, 321 Fed. App'x 266 (4th Cir. 2009) (plaintiff must show more than possible exposure; must show concentration and duration); *Anderson v. Dow Chem. Co.*, 255 Fed. App'x 1 (5th Cir. 2007) (lawsuit dismissed because uncontested data showed that magnitude and duration of exposure was insufficient to cause adverse health effects).

30. See Steve C. Gold et al., *Reference Guide on Epidemiology*, in this manual, for a discussion on sources of error in epidemiology studies.

31. See, e.g., U.S. Env't Prot. Agency, *Exposure Factors Handbook* (2011), <https://perma.cc/D8AR-5FT5>.

approaches (those that measure a stressor at its source and then estimate how much reaches an individual or population) to incorporate more human receptor-oriented approaches (those that measure or model a stressor at the individual or population level). Exposure assessments have also become more sophisticated given advances in technologies: These range from dramatic improvements in sensitivity and specificity of targeted analytical methods and incorporation of nontargeted analytical methods to the use of remote and personal sensors/dosimeters in the measurement of exposure, as well as more robust modeling approaches that have allowed for development of much more refined exposure profiles.

Exposure assessment is generally intended to answer the following questions:

- Who has been or could become exposed to a specific stressor(s) arising from one or more specific sources? Is it the entire general population, or is it a specific subpopulation (e.g., those residing near a certain manufacturing or hazardous waste facility; infants and children; or workers)?³²
- What specific stressors comprise the exposures?
- What are the pathways from the source of the stressor to the exposed population? Pathways include direct product use, or those so-called indirect pathways in which the stressor moves through one or more environmental media to reach the media to which people are exposed (air, water, foods, soils, and dusts). Understanding pathways is necessary to understanding exposure routes (below) and quantifying exposures.
- By what routes are people exposed? Routes include ingestion, inhalation, and dermal contact.³³ Identifying exposure routes is important because those routes affect the magnitude of ultimate exposures and because they often affect health outcomes.
- What is the magnitude and duration of exposure incurred by the population of interest? Magnitude (often reported as concentration, amount, or intensity) is the amount of a stressor entering the body or contacting the surface of the body, usually over some specified period of time (often over a day).³⁴ Duration refers to the number of days over which exposure occurs. Has exposure changed over time? Note that

32. See, e.g., *Hackensack Riverkeeper, Inc. v. Del. Ostego*, 450 F. Supp. 2d 467 (D.N.J. 2006) (river and bay users alleged that hazardous waste runoff and emissions polluted the water); *Bradford v. Citgo Petroleum Corp.*, 237 So. 3d 648 (La. Ct. App. 2018) (affirming jury award where the trial court was given “significant circumstantial evidence” that tied plaintiffs living/working/socializing in areas around the CITGO facility to exposures to the subject chemical spills and emissions).

33. Note that additional routes of exposure (e.g., injection, ocular exposure) may be relevant for some pharmaceuticals, diagnostics, and medical devices.

34. Shorter periods of time may be used when the concern is very short-term exposures to chemicals that have extremely high toxicity.

exposures can be intermittent or continuous and can be highly variable, especially for some air contaminants.

Exposure Assessment Considerations for Chemical Stressors

Problem Formulation: Why Conduct a Given Exposure Assessment?

What an exposure assessment is intended to inform will guide the direction of the assessment itself, including the level of the complexity involved (e.g., screening-level assessment). A specific goal of a given exposure assessment might be identifying exposed individuals, groups, or populations, screening chemicals for potential exposure, or identifying source(s) of contamination. Exposure assessments are carried out for a wide variety of reasons, including use in risk assessment, identifying trends in measurements, mitigation efforts, regulatory decision making, priority setting, and epidemiological studies. For example, an assessment completed as part of a regulatory action may involve certain types of legal considerations (e.g., statutory requirements, mandates under a regulator program), whereas an assessment completed as part of an epidemiologic investigation would not.

Context

The development of exposure estimates can follow different methodological approaches depending on the needs of the evaluation to be carried out. For example, if the interest is directed toward personal exposure, the level of exposure should be measured or estimated at the point of contact with the subject (e.g., dermal, inhalation exposure). If exposure is associated with a specific scenario, as is common with near-field exposures, the exposure can be estimated or measured and, to subsequently refine the estimate, combined with information relating to the frequency and duration of the exposure. An exposure estimate can also be carried out with a retrospective approach (e.g., development of historical profile of exposure, reconstruction of exposure from levels of the chemical or metabolites in an individual) or prospective approach (e.g., estimate of present or future exposures). The prospective approach is typically used for regulatory purposes. The retrospective approach can be used, for example, to characterize exposure based on measures or estimates of concentrations in environmental media but can also be used to estimate past occupational exposures for an individual or a population in relation to specific tasks or professional roles held. Such

retrospective exposure assessments are common in toxic tort claims. Note that regardless of whether a prospective or retrospective approach is warranted, a traditional exposure assessment can be designed to consider an exposure resulting from a single identified source and pathway, or from combined exposures to a single chemical resulting from multiple sources, and/or multiple routes and pathways (typically referred to as aggregate exposure).

An aggregate exposure assessment approach is commonly used when humans can be exposed to a single contaminant in various ways. For example, if residues of the same pesticide could be found on multiple foods, in water, and/or in products used in and around the home, then an individual might have exposure via dermal contact, inhalation, ingestion, and other routes. Note that a cumulative exposure assessment can also be undertaken if there is a need to estimate exposure to multiple stressors by multiple routes and/or multiple pathways. Such cumulative exposure assessments are typically conducted for contaminants that produce toxic responses by the same mode of action, or when a population in a specific location is exposed to a variety of stressors.³⁵ The United States Environmental Protection Agency (EPA) has developed guidance for these assessments,³⁶ particularly because cumulative, community-based assessments that can characterize exposures or risks that disproportionately and unfairly affect certain communities are a cornerstone of assessments of environmental justice issues.

Data for Exposure Assessment: Measurements and Models

As discussed previously, exposure science has moved from a focus on classical source-oriented approaches to incorporate more receptor-oriented approaches. Exposure measures have significantly evolved from limited descriptions of a chemical or other stressor in environmental media, food, consumer products, or biological specimens. Biomonitoring data in particular are increasingly available, both in terms of chemical coverage and diverse populations. Biomonitoring refers to the measurement of cellular, biochemical, analytical, or molecular measures obtained from biological media (e.g., tissues, cells, fluids) that can be used to monitor the presence of (1) a chemical in the human body, (2) biological

35. See, e.g., *Diné Citizens Against Ruining Our Env't v. Haaland*, 59 F.4th 1016 (10th Cir. 2023) (finding that Bureau of Land Management acted arbitrarily and capriciously by failing to account for the cumulative impact of hazardous air pollutant emissions from the more than 3,000 wells; these emissions could result in long-term exposure for individuals living in or visiting the San Juan Basin).

36. See, e.g., U.S. Env't Prot. Agency, *Exposure Assessment Tools by Tiers and Types—Aggregate and Cumulative*, <https://perma.cc/LC2L-28K5>.

responses, or (3) adverse health effects.³⁷ These data are typically combined with pharmacokinetic models that simulate the distribution and movement of chemicals within a living system to reconstruct or estimate the amount of chemical to which a person was exposed. Biomonitoring data are particularly useful for reconstruction of aggregate and cumulative exposure as these measures reflect exposure to chemical(s) of interest from all sources, routes, and pathways as well as uptake and accumulation. However, that does mean that these measures are not source or pathway specific and, depending on the scenario and other available data, it may not be possible to identify specific sources or routes of exposure—which limits utility for certain types of assessments.

Biomarkers relevant to exposure assessment include biomarkers of exposure, biomarkers of effect, and biomarkers of susceptibility. The type of biomarker and the biological matrix in which it can be measured are dependent not only on the chemical of interest and its properties, but on inter-individual variability of intrinsic and extrinsic factors that can modify relevant processes, such as metabolism and excretion (e.g., cigarette smoking induces the activity of human enzymes involved in metabolism of various exogenous substances; genetic polymorphisms in such enzymes).

Biological half-life, the length of time required for the concentration of a particular substance to decrease to half of its starting dose in the body, can be highly variable across species and among individuals of the same species. Consideration of biological half-life is particularly important when evaluating biomonitoring data as some chemicals, such as bisphenol A (BPA) and analogues, have an overall biological half-life on the order of hours, while other chemicals, such as dioxins and polychlorinated biphenyls (PCBs), range from years to over a decade. Matrix-specific biological half-life can further complicate this. For example, lead is cleared relatively quickly from the blood and soft tissues with a half-life of one to two months, but is cleared much more slowly from bones, with a half-life of years to decades. As such, biomarkers can be of varying utility depending on the chemical of interest, window of exposure, and sampling period. More information on application of biomonitoring in exposure assessment can be found elsewhere, including the EPA website.³⁸

The EPA has developed working definitions for the types of biomarkers summarized briefly here using examples from pesticide risk assessment.³⁹ Biomarkers of exposure are used to assess the amount of a chemical that is present within the body. Measures include the chemical itself (the most specific biomarker of exposure), chemical metabolites (specificity varies; if a nonspecific metabolite is

measured, additional information is needed to determine to which specific chemical the original exposure occurred), and endogenous surrogates. Biomarkers may also include a response within the body that is highly characteristic of a chemical or class of chemicals (this is the least specific biomarker of exposure, as there are many factors that can influence endogenous responses, such as inhibition of butyrylcholinesterase). Biomarkers of effect are indicators of a change in biologic function in response to an exposure (e.g., blood cholinesterase is typically depressed following exposure to organophosphate pesticides), and thus more directly related to insight into the potential for adverse health effects compared with biomarkers of exposure. Biomarkers of susceptibility are factors that result in certain individuals being more sensitive to a given exposure; these biomarkers are therefore more directly related to the potential for adverse health effects than biomarkers of exposure. Examples of biomarkers of susceptibility include genetic factors, nutritional status, lifestyle, and age, among others.

For decades the U.S. Centers for Disease Control and Prevention (CDC) was the leading source of biomonitoring data (with over 300 chemicals measured in biological specimens, such as blood or urine from a nationally representative population sample as part of the National Health and Nutrition Examination Survey). However, there are now thousands of individual studies reporting biomonitoring data available for consideration. Those conducting biomonitoring studies have radically diversified, and they include academic research centers across the United States, state and local biomonitoring programs, and even non-governmental organizations. There are now even direct-to-consumer tests for select environmental contaminants facilitated via lab draws or a home testing kit. Note that not all biomonitoring data will be of sufficient quality for use in exposure assessment; the CDC has developed specific guidance regarding assessing the quality of biomonitoring data. Information is available on the CDC National Biomonitoring Program website.⁴⁰

Advances in technologies—from the use of remote and personal sensor systems to new molecular technologies and computational modeling—allow for rapid development of comprehensive exposure profiles. The use of low-cost sensors is also expanding participatory science, including community-based exposure characterization,⁴¹ which coincides with greater availability of personal data from sources such as social media and wearable devices. Such data are increasingly used for exposure assessment, as they are able to provide insight into exposure on

a timescale of minutes so that peak exposures can be determined. Similarly, remote sensing technology, including satellite sensors, is being applied to map gaseous and particulate air pollution levels on a population and global scale. Nontargeted analytical methods, those that assign chemical formulas and structures to unknown compounds without the use of reference standards or target substance lists, are increasingly used, along with similar “suspect screening” methods, to characterize chemical unknowns in environmental media and in biological media. Such advances in exposure science, particularly those in analytical chemistry, alongside developments of hundreds of new databases and tools,⁴² have also allowed for the untargeted discovery of thousands of chemicals in environmental media, in products, and in humans.

Measurement Considerations

Although at first glance it might seem that direct measurements of environmental concentrations would provide the most reliable data, there are limits to what can be gained through this approach. It is important to recognize that there are a variety of factors influencing accuracy and applicability of available environmental measurement data, including but not limited to proximity to sources, activities of the studied individuals, time of day, season, and weather conditions.

- How can we be sure that the physical samples of media taken are representative of the media of interest for exposure assessment? Standard methods are available to design sampling plans that have specified probabilities of being representative, but they can never provide complete assurance. Generally, when the presence of a chemical is likely to be highly homogeneous, there is a greater chance of achieving a reasonably representative sample than is the case when it is highly heterogeneous. In the latter circumstance, obtaining a representative sample, even when very large numbers of samples are taken, may be unachievable.
- How can we be sure that the samples taken represent the presence of a chemical over long periods? Sampling events may provide a good snapshot of current conditions, but in circumstances in which concentrations could be changing over time, and where the health concerns involve long-term exposures, snapshots could be highly misleading. This type of problem may be especially severe when attempts are being made to reconstruct past exposures, based on snapshots taken in the present.
- How can we be sure that the analytical work was done properly? Most major laboratories that routinely engage in this type of analysis have

42. Over 700 tools are listed in the U.S. Environmental Protection Agency’s ExpoBox (A Toolbox for Exposure Assessors). See <https://perma.cc/T6FB-PS3V>.

developed standard operating procedures and quality control procedures. Laboratory certification programs of many types also exist to document performance. When analytical work is performed in certified, highly experienced laboratories, there is a reasonably high likelihood that the analytical results are reliable. But it is very difficult to confirm reliability when analytical work is done in laboratories or by individuals who cannot provide evidence of certification or of long-standing quality control procedures.

- How are data showing the absence of the chemical to be interpreted? In most circumstances involving possible presence of a chemical in either biological matrices or environmental media, the analysis of some (and sometimes many) of the samples will fail to quantify or detect the chemical of interest. The analytical chemist will often report such samples as nondetect (ND). But an ND should never be considered evidence that the concentration of the chemical of interest (or other target analyte, such as a metabolite) is truly zero. In fact, most chemists will (and should) report that the chemical is below the limit of detection (LOD) or below the limit of quantification (LOQ). Every analytical method has a nonzero limit of detection that refers to the lowest chemical concentration that can be distinguished from a concentration of zero with reasonable confidence. A critical issue is that detection limits vary between assay methods, between laboratories, and even within a laboratory over time.⁴³ Thus, for each sample for which a concentration is reported as ND or below LOD, all that can be known with confidence is that the concentration of the chemical, if present, is somewhere below that limit. If there is clear evidence that the chemical is present in some of the samples (i.e., its concentration exceeds the method's LOD), then it is usually assumed that all the samples of the same medium reported as ND or below LOD will actually contain some level of the chemical. In studies using less sensitive methods to detect a chemical in an environmental or biological matrix, the number of samples with levels below the LOD can be substantial. Studies in which the chemical is detected at relatively low frequencies can lose statistical power by omitting samples below the LOD or by imputing samples below the LOD (e.g., assigning a value of zero, the LOD, or some function of the LOD), which can introduce artificial patterns into the data. These approaches can introduce bias into the analysis to varying degrees, based on the sample size, the proportion of observations below the LOD, and the imputation approach used.⁴⁴

44. See, e.g., U.S. Env't Prot. Agency, *Guidance for Data Quality Assessment: Practical Methods for Data Analysis* (2000), <https://perma.cc/SB85-7QKS>. Relevant references from the peer-reviewed

Sampling and measurement are useful, but it is critical to recognize that these are nonetheless limited in important ways. The alternative involves modeling. In fact, a combination of both approaches—one acting as a check on the other—is often the most useful and reliable.

Model Considerations

A model is “a simplification of reality that is constructed to gain insights into select attributes of a particular physical, biological, economic, or social system.”⁴⁵ The simplest model is a conceptual model, from which mathematical processes of the process represented in the conceptual model can be derived (with simplifying assumptions as appropriate). In an exposure assessment, models can be used to extrapolate monitoring data to populations that were not directly analyzed, to reconstruct past exposures, and even to predict future exposures. Models are tools the assessor uses to analyze and characterize processes that are too complex for capturing completely by empirical data or for which empirical data are not available. In the context of chemical exposure assessment, there are a range of models available, including:

- Deterministic modeling (i.e., physical modeling) in which a model describes the relationship between variables mathematically on the basis of knowledge of the physical, chemical, and/or biological mechanisms that are relevant.
 - For example, air particle concentrations in the indoor environment might be modeled by variables such as the air exchange rate, total volume of rooms, and the sources.
- Stochastic modeling (i.e., statistical modeling) in which the statistical relationships are modeled between variables. Such models do not necessarily

literature include the following: Dana B. Lubin, *Epidemiologic Evaluation of Measurement Data in the Presence of Detection Limits*, 112 *Env't Health Persp.* 1691 (2004), <https://doi.org/10.1289/ehp.7199>.

45. Nat'l Rsch. Council, *Models in Environmental Regulatory Decision Making* (2007), <https://doi.org/10.17226/11972>.

require fundamental knowledge of the underlying physical, chemical, and/or biological relationships between the variables.

- For example, use of the EPA's Stochastic Human Exposure and Dose Simulation Model (SHEDS) to estimate a product intake fraction for chemicals in consumer products, or use of land use regression modeling for air pollution modeling in which the relation between land use characteristics such as population density, traffic density, green space, and ambient air pollution levels are modeled using statistical regression techniques and measurements.

Perhaps the most widely used models are those that track the fate and transport pathways followed by substances emitted into the air. Knowledge of the amounts emitted per unit of time (usually obtainable by measurement) from a given location (a stack of a certain height, for example) provides the basic model input. Information on wind directions and velocities, the nature of the physical terrain surrounding the source, and other factors needs to be incorporated into the modeling. Some substances will remain in the vapor phase after emission, but chemical degradation (e.g., because of the action of sunlight) could affect media concentrations. Some models provide for estimating the distributions of soil concentrations for those substances (particulates of a certain size) that may fall during dispersion. Much effort has been put into developing and validating air dispersion models.⁴⁶

Similar models are available to track the movement of contaminants in both surface and ground waters. Other types of exposure models currently being employed use geographic information system (GIS) mapping and various regression (e.g., land use regression) and other statistical tools to estimate regional air concentrations for use in exposure models. These approaches, which map locations of high air pollution, have been used in analyses that estimate large-scale population exposures for chemical pollutants such as ozone and fine particulate matter (PM 2.5). The fate and transport modeling issue becomes more complex when attempts are made to follow a chemical's movement from air, water, and soils into the food chain and to estimate concentrations in the edible portions of plants and animals.⁴⁷ Most of the effort in this area involves the use of empirical data (e.g., What does the scientific literature tell us about the quantitative relationships between the concentration of cadmium in soil and its concentration in the edible portions of plants grown in that soil?). This type of empirical information, together with general data on chemical absorption into,

46. *Id.*

47. Exposure scientists specializing in ecological receptors will also use modeling results to evaluate risks to wildlife, plants, and ecosystems.

distribution in, and excretion from living systems, is the usual approach to ascertain concentrations in these food media.⁴⁸

In addition to environmental fate and transport, a variety of human exposure models are readily available for exposure assessment, particularly for assessment of near-field exposures, such as those from consumer products. Availability, and use, of certain types of exposure models has dramatically increased in recent years. This in part results from the advent of the European Union's Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) legislation, which requires manufacturers and importers of hazardous substances eventually included in consumer products to assess exposure and risk from using these products in a chemical safety report, if a substance is manufactured or imported in sufficient quantities. Given the number and range of exposure models available, it is not always readily apparent which models have established validity and which have not. In some cases, however, a given model may have standing with authoritative bodies (e.g., developed or approved by the EPA for a given application). Further complicating matters, it is often the case that a model intended for a specific purpose is being used in a new context that may not have been anticipated by the original developer. An expert should be able to explain why a model is being used and why other possible models are not as suitable.

As models are the basis of many exposure assessments presented as evidence,⁴⁹ if not the major component of such assessments, it is important that an exposure science expert be able to not only describe the model itself and the rationale for its selection but also the scientific basis and underlying assumptions of the model, and the ways in which the model has been validated,⁵⁰ including comparisons to empirical data as available. If empirical data are available, it may also be reasonable to attempt to reconcile the measurement and modeling results and arrive at the most likely values (or range of likely values). Similarly, it may be useful to have the expert describe the likely size of error associated with model results.

48. Nat'l Rsch. Council, *Models in Environmental Regulatory Decision Making* (2007), <https://doi.org/10.17226/11972>.

49. See, e.g., *Milward v. Acuity Specialty Prods. Grp., Inc.*, 969 F. Supp. 2d 101, 108 (D. Mass. 2013), *aff'd sub nom. Milward v. Rust-Oleum Corp.*, 820 F.3d 469 (1st Cir. 2016) (concluding that expert's exposure assessment was admissible where expert used the Advanced REACH Tool (ART) to calculate plaintiff's benzene exposure from using paint that contained mineral spirits); *Brantley v. Int'l Paper Co.*, No. CV 2:09-230-DCR, 2017 WL 2292767 (M.D. Ala. May 24, 2017) (concluding that expert's exposure assessment was admissible where expert reasonably linked the plaintiffs' claims of property damage to the mill's emissions through his AERMOD study).

50. The process of developing and validating a new model or modifying and evaluating an existing model is beyond the scope of this reference guide but U.S. Env't Prot. Agency, *Guidance on the Development, Evaluation, and Application of Environmental Models* (2009), <https://perma.cc/7ARB-67EK>, describes the steps in detail. This specifies a number of steps including credible and objective peer review, corroborating the model by evaluating the degree to which it corresponds to the system being modeled, and performing sensitivity and uncertainty analyses.

Other issues pertaining to the sources and reliability of the data used in the application of a model can be similarly pursued.

Exposure Assessment Methods

The specific methods used in an exposure assessment depend on the exposure assessment questions, availability and feasibility considerations, the intended applications of the exposure assessment (e.g., use in a type of risk assessment, comparison to a reference value), and, in some cases, the regulatory or statutory requirements. For example, an exposure assessment can inform risk screening, enforcement, remediation decisions, or program and policy evaluation. However, even within an exposure assessment, the use of a given method is not mutually exclusive. Accordingly, an assessor may choose to use several methods. Human exposures can be characterized using various approaches: measurements or estimates in the environment (e.g., ambient air concentrations), at the point of human contact (e.g., personal monitoring or sensors), or after contaminants have entered the human body (e.g., biomonitoring). For environmental data, models can be used to estimate human exposure by combining information about environmental concentrations with information about an individual human receptor or a receptor population. Concentrations and receptor information are referred to as exposure factors, which relate to contact with an agent (e.g., inhalation rates, activity patterns, time in microenvironments). Biomonitoring data that reflect an internal dose can also be used to estimate exposure, using “exposure reconstruction,” an approach that typically involves use of pharmac/toxicokinetic models. This section provides an introduction to the three methods most commonly used in exposure assessment: direct measurement, indirect estimation, and exposure reconstruction. The first two methods use information collected or estimated prior to, or at, the point of exposure to predict exposure, while the third, exposure reconstruction, uses information (e.g., measurements of a chemical or metabolite) collected from the body after exposure has already occurred to back-calculate exposure.

Direct Measurement

Direct measurement methods (i.e., point-of-contact methods) use a number of techniques to measure the contact of a person with the chemical concentration in an exposure medium over a specified period of time. Use of direct measurement methods provides an exposure assessor with chemical concentrations or amounts at the interface between the environment and an individual. So long as the techniques are sufficiently accurate, this method is likely to result in the least amount

of uncertainty in estimating exposure concentration, especially over the time period spanned by samples collected. Note that uncertainty can increase in situations in which few measurements are available and short-term sampling data are extrapolated to long-term exposure. Another important consideration is that a direct measurement is not typically source-specific without further data and information. Further, samples from multiple individuals or other units (e.g., households) may be required in order for these measurements to be sufficiently representative of a population of interest. However, these values can be used to validate or verify assessments conducted using an alternate assessment method. Commonly used direct measurement methods include:

- *Passive and active monitors to measure inhalation exposure.* Such monitors are typically compact and located close to the breathing zone of the individual being studied. For passive sampling studies (e.g., use of a diffusion badge to measure formaldehyde) and active sampling studies (e.g., use of a powered pump to draw air through a filter or similar device in order to measure particulate matter), it is often necessary to extrapolate exposure and subsequently dose from the measured concentration as this is dependent on other factors, including breathing rate (see “Understanding Human Exposure: Key Concepts” above).
- *Duplicate diet studies to measure dietary ingestion exposure.* In these studies, individuals will prepare or collect duplicate samples of all the foods they consume during a given period, allowing investigators to measure concentrations of a contaminant in the diet, which are typically normalized to body weight. While this method gives an accurate estimate of ingestion exposure to such contaminants (and can capture information such as changes in concentration owing to preparation processes such as cooking), it is typically cost-prohibitive and difficult for participants. Note that in order to estimate the applied, internal, or biologically effective dose, an exposure assessor would still need to make other assumptions regarding exposure (e.g., leverage toxicokinetic information to predict absorption across the GI tract).
- *Sampling patches, silicone wristbands, whole-body dosimeters, removal methods, and optimal methods to measure dermal contact with chemicals.* Patches or wristbands are materials limited to placement on specific areas of the body to collect a chemical or chemicals of interest. While these sensors are relatively inexpensive and easy to use, they may miss key contact surfaces and introduce error when extrapolating from a small surface area to a larger surface or the whole body. Whole-body dosimeters are coverall suits or full-length cotton garments that are meant to capture any contact with a contaminant in a specific scenario and time frame during which the dosimeter is worn. Removal methods (e.g., rinsing, wiping, tape

stripping) collect contaminants of concern from the skin at a specific interval. Optical methods include fluorescence analyzers, which have been widely used for measurement of various halogenated compounds. These methods all reflect deposition to the skin, so in order to estimate an absorbed or biologically effective dose, an exposure assessor would still need to make additional assumptions (e.g., leverage toxicokinetic information to predict absorption through the skin).

Indirect Estimation

Indirect estimation, sometimes referred to as scenario evaluation, is a method that estimates exposure after developing a set of facts, assumptions, and inferences about a given exposure scenario, using either measurement or estimation of both the amount of a substance contacted by an individual or population and the frequency and duration of this contact. This method typically relies heavily on assumptions about the sources and releases of a chemical of interest, relevant fate and transport mechanisms, and the concentration at the point of contact with the individual or population. This includes identification of the relevant exposure pathway(s) and route(s) of exposure. Similarly, the human receptor of interest (individual or population) must be characterized to generate inputs regarding physiologic processes and activities/behaviors that influence contact with the chemical (especially those that influence the temporal component—i.e., frequency and duration).

Estimates that quantify intake and uptake rates of the chemical for a given individual or population may also be needed. This process often involves development of a conceptual model, a diagram, or a description that lays out the environmental pathways and routes of exposure in the context of the exposure assessment, distinguishes between what is known/determined and what is assumed/based on default values, and identifies sources of uncertainty. The methods applied for quantification of exposure using indirect estimation will vary depending on the level of complexity and the desired result (e.g., a single value or point estimate of exposure versus a distribution of possible exposure values).

Derivation of a single value for exposure is referred to as a deterministic exposure assessment. These values can be either an estimate of central tendency (e.g., mean, median) that is intended to represent the exposure of the average or typical individual in a population or a high-end exposure within the defined receptor group or population. A high-end estimate is typically a representation of individuals at the upper end of the exposure distribution (e.g., at or above 90th percentile of exposure), which is typically calculated using a combination of high-end and central tendency inputs for given exposure parameters (e.g., intake rate).

Note that, while exposure scenarios can be developed to derive a bounding estimate that captures the highest possible exposure, or a theoretical upper bound, for a given exposure pathway, these are more common in screening-level assessments.⁵¹ In contrast, a probabilistic exposure assessment uses distributions of data for various parameters to generate a distribution of potential exposure estimates. Probability distributions (e.g., Monte Carlo simulation) describe the range of values (probability) that might occur in the given population. The output of a probabilistic assessment is a probability distribution of exposures that reflects the combination of the probability distributions of one or more of the model inputs or parameters. These distributions can help characterize variability, uncertainty, or both, depending on the design of the model and its inputs.

Exposure Reconstruction

Exposure reconstruction uses internal body measurements of a chemical or its metabolite(s) rather than external measurements to estimate dose. Such measurements are known as biomarkers, the cellular biochemical, analytical, or molecular measures obtained via biomonitoring from biological specimens (e.g., blood, urine, saliva) that indicate exposure to a chemical.⁵² Biomonitoring is the process of analyzing such human samples to determine biomarker concentrations. This biomonitoring data can then be combined with computational tools such as pharmacokinetic models to reconstruct or estimate the amount of chemical to which a person was exposed.⁵³ Note that there are circumstances in which biomonitoring data alone may be sufficient to demonstrate exposure, even when there is only a semiquantitative or qualitative determination of the presence of a chemical. Such a situation may arise, for example, when the detection or measured concentration of a chemical is established as an inclusion criterion for a class action. This has occurred recently, with various criteria used across cases dealing with perfluorooctanoic acid (PFOA) exposure, ranging from both detection of PFOA in blood to measurement of PFOA in blood and subsequent comparison to either a specified value or to a concentration that is representative of

51. Note that scenarios developed for bounding estimates are sometimes referred to as “worst case” scenarios in which “everything that can plausibly happen to maximize exposure, dose, or risk does in fact happen. This worst case may occur (or even be observed) in a given population, but since it is usually a very unlikely set of circumstances, in most cases, a worst-case estimate will be somewhat higher than occurs in a specific population.” EPA Guidelines, *supra* note 6. These are useful for screening-level evaluations because if the highest possible exposure is evaluated and found to be not of concern, the more plausible lower exposures will also not be of concern.

52. EPA Guidelines, *supra* note 6.

53. Yu-Mei Tan et al., U.S. Env’t Prot. Agency, Biomonitoring—An Exposure Science Tool for Exposure and Risk Assessment (2012), <https://perma.cc/8QWH-A2GQ>.

general population exposure.⁵⁴ Pharmacokinetics (PK) or toxicokinetics (TK) characterize the absorption, distribution, metabolism, and excretion of a substance in an organism's body. In exposure assessment, pharmac/toxicokinetic (PK/TK) models use data and mathematical equations to evaluate the fate of a chemical in the body after exposure has occurred. These are highly variable in complexity, with the simplest model being a one-compartment, first-order model that assumes immediate distribution within a single compartment, such as blood.

More complex PK/TK models account for an organism's physiology in their equations and are called physiologically based pharmac/toxicokinetic (PBPK or PBTK) models. These models require parameters to simulate movement and fate of chemicals within the body, considering transfers between tissues and organs, metabolism, and deposition or storage. These parameters can be physiological, physiochemical, or biochemical in nature. Many physiological parameters for these models (e.g., ventilation rates, metabolic rates) are derived from clinical or laboratory studies of animals as well as humans—largely pharmacological studies given the data requirements for such agents. Inter- and intra-species differences in these parameters should be evaluated prior to application.

Figure 3 compares predictive exposure models with reconstructive models. Whereas predictive models use information upstream from the point of exposure, such as environmental media concentrations and exposure factors to estimate an exposure or dose, the reconstructive PK/TK models use information downstream of the point of exposure, such as internal body measurements like biomarker concentrations (e.g., amount absorbed, amount at or bound to a target organ or target biological receptor within the body, and, in some cases, a biomarker of effect) and physiologic processes to estimate the original exposure and internal dose. While reconstructing exposure using biomonitoring data represents definitive exposure to an individual, it is often not possible without further information to identify specific sources or routes of exposure (e.g., inhalation, ingestion, or dermal) that contributed to the level measured in the body.

54. See, e.g., *Hardwick v. 3M Co.*, 589 F. Supp. 3d 832, 869 (S.D. Ohio 2022), *motion to certify appeal granted sub nom. In re E.I. DuPont de Nemours & Co. C-8 Pers. Inj. Litig.*, No. 22-0305, 2022 WL 4149090 (6th Cir. Sept. 9, 2022), *vacated and remanded sub nom. In re E.I. du Pont de Nemours & Co. C-8 Pers. Inj. Litig.*, 87 F.4th 315 (6th Cir. 2023) (Certifies class as “Individuals subject to the laws of Ohio, who have 0.05 parts per trillion (ppt) of perfluorooctanoic acid (PFOA) (C-8) and at least 0.05 ppt of any other PFAS in their blood serum.”); *Benoit v. Saint-Gobain Performance Plastics Corp.*, 959 F.3d 491, 501 (2d Cir 2020) (plaintiffs must show that they have a “physical manifestation of or clinically demonstrable presence of” PFOA in their blood); *Sullivan et al. v. Saint-Gobain Performance Plastics Corp.* 226 F. Supp. 3d 288 (D. Vt. 2016) (requires plaintiffs to show that their blood accumulation levels differ from those in the general population and link blood levels with increased risk of disease and appropriate monitoring).

Figure 3. Illustration of predictive exposure models and reconstructive pharmacokinetic models in the source-to-outcome pathway.

Quantification of Exposure to Chemical Stressors

Calculation of Exposure

It is important to note that quantitative calculations may not always be necessary to sufficiently describe exposure;⁵⁵ however, these are standard practice. The general approaches to characterize exposure are measurements, model estimates,

55. Causation may sometimes be established even if quantification of the exposure is not possible. See, e.g., *Bell v. Abb Grp., Inc.*, No. 13-CV-1338-SMY-SCW, 2015 WL 11439279, at *2 (S.D. Ill. Sept. 1, 2015) (in denial of *Daubert* motion, the court found that the opinion of an expert who conducted a qualitative exposure assessment for an individual, based in part on historical data and exposure modeling reliant on historical analyses of asbestos exposure for a similar occupation, and did not intend to quantify exposure levels, was both supported by evidence and rests on authority and, “as such, cannot be fairly characterized as *mere ipse dixit*”); *Lightfoot v. Ga.-Pac. Wood Prods., LLC*, No. 7:16-CV-244-FL, 2018 WL 4517616, at *20 (E.D.N.C. Sept. 20, 2018) (In denial of *Daubert* motion, the court found that qualitative exposure opinions of experts, both with and without quantitative exposure assessments, are both “relevant and reliable for purposes of supporting their specific causation opinions. See *Westberry v. Gislaved Gummi AB*, 178 F.3d 257], 264 (“[T]his clearly is not a case in which the plaintiff was unable to establish any substantial exposure to the allegedly defective product.”)); *Best v. Lowe’s Home Ctrs., Inc.*, 563 F.3d 171 (6th Cir. 2009) (doctor permitted to testify as to causation based on differential diagnosis).

or a combination of both. Regardless of whether an assessment is informed by measures or models (or both), the calculation of exposure follows the same principles. The simplest calculations relate to situations in which direct exposures occur. For example, consider the case of a substance directly added to food (and approved by the U.S. Food and Drug Administration (FDA) for such addition). Suppose the chemical is of well-established identity and is approved for use in nonalcoholic beverages at a concentration of 10 milligrams of additive for each liter of beverage (10 mg/L).⁵⁶ To understand the amount (weight) of the additive ingested each day, it is necessary to know how much of the beverage people consume each day. Data are available for relevant exposure factors (e.g., rates of food consumption in the general population). Typically, those data reflect average consumption rates and also rates at the high end of consumption.

To make sure that the additive is safe for use, the FDA seeks to ensure the absence of risk for individuals who may consume at the high end, perhaps at the 95th percentile of consumption rates.⁵⁷ Assume that surveys of intake levels for the beverage in our example reveal that the 95th percentile intake is 1.2 L per day for adults. The weight of additive ingested by individuals at the 95th percentile of beverage consumption rate is thus obtained as follows:

$$10 \text{ mg/L} \times 1.2 \text{ L/day} = 12 \text{ mg/day}$$

For a number of reasons, toxicologists often express exposure and dose as weight of chemical per unit of body weight. For adults having a body weight (bw) of, on average, 70 kilograms (kg), the dose of additive is therefore:

$$12 \text{ mg/day} \div 70 \text{ kg bw} = 0.17 \text{ mg/kg bw per day}^{58}$$

Chemical exposure resulting from ingestion of other products containing specified amounts of chemicals are calculated in much the same way. It generally would be assumed that the duration of exposure for a substance added to a food or beverage would be continuous and would cover a large fraction of a lifetime, while for other products, particularly pharmaceuticals, exposure durations will vary widely. It will be useful, before proceeding further, to illustrate calculations for exposures occurring by the inhalation and dermal routes.⁵⁹

56. See *infra* Appendix A for a discussion of units used in exposure science.

57. Vasilios H. Frankos & Joseph V. Rodricks, *Food Additives and Nutrition Supplements*, in Regul. Toxicology 133 (Shayne C. Gad ed., 2d ed. 2001).

58. To gain approval for such an additive, FDA would require that no toxic effects are observable in long-term animal studies at doses of at least 17 mg/kg bw per day (100 times the high-end human intake).

59. See, e.g., *Henricksen v. ConocoPhillips Co.*, 605 F. Supp. 2d 1142, 1164 (E.D. Wash. 2009) (benzene exposure on skin and by inhalation); *Bland v. Verizon Wireless (VAW) L.L.C.*, No. 3:06CV00008-CFB, 2007 WL 5681791, at *9 (S.D. Iowa 2007), *aff'd*, 538 F.3d 893 (8th Cir.

Consider a hypothetical workplace setting in which a solvent is present in the air. Measurement by an industrial hygienist reveals its presence at a weight of 2 mg in each cubic meter (m^3) of air. Data on breathing rates reveal that a typical worker breathes in 10 m^3 of air each 8-hour workday.⁶⁰ Thus, the worker exposure will be:

$$\begin{aligned} 2 \text{ mg/m}^3 \times 10 \text{ m}^3/\text{day} &= 20 \text{ mg/day} \\ 20 \text{ mg/day} \div 70 \text{ kg} &= 0.29 \text{ mg/kg bw per day} \end{aligned}$$

As noted earlier, it is likely that only a fraction of this dose will reach and pass through the lungs and enter the bloodstream. As also noted earlier, if the chemical is a fiber or other particle, its dynamics in the respiratory tract will be different than that of a vapor, with a portion of the inhaled dose entering the GI tract.

In contrast to ingestion and inhalation exposure, dermal exposure often is expressed as the weight of chemical per some unit of skin surface area (e.g., per m^2 of skin). The body surface area of an average (70 kg, ~154 lb) adult is 1.8 m^2 . Thus, consider a body lotion containing a chemical of interest. If the lotion is applied over the entire body, then it is necessary to know the total amount of lotion applied and then the total amount of chemical present in that amount of lotion. That last amount will then be divided by 1.8 to yield the dermal exposure in units of milligrams per square meter. If the chemical causes toxicity directly to the skin, that toxicity dose information also will be expressed in milligrams per square meter. Then risk is evaluated by examining the quantitative relationship between the toxic dose (milligrams per square meter) and the (presumably much lower) human dose expressed in the same units. If the chemical can penetrate the skin and produce toxicity within the body, then a dose determination must include an examination of the amount absorbed into the human body.

One final matter concerning exposure estimation, and subsequently dose estimation, concerns the importance of body size and composition, in particular that of infants and growing children. In matters such as food and water intake, and breathing rates, small children are known to take in these media at higher rates per unit of their body weight than do adults.⁶¹ Thus, when a small child is exposed to a food contaminant, that child will often experience a greater relative exposure to the contaminant than will an adult consuming food with the same

2008) (inhalation exposure to Freon in “canned air” sprayed into water bottle). For a discussion of the importance of assessment of dose as a measure of exposure, see David L. Eaton et al., “Fundamental Principles of Toxicology,” in *Reference Guide on Toxicology*, in this manual.

60. The 24-hour inhalation rate outside the workplace setting is ca. 20 m^3 . The lack of direct proportion to time reflects the fact that breathing rates increase under exertion.

61. See, e.g., Northwest Coalition for Alternatives to Pesticides (NCAP) v. E.P.A., 544 F.3d 1043 (9th Cir. 2008) (dispute over how much lower allowable pesticide levels should be to account for children’s greater susceptibility).

level of contaminant. Children also tend to ingest greater amounts of nonfood items, such as soils and dusts, than do adults. In some cases, nursing mothers excrete chemicals in their breastmilk, which forms a unique source of exposure for nursing infants. The exposure scientist generally conducts separate assessments for children—these assessments take into account the possibility of periods of increased exposure during the developmental period.⁶²

Integrated Exposure Assessment

In many cases, the issue of exposure (and subsequent dose) concerns one chemical in one product and only one route of exposure. But numerous variations on this basic scenario are possible: aggregate exposure involving one chemical in several products or environmental media (e.g., lead exposure from lead-based paint, drinking water in contact with leaded pipes, proximity to airports in which leaded aviation gas is used); cumulative exposures involving either many chemicals in one product or environmental medium (e.g., nitrates and arsenic in drinking water); or many chemicals in many environmental media (e.g., exposure to metals from drinking water, air, consumer products, foods). Even though some exposure situations can be complex and involve multiple chemicals through both direct and indirect pathways, the exposure assessment methods and principles described here can be applied. Exposures occurring by different routes can be added together, or they can be reported separately. The decisions on the final exposure or dose estimates and their form of presentation can be made only after discussions with the users of that information—typically the toxicologists and epidemiologists involved in the risk assessment.⁶³ The exposure or dose metrics emerging from the exposure assessment need to match the exposure or dose metrics that are used to describe toxicity risks.

Further, as discussed in the earlier section on exposure assessment methods, it may be useful to consider high-end or even bounding exposures, not only for exposure to chemicals through foods and consumer products but also in environmental settings. This is because, though a worst case may occur (or even be observed) in a given population, it is usually a very unlikely set of circumstances, and such a worst-case estimate will be somewhat higher than what occurs in a specific population. Therefore, if the highest possible exposure is evaluated and

62. For some substances, susceptibility to toxicity is also enhanced during the same periods.

63. See, e.g., *Am. Farm Bureau Fed'n v. EPA*, 559 F.3d 512 (D.C. Cir. 2009) (challenging EPA's risk assessment for fine particulate matter); *Miami-Dade Cnty. v. U.S. EPA*, 529 F.3d 1049 (11th Cir. 2008) (assessment of risk of wastewater disposal methods to drinking water); *Kennecott Greens Creek Min. Co. v. Mine Safety & Health Admin.*, 476 F.3d 946 (D.C. Cir. 2007) (risk assessment of diesel particulate matter to miners); *Rowe v. E.I. DuPont de Nemours & Co.*, No. CIV. 06-1810 (RMB), 2008 WL 5412912, at *12 (D.N.J. 2008) (risk assessment for proposed class).

found to be not of concern, the more plausible lower exposures will also not be of concern. The EPA's *Exposure Factors Handbook* is one authoritative source of recommended values for general exposure factors needed for estimation of exposure distributions, including such high-end and bounding estimates.⁶⁴

Reviewing the relevant recommended values for direct drinking water ingestion from community sources, a 95th percentile value for drinking water ingestion is approximately 3 L per day across consumers of all ages, with the highest 95th percentile intake of approximately 3.4 L per day for adults aged 21 to 30. Thus, for example, it is possible to assert with relatively high confidence that almost no one in the general population consumes more than 3.5 L of water a day and that almost everyone consumes less, though care should be taken to ensure the appropriate exposure factors are used for the population of interest (e.g., athletes or manual laborers may consume even more water). If an exposure or dose calculation assumes a general population water consumption rate of 3.5 L per day, then the risk estimated for that dose is almost certainly an upper limit on the population risk, and regulatory actions based on that risk will almost certainly be highly protective for the general population. For regulatory and public health decision making, such a precautionary approach has a great deal of precedent, although care must be taken to ensure adherence to scientific data and principles.⁶⁵

This approach becomes problematic, however, if applied to assessments of exposures that may have been incurred in the past by individuals claiming to have been harmed. In such cases, an approach based on attempts to accurately describe the individual's exposure would be necessary. Whatever the case, the exposure scientist must be careful to ensure an accurate description of the exposure concentration (and resulting dose) so that the users of the information can understand whether they have been provided with high-end or bounding estimates, or central tendency estimates (e.g., mean, median) that may describe more typical exposure for a population.

64. U.S. Env't Prot. Agency, *Exposure Factors Handbook* (2011), <https://perma.cc/D8AR-5FT5>. Note: The EPA has developed a companion software tool, ExpoFIRST, that utilizes data from the *Exposure Factors Handbook* in development of user-defined exposure scenarios for a given assessment. ExpoFIRST can then be used to calculate deterministic exposure estimates as point estimates for various receptor populations and life stages. This tool is accessible via the EPA Expo-Box (see <https://perma.cc/T6FB-PS3V>).

65. Nat'l Rsch. Council, *Evolution and Use of Risk Assessment in the Environmental Protection Agency: Current Practice and Future Prospects*, in *Science and Decisions: Advancing Risk Assessment* 26 (2009), <https://doi.org/10.17226/12209>. Those who must comply with regulations that were developed based on a high degree of caution often protest that more accurate assessments should be used as their basis. For several reasons, truly accurate prediction of risk is difficult to achieve (see David L. Eaton et al., *Reference Guide on Toxicology*, in this manual), while predicting an upper bound on the risk is not. At the same time, unless carefully done and described, upper-bound estimates may be so remote from reality that decisions based on them should be avoided.

Exposure Assessment of Biologic and Physical Stressors

In addition to chemical stressors, humans are exposed to a wide range of non-chemical stressors, including biologic stressors (e.g., bacteria, viruses) and physical stressors (e.g., radiation, heat, noise). Much like chemical stressors, these exposures may arise from typical activities, such as consumption of food, or from specific incidents, such as an industrial accident or a natural disaster. Exposure assessment considerations specific to biological and physical stressors are not enumerated here. For many nonchemical stressors, the general conceptual approach, including calculations, to exposure assessment is comparable to those outlined for chemical stressors in the earlier sections, “Exposure Assessment Considerations for Chemical Stressors” and “Quantification of Exposure to Chemical Stressors.” For example, much like a chemical stressor, exposure assessment for radiation can involve various measurements, including the amount of radioactivity, ambient radiation levels in environmental media such as water, soil, or air, and an internal or absorbed dose (energy deposited per unit mass) that a person has received from a radioactive source. However, it is important to note that there can be substantial differences in the type and scope of information and data required, as well as in the exposure measurements and models used to characterize exposure and inform risk assessment for certain nonchemical stressors.

There are considerable differences even in the approach to description of radiation, with four different but interrelated types of units for measuring radioactivity, exposure, absorbed (internal) dose, and effective dose (also referred to as dose equivalent). Typically, the amount of radioactivity refers to the amount of ionizing radiation released by a material, whether it emits alpha particles, beta particles, gamma rays, x-rays, or neutrons. The quantity of radioactive material is expressed in terms of its radioactivity, which represents how many atoms in the material decay in a given time period, with units of measure most commonly reported in becquerels (Bq, international unit, equivalent to one radioactive decay per second) or Curie (Ci, U.S. unit, approximate number of radioactive decays in one gram of radium per second). Such radioactivity can be measured by a variety of detectors, including the commonly used Geiger counter. For measurement of ambient radiation in the environment, other instrumentation, such as pressurized ionization chambers, are best suited, and levels are reported in units such as roentgen per hour (R/h) or coulomb per kilogram (C/kg).

In contrast, an absorbed radiation dose reflects the amount of energy that a radioactive source deposits in an organism through which the radiation passes. Absorbed radiation can be measured using additional specialized instruments, including alarming dosimeters that are typically used to monitor exposure rates and accumulated dose in real time. The conventional unit for absorbed radiation dose is now the international unit Gray (Gy), though the older term rad

(for radiation absorbed dose) may still be used (one Gy is equivalent to 100 rad).⁶⁶ Lastly, the dose equivalent, or effective dose, of radiation is a term that addresses an individual's biological risk given the type of radiation exposure by adjusting the absorbed dose by radiation type and relative organ sensitivity. The conventional unit for dose equivalent is now the sievert (Sv), though the roentgen equivalent man (rem) may still be used in some cases. The dose equivalent is commonly used to set protective levels for groups of people. For example, the annual radiation dose limit for workers in the United States is 0.05 Sv or 5 rem.⁶⁷

Other physical stressors, such as noise and temperature, have their own terminology and approaches, as do the various types of pathogens. As such, appropriate stressor-specific guidance should be considered when evaluating such an assessment. A variety of guidance documents and tools have been developed to support measurement of specific biological and physical stressors, with various federal agencies and nongovernmental organizations having also developed specific guidance for risk assessment of such stressors, particularly for radiation and microbial exposures. For example, to support the assessment of radiation, the EPA and the Oak Ridge National Laboratory (ORNL) have developed a comprehensive software system specifically for the calculation of tissue dose and subsequent health risk from radionuclides in environmental media. Interpretation of these model results requires specialized knowledge of exposure assessment and the integration period of radiological decay. Health physicists, for example, are individuals who have received such specialized training in nuclear physics, radiation biology, radiation detection, radiation chemistry, and other related sciences. Microbial risk assessment has similar specificity, with the U.S. Department of Agriculture/Food Safety and Inspection Service (USDA/FSIS) and EPA jointly developing a guideline for microbial risk assessment with an emphasis on pathogenic organisms in food and water.⁶⁸ Accordingly, exposure assessment for a nonchemical stressor should be conducted by an expert sufficiently familiar with the stressor and appropriate means of exposure and risk assessment.⁶⁹

Mass. 2000), *aff'd*, 256 F.3d 36 (1st Cir. 2001) (The most authoritative risk assessment of one water treatment option was attributed to a scientist with expertise in assessment of microbial risks of drinking water; the court discounted the testimony of another scientist who testified only in general terms about water filtration as the court found him to have "no expertise in water quality issues. He has testified 'maybe a hundred times as a plaintiff's expert in asbestosis cases.'").

How Exposure Science Informs Evaluation of Disease Causation in Individuals

In the evaluation of disease causation for an individual, exposure science is applied to characterize the individual's contact with a stressor, either qualitatively⁷⁰ or quantitatively. The resulting exposure assessment is then linked to evidence of disease causation (e.g., a causal link established using epidemiological and toxicological investigations,⁷¹ but also possibly an association between exposure and outcome identified by the same means). Note that an individual is generally not faced with the burden of demonstrating causality with absolute proof; rather, the legal standard is typically expressed as a need to show that causality is demonstrable by a preponderance of the evidence (e.g., more likely true than not true that the harm observed was caused by the exposure).⁷² Establishing general causality, and providing an expert opinion as to whether it is reasonable to conclude that the exposure caused harm to an individual, is the domain of epidemiology, toxicology, and/or medicine.⁷³ Exposure experts are needed to assess the exposures incurred by an individual and to evaluate the quality and validity of such assessments, while appropriate causation experts are called upon to offer testimony on whether those exposures are of a magnitude sufficient to cause the claimed harm.

70. As discussed in the section titled “Quantification of Exposure to Chemical Stressors” above, causation may sometimes be established even if quantification of the exposure is not possible. See, e.g., cases cited *supra* note 55 (*Bell, Lightfoot, Westberry, & Best*); *Allen v. Martin Surfacing*, 263 F.R.D. 47 (D. Mass. 2009).

71. See Steve C. Gold et al., *Reference Guide on Epidemiology*, and David L. Eaton et al., *Reference Guide on Toxicology*, in this manual, for discussions on epidemiological and toxicological approaches to disease causation, respectively. Regulations and public health actions are usually driven by findings of excessive risk of harm (although sometimes evidence of actual harm).

72. Did the plaintiff incur exposures to the suspect chemical of sufficient magnitude and duration to make it more likely true than not that the chemical, and not some other factor, was the cause of the plaintiff's medical condition? See, e.g., *Barrett v. Rhodia, Inc.*, 606 F.3d 975, 984 (8th Cir. 2010) (No appellant expert was qualified to present evidence that Barrett was exposed to toxic levels of hydrogen sulfide gas as opposed to another harmful exposure; the defense presented such an alternative cause supported by expert testimony. Court noted that “[e]xpert testimony ‘based on possibility or speculation is insufficient [to establish causation]; it must be stated as being at least ‘probable,’ in other words, more likely than not.’ *Fackler v. Genetzky*, 263 Neb. 68, 638 N.W.2d 521, 527–28 (2002).”).

73. Note that a statistical association between exposure and disease does not prove causation, so plausible alternative hypotheses must be eliminated by careful statistical adjustment and/or consideration of all relevant scientific knowledge. Epidemiologic studies can show an association after such adjustment. Such studies, reasonably free of bias and further confounding, provide evidence for but not definitive proof of causation; causal associations can be further strengthened by mechanistic knowledge about how particular agents might produce adverse health effects.

Exposures of concern for individual disease causation can be highly variable in scope, including hazards present in a workplace, contamination of environmental media in a particular location (e.g., release of toxic air contaminants from a facility), and even use of a given product or products. In many cases, exposure to the same stressor may occur simultaneously through multiple media (e.g., air, food, water). This complicates both exposure assessment itself and attribution of exposure to a specific source, which is often relevant. In any such instance, however, assessment of exposure can involve either exposure measurements or modeling (see sections titled “Exposure Assessment Considerations for Chemical Stressors” and “Exposure Assessment of Biologic and Physical Stressors” above). Unless a personal monitoring study has been conducted, at least some modeling is expected regardless of what measured data may be available. Evidence presented should, at minimum, include exposure and dose estimates, and should identify and quantify important source(s) and significant pathway(s) and route(s) of exposure from the source to the individual. As an individual’s exposure is expected to vary over time, often on several different time scales and usually depending on the individual’s pattern of activities and locations, these variables must be described in some level of detail and incorporated into an exposure assessment, in addition to information about the concentration of the exposure in relevant media. This is of critical importance as it is generally expected that there is some degree of association between the intensity and temporal characteristic of the exposure and the biology of the disease; this information can therefore provide information to mitigate a source or end exposure to an individual at risk.

There are two general scenarios in which an individual’s exposure must be characterized. In the first, exposure to a stressor is currently occurring or anticipated to occur. This is typically more straightforward than in the second scenario, most common in toxic tort claims, in which an individual claims to have been harmed by prior exposure to a stressor, often by alleging that some existing medical condition has been caused by exposure, or exposures, occurring in the past. In both scenarios, exposure assessments are used to ascertain whether an individual would be exposed to a stressor, and to what extent.

Assessment of past exposures is especially difficult when considering diseases with very long latency periods.⁷⁴ By the time disease occurs, documentary proof of exposure and magnitude may have disappeared; however, courts regularly deal with evidence reconstructing the past, and assessment of exposure is another

74. In certain tort and insurance litigation, diseases with a long latency period, especially those attributable to continuous or repeated exposure to a substance, may be referred to as “long-tail harm.” See, e.g., *Danaher Corp. v. Travelers Indem. Co.*, 414 F. Supp. 3d 436 (S.D.N.Y. 2019) (resolution of disputes concerning insurance coverage for asbestos- and silica-related claims against a former subsidiary).

application of this common practice.⁷⁵ Depending on the stressor, there may be measurable evidence of past exposure at the time of assessment, such as bio-monitoring data (more likely for a persistent chemical⁷⁶ than for a short-lived chemical). However, such a scenario typically requires reconstruction of exposure, an undertaking that also requires appropriate consideration of factors that may have influenced the disease process, or both the exposure and disease process.⁷⁷ Although there may in some cases be historical measured data available, such as monitoring data in a relevant environmental medium or location (e.g., historic levels of water or air contaminants in a community, which are available for relatively few stressors, mostly chemical or biological), reconstructions of exposure are typically heavily reliant on modeling. Reconstruction of occupational exposures has been a relatively successful pursuit, because often historical industrial hygiene data are available involving the measurement of workplace air levels of chemicals. If it is possible, through the examination of employment records, to understand an individual's job history, it may be possible to ascertain that individual's exposure history and develop a retrospective exposure assessment.⁷⁸ Guidelines for such retrospective occupational exposure

75. Courts have accepted indirect evidence of exposure. For example, differential diagnosis may support an expert's opinion that the exposure caused the harm. *Best v. Lowe's Home Ctrs., Inc.*, 563 F.3d 171 (6th Cir. 2009). On occasion, qualitative evidence of exposure is admitted as evidence that the magnitude was great enough to cause harm. *See, e.g., Westberry v. Gislaved Gummi AB*, 178 F.3d 257 (4th Cir. 1999) (no quantitative measurement required where evidence showed plaintiff was covered in talc and left footprints); *Allen v. Martin Surfacing*, 263 F.R.D. 47 (D. Mass. 2009) (accounts of symptoms at the time of exposure formed the basis for expert's opinion that exposure was high enough to cause harm). And courts have accepted the government's reconstruction of exposure to radiation. *Hayward v. U.S. Dep't of Labor*, 536 F.3d 376 (5th Cir. 2008); *Hannis v. Shinseki*, No. 09-0593, 2009 WL 3157546 (Vet. App. 2009) (no direct measure of veteran's exposure to radiation was possible but VA's dose estimate was not clearly erroneous).

76. *See, e.g., Benoit v. Saint-Gobain Performance Plastics Corp.*, 959 F.3d 491, 501 (2d Cir. 2020) (plaintiffs must show that they have a "physical manifestation of or clinically demonstrable presence of" PFOA in their blood); *Sullivan et al. v. Saint-Gobain Performance Plastics Corp.*, 226 F. Supp. 3d 288 (D. Vt. 2016) (requires plaintiffs to show that their blood accumulation levels differ from those in the general population and link blood levels with increased risk of disease and appropriate monitoring).

77. Confounding factors must be carefully addressed. *See, e.g., Allgood v. Gen. Motors Corp.*, No. 102CV1077DFHTAB, 2006 WL 2669337, at *11 (S.D. Ind. 2006) (selection bias rendered expert testimony inadmissible); *Am. Farm Bureau Fed'n v. E.P.A.*, 559 F.3d 512 (2009) (in setting particulate matter standards addressing visibility, the data relied on should avoid the confounding effects of humidity); *Avila v. Willits Env't Remediation Tr.*, No. C 99-3941 SI, 2009 WL 1813125 (N.D. Cal. 2009) (failure to rule out confounding factors of other sources of exposure or other causes of disease rendered expert's opinion inadmissible); *Adams v. Cooper Indus., Inc.*, No. CIVA 03-476 JBC, 2007 WL 2219212 (E.D. Ky. 2007) (differential diagnosis includes ruling out confounding causes of plaintiffs' disease).

78. *See, e.g., T.W. Armstrong, Exposure Reconstruction, in Mathematical Models for Estimating Occupational Exposures to Chemicals* (Charles B. Keil et al. eds., 2d ed. 2009); Francesca Borghi et al., *Retrospective Exposure Assessment Methods Used in Occupational Human Health Risk Assessment*:

assessments have been published by various agencies, as well as nongovernmental organizations such as the American Industrial Hygiene Association.⁷⁹

A retrospective exposure assessment outside of occupational settings is typically more difficult because there are usually many changes over time—for example, changes in technologies of the pollution sources, and also changes in people’s behavior and location over time.

How Exposure Science Informs Evaluation of Risk in Populations

Exposure assessment is one of the core components of regulatory quantitative risk assessment; the quality of exposure information and the exposure assessment itself are critical to the quality and utility of risk assessment. Risk assessments are typically directed at an existing exposure situation, such as the risks incurred by populations residing in the vicinity of a manufacturing or hazardous waste facility, or at the exposure situation expected if certain regulatory actions are taken. In considering exposures in a population, as opposed to an individual, it is critical to recognize that for any one exposure scenario there is inherently a range of exposures to a given stressor that are experienced by the individuals who compose the population. For example, assuming a toxicant is released from a manufacturing facility into the air in a community, some individuals may have a high degree of contact for an extended period (e.g., factory workers exposed to a substance on the job) while other individuals may have a lower degree of contact for a shorter period (e.g., individuals using a recreational site downwind of the facility). These exposures will be a function not only of the substance’s concentration in the air at the respective points of contact, but also of the characteristics of the individual or population (e.g., inhalation rate is variable across life stage and differs substantially with various activities).

To be useful for population risk assessment, an exposure assessment needs to be capable of identifying and quantifying the exposure of the populations that are most highly exposed and the populations that are most vulnerable. The assessment should include all relevant exposure pathways and allow the pathways to be identified and defined individually (for example, to allow for quantification of exposure from water or from food, as well as total exposure). Exposure assessment also needs to consider background exposures to other stressors that could influence exposure or risk within a population.

A Systematic Review, 17 Int’l J. Env’t Rsch. & Pub. Health 6190 (2020), <https://doi.org/10.3390/ijerph17176190>.

79. Am. Indus. Hygiene Ass’n, Guideline on Occupational Exposure Reconstruction (Susan Marie Viet et al. eds., 2008).

The assessment must also consider inherent uncertainty in the process to determine the level of confidence in the overall risk assessment. Note that in some cases, exposure science can also inform risk to a population in a given scenario through comparison of estimated or measured concentrations of stressors in environmental media (e.g., air, water) to established reference values or standards delineating a level at which no harm is anticipated from exposure. The most common such values are regulatory tolerances for pesticide residues in food, maximum contaminant levels (MCLs) for drinking water contaminants, National Ambient Air Quality Standards (NAAQS), and, for workplace exposure, permissible exposure limits (PELs) or threshold limit values (TLVs).⁸⁰ Such comparisons are intended to determine whether products and environmental media contain substances at concentrations that meet existing regulatory requirements.

Evaluating the Scientific Quality of an Exposure Assessment

Though there is no standard set of criteria for evaluating the quality of an exposure assessment across all possible stressors, some concepts are universally relevant. Regardless of the stressor, all exposure assessments must reflect at least the two principal dimensions of exposure: its magnitude (often reported as concentration, amount, or intensity) and time. Temporal considerations include duration as well as pattern or frequency (e.g., continuous or intermittent exposure), and any relevant windows of susceptibility. Exposure scientists may offer expert testimony regarding exposures to stressors incurred by individuals or populations. In some cases, expert testimony will include description and quantification of concentrations in environmental media or a description and quantification of body burden, while in others, testimony may rely entirely on models rather than measurements of any kind. In each case, such assessments typically include a description of how and when exposures did or could occur, the identities of the chemicals involved, the routes of exposure, the magnitudes of exposure incurred, and the durations of exposure. These may be qualitative, quantitative, or semiquantitative in nature; an

80. PELs are official standards promulgated by the Occupational Safety and Health Administration. TLVs are guidance values offered by an organization called the American Conference of Governmental Industrial Hygienists. See, e.g., *In re Howard*, 570 F.3d 752, 754 (6th Cir. 2009) (challenging PELs for coal mine dust); *Jowers v. BOC Grp., Inc.*, 608 F. Supp. 2d 724, 735–36 (S.D. Miss. 2009) (PELs and TLVs for welders' manganese fume exposure); *Int'l Brominated Solvents Ass'n v. Am. Conf. of Governmental Indus. Hygienists, Inc.*, 625 F. Supp. 2d 1310 (M.D. Ga. 2008) (challenging TLVs for several chemicals); *Miami-Dade Cnty. v. U.S. E.P.A.*, 529 F.3d 1049 (11th Cir. 2008) (MCLs for public drinking water).

exposure assessment does not have to be quantitative to be of use,⁸¹ but typically an estimation of at least semiquantitative⁸² magnitude and duration of incurred exposure is necessary to evaluate plausibility of a causation claim.⁸³

For the purposes of this reference guide, it is assumed that questions regarding disease risk and causation are beyond the bounds of exposure science and are instead within the domains of other sciences, such as epidemiology and toxicology.⁸⁴ However, if the exposure scientist is also an epidemiologist or toxicologist,⁸⁵ or has a relevant medical background, he or she may offer additional testimony on the health risks associated with those exposures or even regarding the question of whether such exposures may have caused disease. Below is a set of questions that exposure scientists should be able to answer, with appropriate documentation and scientific reasoning, to support any given exposure assessment.

- Is the purpose of the assessment clear? Is the exposed individual or population specified?
- Has the source(s) of exposure been identified?
- When did the exposure occur: Past? Present? Future? If exposure is occurring now, will it continue to occur? Under what conditions is future exposure anticipated?
- What is known or assumed about the nature and extent of media contact by members of the exposed population? How has this been ascertained?
- What is the assumed frequency and duration of exposure, and what is the basis for these assumptions?

81. As discussed in the section titled “Quantification of Exposure to Chemical Stressors” above, causation may sometimes be established even if quantification of the exposure is not possible. See cases cited *supra* note 55; *Allen v. Martin Surfacing*, 263 F.R.D. 47 (D. Mass. 2009) (accounts of symptoms at the time of exposure formed the basis for expert’s opinion that exposure was high enough to cause harm).

82. See, e.g., *Rhyne v. United States Steel Corp.*, 474 F. Supp. 3d 733, 761 (W.D.N.C. 2020) (Expert exposure assessment found to be based on sufficient data and to be the product of a reliable methodology, even though estimates are not based on exact data on how often the plaintiff used the product in question at home. The court notes that “[t]o require expert testimony to be based on exact information as to how frequently plaintiff used a product fifty years ago, as Savogran suggests, would effectively prohibit a plaintiff from ever recovering in a latent disease case.”).

83. See Steve C. Gold et al., *Reference Guide on Epidemiology*, in this manual; see also section titled “How Exposure Science Informs Evaluation of Risk in Population” above.

84. See Steve C. Gold et al., *Reference Guide on Epidemiology*, and David L. Eaton et al., *Reference Guide on Toxicology*, in this manual, for discussions on epidemiological and toxicological approaches to disease causation, respectively.

85. See “Qualifications of Exposure Scientists or Other Exposure Assessors” below, which deals with the question of the qualifications of exposure scientists. In many cases, the work of exposure experts is turned over to health experts to incorporate into their evaluation of risk and disease causation. In some cases, usually the less complex ones, exposure assessments may be undertaken by the health experts.

- What are the pathways from the source to the exposed individuals or population(s)? How has it been established that those pathways exist? (Past? Present? Future?)
- What is the concentration of the chemical in the media with which the exposed individual or population comes into contact? (Past? Present? Future?) What is the basis for this concentration: Direct measurement? Indirect estimation? Exposure reconstruction?
- If the concentration is based on direct measurement, what procedures were followed in obtaining that measurement? Was sampling of environmental media sufficient to ensure that it was representative? If not, why is representativeness not important? If a biomarker was measured, how does it relate to the original exposure—is this the stressor itself or a metabolite? Were validated analytical methods used by an accredited laboratory? If not, how can one ensure that the analytical results are reliable?
- If models were used, what is their reliability? (See “Exposure Assessment of Biologic and Physical Stressors.”) What is the variability over time in concentrations in the media of concern? How has the variability been determined? Has the model been validated? Has the selected model output been compared to those from other similar models, and are they similar (e.g., estimates in the same direction)?
 - Models developed by or accepted by authoritative bodies (e.g., the EPA⁸⁶) are generally considered reliable, at least for the intended applications. Other models should be more carefully evaluated to determine validity and applicability.
- What exposure, over what period of time, by which routes, has been incurred? What calculations support this determination?
- What is the variability among members of the population in their exposure to the chemical of concern? How is this known?
- What is the likely error in the exposure estimates?
- What uncertainties are associated with the exposure/duration findings? Is it a “most likely” estimate, or is it an upper limit? To what fraction of the population is the upper limit likely to apply?
- What has been omitted from the exposure assessment, and why?

These questions are perhaps the minimum that an expert should be able to address when offering testimony. An expert should be able to support such answers with documentation.

86. Such exposure models are enumerated in EPA’s ExpoBox. U.S. Env’t Prot. Agency, EPA ExpoBox (A Toolbox for Exposure Assessors), <https://perma.cc/T6FB-PS3V>.

Qualifications of Exposure Scientists or Other Exposure Assessors

As discussed generally by Liesa L. Richter and Daniel J. Capra in their reference guide in this manual, *The Admissibility of Expert Testimony*,⁸⁷ the court is expected to perform a gatekeeping function with regard to proposed experts involved in the evaluation of exposure-related information and assessment of exposure experts for a given case.

A determination of whether or not a proposed exposure expert is qualified is complicated by the fact that exposure science is a heterogeneous field with various subspecialties (e.g., biomonitoring, environmental monitoring, modeling, remote sensing, use of sensors/dosimeters) as well as specialized applications, such as industrial hygiene/occupational exposures. No single academic degree, research specialty, or career path qualifies an individual as an expert in and of itself. Further complicating evaluation of expert qualifications, a given exposure assessment may involve collaborative efforts among members of various disciplines. However, there are a number of indicia of expertise that can be ascertained for an individual proffering an opinion on exposure, outlined as follows.

Does the Proposed Expert Have an Advanced Degree or Certification in Exposure Science, Industrial Hygiene, Environmental Health, or a Related Field?

Historically, exposure scientists and related experts have possessed a wide range of academic backgrounds, spanning industrial hygiene, environmental and analytical chemistry, chemical and environmental engineering, geology and hydrogeology, toxicology (toxicokinetic applications in particular), epidemiology, and even behavioral sciences (pertaining to those aspects of human behavior that affect exposures). Note that a single course in exposure assessment or risk assessment is unlikely to provide sufficient background for developing expertise in exposure science. An increasing number of schools offer either a graduate degree in the area of exposure science and/or exposure assessment or, more commonly, a concentration or emphasis in these areas within a broader degree program such as Environmental Health Sciences.⁸⁸ Such a focused graduate degree demonstrates

87. See Liesa L. Richter & Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual.

88. While some institutions have dedicated exposure science degree programs, such as the doctoral program in Human Exposure Assessment at Rutgers University, many leading U.S.

that the proposed expert has a substantial background in the basic issues and tenets of exposure science and exposure assessment. There are currently no certification programs available specifically for exposure scientists, although the Europe Regional Chapter of the International Society of Exposure Science (ISES Europe) has developed a program to begin certifying International Registered Exposure Scientists (IRES) by 2026. However, experts may hold other certifications, many as certified industrial hygienists.⁸⁹

Is the Proposed Expert Established Professionally in the Field?

The success of academic scientists in exposure science, as in other applied sciences, is usually ascertained using the following types of criteria: the quality and number of peer-reviewed publications, the ability to compete for research grants, service on scientific advisory panels and/or working groups, university appointments, and participation or service in professional organizations and societies. Publication of articles in relevant peer-reviewed journals or peer-reviewed technical reports or exposure assessments (as is often more common for governmental experts) generally is construed to indicate some degree of expertise in exposure science. The number of articles, their topics, and whether the individual is the principal or senior author are important factors in determining the expertise of such a scientist.⁹⁰ Selection for local, national, and international regulatory advisory panels or working groups (including those convened by the

institutions with environmental and public health programs now offer various degrees with a concentration or focused track in exposure science and/or exposure assessment, including Harvard University (Environmental Health Exposures/Exposure Assessment specialty), the Johns Hopkins University (Exposure Sciences and Environmental Epidemiology track), the University of Michigan (Exposure Science-Industrial Hygiene track), and the University of Washington (area of emphasis in Occupational Hygiene/Exposure Science).

89. See, e.g., *Allen v. Martin Surfacing*, 263 F.R.D. 47 (D. Mass. 2009) (industrial hygienist qualified to testify regarding concentration and duration of plaintiffs' decedent's exposure to toluene and other chemicals); *Buzzerd v. Flagship Carwash of Port St. Lucie, Inc.*, 669 F. Supp. 2d 514 (M.D. Pa. 2009) (industrial hygienist qualified to opine on carbon monoxide exposure, but his conclusions were not based on reliable methodology).

90. Examples of reputable, peer-reviewed journals that publish exposure-related research are the *Journal of Exposure Science & Environmental Epidemiology*; *American Journal of Industrial Medicine*; *Annals of Work Exposures and Health* (previously *Annals of Occupational Hygiene*); *Archives of Environmental & Occupational Health* (formerly the *Archives of Environmental Health*); *Atmospheric Environment*; *Biomarkers*; *Chemosphere*; *Environmental Health Perspectives*; *Environment International*; *Environmental Research*; *Environmental Science & Technology*; *Environmental Toxicology and Chemistry*; *Exposure and Health*; *Indoor Air*; *Integrated Environmental Assessment and Management*; *International Journal of Environmental Research and Public Health*; *International Journal of Hygiene and Environmental Health*; *Journal of Occupational and Environmental Hygiene*; *Journal of Toxicology and Environmental Health*; *Journal of*

EPA, FDA, National Academies, National Institutes of Health (NIH), and World Health Organization (WHO)) also typically implies recognition in the field. Similarly, exposure-focused research grants from government agencies (including the National Institute of Environmental Health Sciences, the National Institute of Occupational Safety and Health, and the EPA) and private foundations are highly competitive. Successful competition for funding may also be construed to indicate competence in this area. A university appointment in exposure science, industrial hygiene/occupational health, environmental health, risk assessment, or a related field signifies relevant expertise, particularly if the university has a graduate education program in that area and the expert provides formal instruction or mentoring of trainees and fellows.⁹¹ Participation in professional societies⁹² is common for advanced practitioners; not only do meetings and events allow for presentation of research and networking activities, but most societies give awards to notable professionals based on scientific contributions to the field.

Does the Proposed Expert Have Experience Relevant to the Topic or Method of Interest?

Given the heterogeneity of exposure science, a given expert's body of work and training should be carefully evaluated for relevance to the exposure-related issue(s) of interest in a given case. Exposure scientists are increasingly scrutinized not just for the scope of their expertise in general,⁹³ but for their scope of

Occupational and Environmental Medicine; Regulatory Toxicology and Pharmacology; Risk Analysis; Science of the Total Environment; Toxicology; Toxicology Letters; and Toxicological Sciences.

91. See, e.g., *Bearden v. Honeywell Int'l, Inc.*, No. 3:09-CV-1035, 2015 WL 7574344 (M.D. Tenn. Nov. 23, 2015).

92. Note that only one professional society, the International Society of Exposure Science, is dedicated to exposure science and/or exposure assessment. Such membership has been referenced in expert qualifications, see, e.g., *Bearden v. Honeywell Int'l*, *supra* note 91. However, other professional organizations and societies relevant to toxicology and risk assessment have established specialty groups or technical sections in exposure science or assessment, including the Society of Environmental Toxicology and Analytical Chemistry's Exposure Modeling Interest Group, the Society of Toxicology's Exposure Specialty Section, the Society of Risk Analysis' Exposure Assessment Specialty Group, and the American Industrial Hygiene Association's Exposure Assessment Strategies Committee. Of these, only the Society of Toxicology has qualifications-centered requirements for membership, based either on peer-reviewed publications or on the active practice of toxicology or a related discipline that informs toxicology.

93. See, e.g., *United States v. Burkich*, No. 1:19-CV-3510-MLB, 2022 WL 4236243, at *4 (N.D. Ga. Sept. 14, 2022) (exclusion of opinions offered in the area of patient care following exposure by an exposure expert without a background in healthcare based on determination that the expert is "seeking to testify outside the scope of [her] academic and professional specialty") (quoting *Moore v. Intuitive Surgical, Inc.*, 995 F.3d 839, 853 n.12 (11th Cir. 2021)).

expertise within the field itself⁹⁴ as the types of exposure data and exposure issues presented as evidence continue to evolve. For example, a scientist specializing in dispersion modeling of toxic air contaminants may not have sufficient expertise to address exposure and/or dose reconstruction from biomonitoring data. And while some healthcare professionals specializing in occupational and environmental health may have training in certain elements of exposure assessment (particularly those who work in the chemical, petrochemical, and pharmaceutical industries, in which the surveillance of workers exposed to chemicals is a major responsibility), these individuals⁹⁵ may not be sufficiently familiar with exposures outside of occupational settings or with certain aspects of data collection and analysis. While a review of a proposed expert's biosketch, curriculum vitae, and/or publication record should give some indication of areas of specialization, additional focused questions may be necessary.

94. See, e.g., *In re 3M Combat Arms Earplug Prods. Liab. Litig.*, No. 3:19MD2885, 2021 WL 948839 (N.D. Fla. Mar. 13, 2021) (expert's professional experience in the past decade was related to chemical and product exposure and risk assessment, rather than the exposure of interest, which was noise exposure); *Jones v. United States*, No. 2:16-cv-00435-JRS-DLP, 2019 WL 367622 (S.D. Ind. Jan. 30, 2019) (expert's training and professional experience, which were in laser and air particulates, were deemed not relevant to provide an opinion regarding the presence of *H. pylori* in water and the transmission of *H. pylori* through waterborne sources).

95. See David L. Eaton et al., *Reference Guide on Toxicology*, in this manual ("Most practicing physicians have little knowledge of environmental and occupational medicine.").

Appendix A: Units of Exposure and Dose

Choosing the proper units to express concentrations of chemicals in environmental media is crucial for precisely defining exposure. Chemical concentrations in environmental media usually are reported in one of two forms: as numeric ratios, such as parts per million or billion (ppm and ppb, respectively), or as unit weight of the chemical per weight or volume of environmental media, such as milligrams per kilogram (mg/kg) or milligrams per cubic meter (mg/m³). Although concentrations expressed as parts per million or parts per billion are easier for some people to conceptualize, their use assumes that media are always sampled at standard temperature and pressure (25°C and 760 torr, respectively). Consequently, scientists often prefer to express chemical concentrations as weight of chemical per unit weight or volume of media. This method also makes conversions to exposure and dose equivalents, usually expressed in terms of weight of chemical per unit body weight (mg/kg bw), more convenient. To permit the presentation of results without excessive zeroes before or after the decimal point, appropriate units are needed. The choice of units depends on both the medium in which the chemical is present and the amount of chemical measured. For example, if 50 nanograms of chemical were found in one liter of water, the appropriate units would be ng/L, rather than 0.00005 mg/L. If 50 grams were found instead, the appropriate units would be 50,000 mg/L, because milligrams are generally the largest units used to express the mass of a chemical in media (Table 1).

Table 1. Weight of Chemical Per Unit Weight of Medium

Preferred Unit	Alternative Unit
mg/kg	ppm (parts per million)
µg/kg	ppb (parts per billion)
ng/kg	ppt (parts per trillion)
pg/kg	ppq (parts per quadrillion)

In water or food, concentration expressed by the preferred unit equals concentration expressed by alternative unit; thus, 2 mg/kg = 2 ppm. One mg (10⁻³ g) per kg (10³ g) equals 1 part per million (10⁻³/10³ = 10⁻⁶). Similarly, 1 µg (10⁻⁶ g) per kilogram (10³ g) equals 1 part per billion (10⁻⁶/10³ = 10⁻⁹), and so on (Table 2).

Table 2. Weight of Chemical Per Unit Volume of Medium

Water	Air
mg/L = ppm	mg/m ³ ≠ ppm
μg/L = ppb	mg/m ³ ≠ ppb
ng/L = ppt	ng/m ³ ≠ ppt

Note that in air, parts per million and parts per billion have different meanings than they do in water or food; to avoid confusion, it is always preferable to express air concentrations in weight of chemical per unit volume (rather than weight) of air (usually cubic meters, m³).

Glossary of Terms

The following definitions are derived from a range of sources, including the ES21FWG Glossary released in June 2015,⁹⁶ the U.S. EPA *Exposure Factors Handbook*,⁹⁷ various National Academies reports,⁹⁸ and the official glossary adopted by the International Society of Exposure Science.⁹⁹

absorbed dose. The amount of a substance that actually enters the body following absorption.

absorption. The penetration of a substance through a barrier (e.g., the skin, the gut, or the lungs).

absorption barrier. Any exposure surface that may retard the rate of penetration of an agent into an organism. Examples of absorption barriers are the skin, respiratory tract lining, and gastrointestinal tract wall.

accuracy. The ability of a method to determine the “true” concentration of the environment sampled, or the theoretical maximum error of measurement.

activity pattern data. Information on human activities used in exposure assessments. These may include a description of the activity, frequency of activity, duration spent performing the activity, and the microenvironment in which the activity occurs.

acute exposure. A contact between a stressor and an individual occurring over a short time, generally less than a day. (Other terms, such as short-term exposure and single dose, are also used.)

agent. A chemical, biological, or physical stressor that contacts a receptor (individual or population).

aggregate exposure. The sum of an individual’s exposures to a single stressor from all sources, routes, and pathways over a period of time.

analyte. A specific chemical moiety being measured, which can be an intact drug, a biomolecule or its derivative, a metabolite, and/or a degradation product in a biologic matrix.

97. U.S. Env’t Prot. Agency, *Exposure Factors Handbook* (2011), <https://perma.cc/D8AR-5FT5>. Note: The EPA has developed a companion software tool, ExpoFIRST, that utilizes data from the handbook in development of user-defined exposure scenarios for a given assessment. ExpoFIRST can then be used to calculate deterministic exposure estimates as point estimates for various receptor populations and life stages. This tool is accessible via the EPA website. U.S. Env’t Prot. Agency, EPA ExpoBox (A Toolbox for Exposure Assessors), <https://perma.cc/T6FB-PS3V>.

98. See Nat’l Rsch. Council, *Human Biomonitoring for Environmental Chemicals* (2006), <https://doi.org/10.17226/11700>.

99. Valerie Zartarian, Tina Bahadori & Tom McKone, *Adoption of an official ISEA glossary*, 15 J. Exposure Analysis & Env’t Epidemiology 1 (2005), <https://doi.org/10.1038/sj.jea.7500411>.

average daily dose (ADD). The average dose received on any given day during a period of exposure, expressed in mg/kg body weight per day. Ordinarily used in assessing noncancer risks.

background level. The amount of an agent in a medium (e.g., water, soil) that is not attributed to the source(s) under investigation in an exposure assessment. Background level(s) can be naturally occurring or the result of human activities.

bias. In exposure measurements, the difference between the average measured mass or concentration and reference mass or concentration expressed as a fraction of reference mass or concentration. In epidemiology, this typically refers to any effect at any stage of investigation or inference tending to produce results that depart systematically from the true values.

bioavailability. The rate and extent to which a chemical (or chemical metabolite) enters the general circulation, thereby permitting access to the site of toxic action.

biological matrix. Discrete material of biological origin that can be sampled and processed in a reproducible manner. Examples are blood, serum, plasma, urine, feces, saliva, sputum, breast milk, semen, and various tissues.

biomarker of effect or biomarker of response. A measurable biochemical, physiologic, behavioral, or other alteration in an individual that, depending on the magnitude, can be recognized as associated with an established or possible health impairment or disease.

biomarker of exposure. A chemical, its metabolite, or the product of an interaction between a chemical and some target molecule or cell, that is measured in an individual.

biomarker of susceptibility. A measurable factor, such as genetic polymorphism, nutritional status, or age, that can result in certain individuals being more sensitive to a given exposure.

biomonitoring. A method used to assess human exposure to chemicals by measuring a chemical, its metabolite, or a reaction product in human tissues or specimens, such as blood and urine.

body burden. The total amount of a chemical present or stored in the body. In humans, body burden is an especially important measure of exposure to chemicals that tend to accumulate in fat cells. These chemicals include DDT, PCBs, and dioxins.

bounding estimate. An estimate of exposure, dose, or risk that is higher than that incurred by the person with the highest exposure, dose, or risk in the population being assessed. Bounding estimates are useful in developing statements that exposures, doses, or risks are “not greater than” the estimated value.

chronic exposure. A continuous, recurring, or intermittent long-term contact between a stressor and a receptor population. (Other terms, such as “long-term exposure,” are also used.)

cumulative exposure. The sum of an individual’s exposures to stressors that affect a single biological target over a period of time.

direct exposure. Exposure of a subject who comes into contact with a chemical via the medium in which it was initially released to the environment. Examples include exposures mediated by cosmetics, other consumer products, some food and beverage additives, medical devices, over-the-counter drugs, and single-medium environmental exposures.

dose. The amount of a substance entering a person, usually expressed for chemicals in the form of weight of the substance (generally in milligrams (mg) or micrograms (μg)) per unit of body weight (generally in kilograms (kg)). The time over which it is received must also be specified. The time of interest is typically one day. If the duration of exposure is specified, dose is actually a dose rate and is expressed as mg or $\mu\text{g/kg}$ per day. In human epidemiological studies or experimental animal models, dose typically indicates the amount of chemical or physical agent that is absorbed into the body, not just the amount or concentration to which a person or animal is externally exposed. Some toxicologists may also refer to the external exposure as an external dose.

dose–response assessment. In risk assessment, an analysis of the relationship between the dose administered to a group and the frequency or magnitude of the biological effect (response).

duration of exposure. Toxicologically, there are four general categories describing duration of exposure: acute (one time), subacute (repeated over a short period, generally less than two weeks), subchronic (repeated, generally up to 90 days), and chronic (repeated, for nearly a lifetime).

environmental media. Air, water, soils, and food; consumer products may also be considered media. Chemicals may be directly and intentionally introduced into certain media. Others may move from their sources through one or more media before they reach the media with which people have contact.

exposure. Contact made between a chemical, physical, or biological agent and the outer boundary of an organism. The opportunity to receive a dose through direct contact with a chemical or medium containing a chemical. See also direct exposure; indirect exposure.

exposure assessment. The process of describing, for a population at risk, the amounts of chemicals to which individuals are exposed, or the distribution of exposures within a population, or the average exposure over an entire population. Also a formal step in the risk assessment process.

exposure frequency. The number of times an exposure occurs in a given period; exposure may be continuous, discontinuous but regular (e.g., once daily), or intermittent (e.g., less than daily, with no standard quantitative definition).

exposure pathway. The connected media that transport a chemical from source to receptor populations.

exposure route. The way an agent enters the body after contact (e.g., by ingestion, inhalation, or dermal absorption).

indirect exposure. Often defined as an exposure involving multimedia transport of chemicals from source to exposed individual. Examples include exposures to chemicals deposited onto soils from the air, chemicals released into the ground water beneath a hazardous waste site, or consumption of fruits or vegetables with pesticide residues.

intake. The amount of contact between an organism and a medium containing a chemical; used for estimating the exposure received from a particular medium. In toxicology, this may also refer to the amount of contact between a biological surface with a medium containing a chemical; used for estimating the dose received from a particular medium.

levels. An alternative term for expressing chemical concentration in environmental media. Usually expressed as mass per unit volume or unit weight in the medium of interest.

lifetime average daily dose (LADD). Total dose received over a lifetime multiplied by the fraction of lifetime during which exposure occurs, expressed in mg/kg body weight per day. Ordinarily used for assessing cancer risk.

limit of detection (LOD). Typically, the smallest amount of analyte distinguishable from background, or the lowest concentration of an analyte that the bioanalytical procedure can reliably differentiate from background noise. See, for example, the FDA's Bioanalytical Method Validation Guidance for Industry (<https://www.fda.gov/regulatory-information/search-fda-guidance-documents/bioanalytical-method-validation-guidance-industry>). A common estimate for unbiased analyses, with media blanks not distinguishable from background, is three times the standard error of the calibration graph for low concentrations, divided by the slope (instrument reading per unit mass or per unit concentration of analyte).

limit of quantification (LOQ) or limit of quantitation (LLOQ). Typically refers to the smallest amount of analyte that can be quantitatively determined with acceptable precision and accuracy from background. See, for example, the FDA's Bioanalytical Method Validation Guidance for Industry (<https://www.fda.gov/regulatory-information/search-fda-guidance-documents/bioanalytical-method-validation-guidance-industry>) and the

CDC's NIOSH Manual of Analytical Methods (NMAM), 5th Edition (<https://perma.cc/FU2Q-LNXV>).

metabolite. Chemical compound that results from biotransformation (i.e., metabolism) of a chemical (e.g., phenol in urine is a metabolite of benzene and is representative of benzene absorption in an exposed worker). Note that often a chemical that enters the body is rapidly metabolized or otherwise difficult to measure or distinguish from external contamination. A metabolite may be more stable and also may be eliminated in urine, making it more accessible and easier to measure.

model. Idealized mathematical expression of the relationship between two or more factors (variables). In toxicology, may also describe the use of animals as a substitute for humans in an experimental system to ascertain an outcome of interest.

particulate matter. General term for complex mixtures of solids and aerosols composed of small droplets of liquid, dry solid fragments, and solid cores with liquid coatings that are suspended in the air. These particles vary widely in size, shape, and chemical composition and are typically defined by their diameter for air quality regulatory purposes and human health risk assessment (e.g., PM 10 for particles with a diameter of 10 microns or less and PM 2.5 for particles with a diameter of 2.5 microns or less).

point-of-contact exposure. Exposure expressed as the product of the concentration of the chemical in the medium of exposure and the duration and surface area of contact with the body surface, for example, mg/cm²-hours. Some chemicals do not need to be absorbed into the body but rather produce toxicity directly at the point of contact—for example, the skin, mouth, GI tract, nose, bronchial tubes, or lungs. In such cases, the absorbed dose is not the relevant measure for toxicity; rather, it is the amount of toxic chemical coming directly into contact with the body surface that would be relevant for toxic effects.

population at risk. A group of subjects with the opportunity to be exposed to a chemical.

receptor population. People who could come into contact with a stressor. See exposure pathway.

risk. The nature and probability of occurrence of an unwanted, adverse effect on human life or health or on the environment.

risk assessment. Characterization of the potential adverse effects on human life or health or on the environment. According to the National Research Council's Committee on the Institutional Means for Assessment of Health Risk, human health risk assessment includes the following:

- description of the potential adverse health effects based on an evaluation of results of epidemiologic, clinical, toxicologic, and environmental research (hazard identification);

- extrapolation from those results to predict the type and estimate the extent of health effects in humans under given conditions of exposure (dose–response assessment);
- judgments regarding the number and characteristics of persons exposed at various intensities and durations (exposure assessment);
- summary judgments on the existence and overall magnitude of the public-health problem; and
- characterization of the uncertainties inherent in the process of inferring risk (risk characterization).

setting. The place or situation in which a person is exposed to the chemical. Setting is often modified by the activity a person is undertaking—for example, occupational or in-home exposures.

sensor. A technology that includes small, portable, autonomous, low-cost, real-time devices. Sensors are air or water monitoring technologies supporting very large numbers of measurement locations, including wearable, mobile (e.g., on autonomous/robotic platforms), or stationary applications. Key traits of sensor devices include direct measurement of one or more toxicants, toxins, and/or pathogens; portability; low power draw; turnkey operation; and market price supporting large numbers to be purchased by the public as individuals or community groups.

source. The activity or entity from which the chemical is released for potential human exposure.

stressor. Any entity, stimulus, or condition that can modulate normal functions of the organism or induce an adverse response (e.g., agent, lack of food, drought).

subchronic exposure. Contact between a stressor and an individual that is of intermediate duration between acute and chronic exposures.

subject. An exposed individual, whether a human or an exposed animal or organism in the environment. An exposed individual is sometimes also called a receptor, while a group of exposed individuals is sometimes called a receptor population.

systemic dose. A dose of a chemical within the body—that is, not localized at the point of contact. Thus, skin irritation caused by contact with a chemical is not a systemic effect, but liver damage due to absorption of the chemical through the skin is. Often referred to as target site dose.

total dose. The doses received by more than one route of exposure are added to yield the total dose. See also aggregate exposure.

uncertainty. A limited knowledge of the agreement between data, information, or outcomes relative to an unknown truth. The uncertainty of a measurement is the parameter associated with the result of a measurement

that characterizes the dispersion of the values that could reasonably be attributed to the quantity being measured (the measurand).

validated method. A method that meets or exceeds certain sampling and measurement performance criteria (e.g., Guidelines for Air Sampling and Analytical Method Development and Evaluation (NIOSH Technical Report)).

validated model. A model that meets or exceeds certain criteria, including credible and objective peer review, corroborating the model by evaluating the degree to which it corresponds to the system being modeled, and performing sensitivity and uncertainty analyses (e.g., EPA Guidance on the Development, Evaluation, and Application of Environmental Models).

validation. The confirmation that an observation meets a defined standard or objective reference.

Introduction

Epidemiology is the field of public health and medicine that studies the occurrence, distribution, and determinants of health and disease in human populations. The purpose of epidemiology is to better understand disease causation and to prevent disease in groups of individuals.¹ Epidemiology assumes that disease is not distributed randomly in a group of individuals and that identifiable subgroups, including those exposed to certain agents, are at increased risk of contracting particular diseases.²

Judges and juries increasingly are presented with epidemiologic evidence as the basis of an expert's opinion on causation.³ In the courtroom, epidemiologic research findings are offered to establish or dispute whether exposure to an agent⁴ caused a harmful effect or disease.⁵ Since *Daubert v. Merrell Dow*

1. More generally, epidemiologists study and seek to improve health outcomes in populations; this may go beyond the study of “diseases.” For example, an epidemiologist might be interested in suspected causes of osteoarthritis of the knee (a health outcome that is a disease) and also in interventions thought to improve osteoarthritic knees’ range of motion (a health outcome that is not a disease). In this reference guide, we generally refer to the dependent variable being assessed in an epidemiologic study as a *health outcome*. In certain contexts, however, we use the term *disease*, because a plaintiff’s disease is the type of outcome most often at issue in cases in which epidemiology serves as evidence of causation. In any case, in the legal context, references to health outcomes or diseases should be understood, unless stated otherwise, as constituting adverse changes that are legally cognizable. In addition, in this reference guide we generally discuss outcomes as if they are discrete variables that either are present or absent (such as cancer), even though many health outcomes are continuous variables (such as blood pressure or body mass index).

2. Epidemiologists also conduct studies of beneficial agents that reduce disease risk or that prevent or cure disease or otherwise improve health outcomes.

3. Epidemiologic studies have been well received by courts deciding cases involving toxic substances. See, e.g., *Norris v. Baxter Healthcare Corp.*, 397 F.3d 878, 882 (10th Cir. 2005) (“[E]pidemiology is the best evidence of general causation in a toxic tort case.”); *Newman ex rel. Newman v. McNeil Consumer Healthcare*, No. 10 C 1541, 2013 WL 9936293, at *10 (N.D. Ill. Mar. 29, 2013) (“Epidemiological studies are important . . . [and provide] ‘the primary, generally accepted methodology for demonstrating a causal relation between a chemical and a set of symptoms or a disease.’” (quoting *Conde v. Velsicol Chem. Corp.*, 804 F. Supp. 972, 1025–26 (S.D. Ohio 1992), *aff’d*, 24 F.3d 809 (6th Cir. 1994))). Well-conducted studies are uniformly admitted. 3 *Modern Scientific Evidence: The Law and Science of Expert Testimony* § 23.1, at 321 (David L. Faigman et al. eds., 2021–2022) [hereinafter *Modern Scientific Evidence*].

4. We use the term *agent* to refer to any substance external to the human body that potentially causes disease or other health effects. Drugs, medical devices, chemicals, radiation, vaccines, pathogens (e.g., viruses or bacteria), and minerals (e.g., asbestos) are all agents whose toxicity an epidemiologist might explore. A single agent or a number of independent agents may cause disease, or the combined presence of two or more agents may be necessary for the development of the disease. Epidemiologists also conduct studies of individual characteristics that might pose risks, such as blood pressure and diet, but those studies are rarely of interest in judicial proceedings except as possible alternative causes to an alleged tortious cause. Epidemiologists also may conduct studies of drugs and other pharmaceutical products to assess their efficacy and safety in clinical trials.

5. E.g., *In re Testosterone Replacement Therapy Prods. Liab. Litig.* Coordinated Pretrial Proc., No. 14 C 1748, 2017 WL 1833173 (N.D. Ill. May 8, 2017) (assessing whether plaintiffs’ arterial

Pharmaceuticals,⁶ the predominant use of epidemiologic studies is in connection with motions to exclude the testimony of expert witnesses. Courts deciding such motions routinely address epidemiologic studies and whether they are sufficient to support an expert's causation testimony.⁷

Epidemiology aims to develop evidence to identify agents that are associated with an increased risk of disease in groups of individuals, quantify the amount of excess disease that is associated with an agent, and attempt to provide a profile of the type of individual who is more likely to contract a disease after being exposed to an agent. Epidemiology focuses on the question of general causation (i.e., is the agent capable of causing disease?) rather than that of specific causation (i.e., did it cause disease in a particular individual?).⁸ For example, in the 1950s, Doll and Hill and others published articles about the increased risk of lung cancer in cigarette smokers. Doll and Hill's studies showed that smokers

cardiovascular injuries or venous thromboembolisms were caused by prescription testosterone-replacement-therapy drugs); *In re Mirena IUD Prods. Liab. Litig.*, 169 F. Supp. 3d 396 (S.D.N.Y. 2016) (assessing whether uterine perforation was caused by intrauterine devices); *In re Lipitor (Atorvastatin Calcium) Mktg., Sales Pracs. & Prods. Liab. Litig.*, 174 F. Supp. 3d 911 (D.S.C. 2016) (assessing whether Lipitor caused the development of type 2 diabetes); *In re E.I. du Pont de Nemours & Co. C-8 Pers. Inj. Litig.*, No. 2:13-MD-2433, 2015 WL 4092866 (S.D. Ohio July 6, 2015) (assessing whether water sources contaminated with ammonium perfluorooctanoate (C-8, or PFOA) caused residents to develop certain diseases, including testicular cancer and preeclampsia).

6. 509 U.S. 579 (1993).

7. See Michael D. Green & Joseph Sanders, *Admissibility Versus Sufficiency: Controlling the Quality of Expert Witness Testimony*, 50 Wake Forest L. Rev. 1057 (2015). Often the expert witness in a case in which a study bears on causation is not the investigator who conducted the study. See, e.g., *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 953 (3d Cir. 1990) (holding a pediatric pharmacologist expert's credentials sufficient pursuant to Fed. R. Evid. 702 to interpret epidemiologic studies and render an opinion based thereon); *In re Deepwater Horizon Belo Cases*, No. 3:19CV963-MCR-HTC, 2022 WL 17721595, at *13 (N.D. Fla. Dec. 15, 2022) (stating that non-practicing physician who worked in public health and biomedical research was qualified to testify about general causation); *Donner v. Alcoa Inc.*, No. 10-CV-00908-DW, 2014 WL 12600281, at *5 (W.D. Mo. Dec. 19, 2014) (holding admissible a pathologist's opinion about general and specific causation regarding exposure to aluminum dust and pulmonary fibrosis); *Watson v. Dillon Cos., Inc.*, 797 F. Supp. 2d 1138, 1162 (D. Colo. 2011) (holding medical doctors' opinions about general and specific causation regarding inhalation of butter flavoring ingredients in microwave popcorn and a rare lung condition were admissible); *Sugarman v. Liles*, 190 A.3d 344, 345–68 (Md. 2018) (holding admissible a physician's testimony about general and specific causation regarding lead paint and cognitive injuries).

8. The distinction between general causation and specific causation is widely recognized in court opinions. See, e.g., *Norris v. Baxter Healthcare Corp.*, 397 F.3d 878, 881 (10th Cir. 2005) ("Plaintiff[s] must first demonstrate general causation because without general causation, there can be no specific causation."); *Harrison v. BP Expl. & Prod. Inc.*, No. CV 17-4346, 2022 WL 2390733, at *4 (E.D. La. July 1, 2022) ("Once a plaintiff's diagnoses have been confirmed, the plaintiff has the burden of establishing general causation and specific causation."); *Rhynne v. United States Steel Corp.*, 474 F. Supp. 3d 733, 743 (W.D.N.C. 2020) ("Plaintiffs must prove both general causation and specific causation."). For a discussion of specific causation, see the section titled "Specific Causation" below.

who smoked 10 to 20 cigarettes a day had a lung-cancer mortality rate that was about 10 times higher than that of nonsmokers.⁹ These studies identified an association between smoking cigarettes and death from lung cancer that contributed to the determination that smoking causes lung cancer.

However, it should be emphasized that an association is not equivalent to causation.¹⁰ An association is the relationship between two events (e.g., exposure to a chemical agent and development of disease) that occur more frequently together than one would expect by chance. An association identified in an epidemiologic study may or may not be causal.¹¹

Assessing whether an association is causal requires an understanding of the strengths and weaknesses of the study's design and implementation, as well as a judgment about how the study findings fit with other similar studies and

9. Richard Doll & A. Bradford Hill, *Lung Cancer and Other Causes of Death in Relation to Smoking: A Second Report on the Mortality of British Doctors*, 2 Brit. Med. J. 1071 (1956), <https://doi.org/10.1136/bmj.2.5001.1071>.

10. In *In re Lipitor* (Atorvastatin Calcium) Mktg., Sales Pracs. & Prod. Liab. Litig., 227 F. Supp. 3d 452 (D.S.C. 2017), *aff'd sub nom. In re Lipitor* (Atorvastatin Calcium) Mktg., Sales Pracs. & Prod. Liab. Litig. (No II) MDL 2502, 892 F.3d 624 (4th Cir. 2018), the court explained the relationship between an association and causation:

Establishing an association is the first threshold step in establishing general causation, and it is not surprising that courts may invoke this language to help differentiate the inquiries of general and specific causation. However, this fact does not change voluminous and well-established precedent that association, alone, is not sufficient to establish causation and does not change the simple fact that association is not causation. The parties have always agreed that establishing association is just the first step of a two-step process for establishing general causation.

Id. at 483 n.23. *See also* Harris v. CSX Transp., Inc., 753 S.E.2d 275, 282 (W. Va. 2013) (“It should be clearly understood that the term “association” is a term of art in epidemiology . . . [and] is not the same as causation. An epidemiological association identified in a study may or may not be causal.”); Soldo v. Sandoz Pharms. Corp., 244 F. Supp. 2d 434, 461 (W.D. Pa. 2003) (discussing Hill criteria developed to assess whether an association is causal; *see* section titled “General Causation” below); Magistrini v. One Hour Martinizing Dry Cleaning, 180 F. Supp. 2d 584, 591 (D.N.J. 2002) (“[A]n association is not equivalent to causation.” (quoting the second edition of this reference guide). Association is more fully discussed in the section titled “Interpreting the Results of an Epidemiologic Study” below.

Causation is used to describe the relation between two events when one event (the cause) is a necessary link in a chain of events that results in the effect. Of course, alternative causal chains may exist that do not include the agent but that result in the same effect. For general treatment of causation in tort law and an explanation that for factual causation to exist an agent must be a necessary link in a causal chain sufficient for the outcome, *see Restatement (Third) of Torts: Liability for Physical and Emotional Harm* § 26 (2010). Epidemiologic methods cannot deductively prove causation; indeed, all empirically based science cannot directly prove a causal relation. *See, e.g.,* Kenneth J. Rothman & Sander Greenland, *Causation and Causal Inference in Epidemiology*, 95 Am. J. Pub. Health S144 (2005), <https://doi.org/10.2105/AJPH.2004.059204>. However, epidemiologic evidence can justify an inference, and sometimes a very strong inference, that an agent causes a disease. *See* section titled “Effect Modification” below.

11. *See* section titled “Sources of Error in Epidemiologic Studies” below.

scientific knowledge. It is important to emphasize that all studies have limitations that must be considered to interpret their results properly.¹² Some limitations are inevitable given the limits of technology, resources, the ability and willingness of persons to participate in a study, participant burden, and ethical constraints. In evaluating epidemiologic evidence, the key questions, then, are the extent to which a study's limitations compromise its findings and permit inferences about causation.

Judges should also appreciate that, with some frequency, courts may confront cases in which there is little or no epidemiologic evidence available that addresses the agent–disease causation issue in dispute. Epidemiology studies can be expensive and time-consuming to conduct. Other constraints, such as the rarity of exposure to the suspected toxicant, may prevent development of meaningful epidemiologic evidence. Cases in which agent–disease causation is strongly disputed also tend to be ones in which there is not a robust body of epidemiology that provides persuasive evidence of the existence of general causation *vel non*.

Epidemiology studies risk in samples of populations. Employing the results of group-based studies of risk to make a causal determination for an *individual* plaintiff is beyond the limits of epidemiology. Nevertheless, a substantial body of legal precedent has developed that addresses the use of epidemiologic evidence to prove causation for an individual litigant through probabilistic means. The law developed in these cases is discussed later in this reference guide.¹³

The following sections of this reference guide address a number of critical issues that arise in considering the admissibility of, and weight to be accorded to, epidemiologic research findings. A glossary of oft-encountered epidemiologic terms is appended to the guide.¹⁴

Over the past several decades, courts frequently have confronted the use of epidemiologic studies as evidence and have recognized their utility in proving causation. As the Third Circuit observed in *DeLuca v. Merrell Dow Pharmaceuticals*: “The reliability of expert testimony founded on reasoning from epidemiologic

12. See *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1240 (W.D. Wash. 2003) (quoting the second edition of this reference guide and criticizing defendant’s “ex post facto dissection” of a study, recognizing that “scientific studies almost invariably contain flaws.”); *Henricksen v. ConocoPhillips Co.*, 605 F. Supp. 2d 1142, 1169 (E.D. Wash. 2009) “[T]his court understands that in epidemiology hardly any study is ever conclusive, and the court does not suggest that an expert must back his or her opinion with published studies that unequivocally support his or her conclusions.”); *Barrera v. Monsanto Co.*, 2019 WL 2331090, at *8 (Del. Super. Ct. May 31, 2019) (discussing flaws in cohort and case control studies relied on by expert witnesses); Joseph L. Gastwirth, *Reference Guide on Survey Research*, 36 *Jurimetrics J.* 181, 185 (1996), <https://www.jstor.org/stable/29762414> (review essay) (“One can always point to a potential flaw in a statistical analysis.”).

13. See section titled “Specific Causation” below.

14. See Glossary of Terms below.

data is generally a fit subject for judicial notice; epidemiology is a well-established branch of science and medicine, and epidemiologic evidence has been accepted in numerous cases.”¹⁵ Indeed, much more difficult problems arise for courts when there is a paucity of epidemiologic evidence.

Three basic issues arise when epidemiology is used in legal disputes and the methodological soundness of a study and its implications for resolution of the question of causation must be assessed:

1. Do the results of an epidemiologic study or studies reveal an association between an agent and disease?
2. Could this association have resulted from limitations of the study (bias or sampling error), and if so, from which?
3. Based on the analysis of limitations in Question 2 above, and on other evidence, how plausible is a causal interpretation of the association?

In this reference guide, the section titled “The Different Kinds of Epidemiologic Studies” explains the nature and relative strengths and weaknesses of various types of epidemiologic research designs; the “Interpreting the Results of an Epidemiologic Study” section addresses the meaning of their outcomes, including discussion of how to assess the validity of an epidemiologic study and of how to evaluate the existence and significance of several potential sources of error.¹⁶ The “General Causation” section discusses general causation, considering whether an agent is capable of causing disease. The “Methods for Synthesizing or Combining the Results of Multiple Studies” section deals with methods for combining the results of multiple epidemiologic studies and the difficulties entailed in extracting a single global measure of risk from multiple studies. The “Specific Causation” section addresses the matter of whether a specific agent caused the disease in a given plaintiff, including the recurrent issue of whether

Stern, *Reference Guide on Statistics and Research Methods*, in this manual, and two case studies: Joseph Sanders, *The Bendectin Litigation: A Case Study in the Life Cycle of Mass Torts*, 43 *Hastings L.J.* 301 (1992), <https://perma.cc/C2LN-SB53>; Devra L. Davis et al., *Assessing the Power and Quality of Epidemiologic Studies of Asbestos-Exposed Populations*, 1 *Toxicological & Indus. Health* 93 (1985), <https://doi.org/10.1177/074823378500100407>; *see also* section titled “References” below.

and how population-based epidemiologic evidence can be used to address specific causation *vel non*.

The Different Kinds of Epidemiologic Studies

Experimental and Observational Studies of Suspected Toxic Agents

To determine whether an agent affects the risk of developing a certain disease or an adverse health outcome, we might ideally want to conduct an experimental study in which the subjects would be randomly assigned to one of two groups: one group exposed to the agent of interest and the other not exposed. After a period of time, the study participants in both groups would be evaluated for the development of the disease. This type of study, called a randomized trial, randomized controlled trial (RCT), clinical trial, or true experiment, is considered the gold standard to estimate the causal effect of an agent on a health outcome or adverse side effect. Such a study design is often used to evaluate new drugs or medical treatments and is the best way to determine whether the observed difference in outcomes between the two groups is caused by exposure to the drug or medical treatment.

Randomization minimizes the likelihood that there are differences in relevant characteristics between those exposed to the agent and those not exposed. Researchers conducting clinical trials generally attempt to use study designs that are placebo-controlled, which means that the group not receiving the active agent or treatment is given an inactive ingredient that appears similar to the active agent under study. Where possible, they are also double-blinded, which means that neither the participants nor those conducting the study know which group is receiving the agent or treatment and which group is receiving the placebo. However, ethical and practical constraints limit the use of such experimental methodologies to studies that aim to assess the effects of agents or interventions that are potentially beneficial to human beings or the withdrawal of an agent thought to be harmful, such as studies of smoking cessation.¹⁷

17. Although clinical trials cannot intentionally expose subjects to suspected toxicants, those studies can provide evidence that a new drug or other beneficial intervention also has adverse effects. See *In re Lipitor* (Atorvastatin Calcium) Mktg., Sales Pracs. & Prods. Liab. Litig., 227 F. Supp. 3d 452, 481 & n.19 (D.S.C. 2017) (explaining clinical trial that found an association between Lipitor and diabetes), *aff'd*, 892 F.3d 624 (4th Cir. 2018); *In re Bextra & Celebrex* Mktg. Sales Pracs. & Prod. Liab. Litig., 524 F. Supp. 2d 1166, 1181 (N.D. Cal. 2007) (relying on a clinical study of Celebrex that revealed increased cardiovascular risk to conclude that the plaintiff's experts' testimony on causation was admissible).

When an agent's effects are suspected to be harmful, researchers cannot knowingly expose people to the agent.¹⁸ Instead, epidemiologic studies typically "observe" a group of individuals who have been exposed to an agent of interest, such as cigarette smoke or an industrial chemical, and compare them with another group of individuals who have not been exposed.¹⁹ Thus, the investigator identifies a group of subjects who have been exposed²⁰ and compares their rate of disease or death with that of an unexposed group or compares health outcomes among groups of individuals with different levels of exposure.

In contrast to clinical trials, in which other potential risk factors can be controlled by randomizing exposure, observational epidemiologic studies entail the possibility that some other characteristic (a confounder)²¹ may be nonrandomly distributed between the exposed and unexposed groups, which could distort a study's results.²²

Epidemiologic investigators address the possible role of these other characteristics—such as sex, age, social class, diet, exercise, exposure to other environmental agents, and genetic background—by measuring them when possible and by considering them in the design of the study and in the analysis and

18. See, e.g., Gordon H. Guyatt, *Using Randomized Trials in Pharmacoepidemiology*, in Drug Epidemiology and Post-Marketing Surveillance 59 (Brian L. Strom & Giampaolo Velo eds., 1992), https://doi.org/10.1007/978-1-4899-2587-9_8; Comm'n on Use of Third Party Toxicity Rsch. with Hum. Rsch. Participants, Nat'l Rsch. Council, Intentional Human Dosing Studies for EPA Regulatory Purposes: Scientific and Ethical Issues 9 (2004), <https://doi.org/10.17226/10927> ("No study is ethically justifiable if it is expected to cause lasting harm to study participants."); 45 C.F.R. § 46.111 (2022) (requiring that in federally funded research on human subjects, risks to subjects be minimized and be reasonable in relation to anticipated benefits to subjects and the importance of knowledge gained); see also *McClellan v. I-Flow Corp.*, 710 F. Supp. 2d 1092, 1109 (D. Or. 2010) ("ethical considerations preclude randomized, controlled epidemiological studies of continuous infusion given the [risk of harm]"). Experimental studies can be used where the agent under investigation is believed to be beneficial, as is the case in the development and testing of new pharmaceutical drugs. See, e.g., *McDarby v. Merck & Co.*, 949 A.2d 223, 270 (N.J. Super. Ct. App. Div. 2008) (involving an expert witness relying on a clinical trial of a new drug to find the adjusted risk for the plaintiff).

19. Classifying these studies as observational in contrast to randomized trials can be misleading to those who are unfamiliar with the area, because subjects in a randomized trial are observed as well. Nevertheless, the term observational studies is widely used to distinguish them from experimental studies.

20. The subjects may have voluntarily exposed themselves to the agent of interest, as is the case, for example, for those who smoke cigarettes, or subjects may have been exposed to an agent involuntarily or even without their knowledge, such as in the case of employees who are exposed to chemical fumes at work.

21. Confounding is a type of bias, discussed in the section titled "Biases" below.

22. Both experimental and observational studies are subject to random error. See section titled "Sampling Error" below.

interpretation of the study results (see section titled “Sources of Error in Epidemiologic Studies” below).²³

Types of Observational Study Design

Several different types of observational epidemiologic studies can be conducted. Study designs may be selected based on their suitability to investigate the question of interest, feasibility, timing and ethical constraints, resource limitations, or other considerations.

Most observational studies collect data about both exposure and health outcome in every individual in the study. While many study designs exist, the three main types of observational studies are cohort, case-control, and cross-sectional studies. These studies collect data about a sample of individuals selected from a “source” population, from which the researcher seeks to make inferences about the population.²⁴ A final type of observational study is an ecological study, which uses aggregate data collected about groups of people rather than individuals.²⁵

The difference between cohort and case-control studies is that cohort studies measure and compare health outcomes (such as the presence or absence of a particular disease)²⁶ in the exposed and unexposed groups (or between individuals that experienced different levels of exposure), while case-control studies measure and compare the frequency (or level) of exposure in the group with the disease (the cases) and the group without the disease (the controls). In a cohort study, the subjects’ exposure is determined before their health status (see Figure 1). The risk of disease among the exposed can then be compared with the risk of disease among the unexposed. In a case-control study, the health status is determined first. The odds that someone with the disease was exposed to a suspected agent can then be compared with the odds that someone without the disease was similarly exposed. As for most epidemiologic studies, these study designs aim to determine if there is an association between exposure to an agent and a health outcome and the strength (magnitude) of that association.

23. See David A. Freedman, *Editorial: Oasis or Mirage?*, 21 *Chance* no. 1, 59–61 (2008), <https://doi.org/10.1080/09332480.2008.10722888>.

24. Sometimes, for practical reasons, the source population from which the researcher draws study subjects is not exactly the same as the population about which the researcher wants to make inferences, in which case the term *target population* is used to distinguish the population about which inferences are made from the source population.

25. See section titled “Ecological Studies” below. For thumbnail sketches on all types of epidemiologic study designs, see Brian L. Strom, *Basic Principles of Clinical Epidemiology Relevant to Pharmacoepidemiologic Studies*, in *Pharmacoepidemiology* 44, 50–55 (Brian L. Strom et al. eds., 6th ed. 2020), <https://doi.org/10.1002/9781119413431.ch3>.

26. Although epidemiologists refer generally to “health outcomes,” some disease is usually the health outcome of interest in the types of court cases in which epidemiologic research plays an important role. See *supra* discussion, note 1.

Figure 1. Design of a cohort study.

Cohort Studies

In cohort studies, researchers define a study population without regard to the participants' disease status. The cohort may be defined in the present and followed forward into the future (prospectively), in which case they are known as prospective, longitudinal, or follow-up studies. Alternatively, a cohort study may be constructed retrospectively as of some time period in the past and followed from that historical time toward the present. In cohort studies, there is usually a group that is unexposed and another that is exposed, or several groups with different levels of exposure (including, in appropriate cases, a group with no exposure). Exposure may also be measured continuously (e.g., blood lead levels). In a prospective study, individuals are enrolled and followed over time, during which exposure and subsequent health outcomes are measured, while in a retrospective study, the researcher will obtain data on past exposure from available records, samples, questionnaires, or other evidence.²⁷ So, for a study aiming to determine the association between an exposure and the occurrence of a disease, a researcher would compare the proportion of unexposed individuals who have the disease with the proportion of exposed individuals who have the

27. Sometimes in retrospective cohort studies, the researcher gathers historical data about exposure and disease outcome of a cohort. See Harold A. Kahn, *An Introduction to Epidemiologic Methods* 39–41 (1983); Mark A. Klebanoff & Jonathan M. Snowden, *Historical (Retrospective) Cohort Studies and Other Epidemiologic Study Designs in Perinatal Research*, 219 *Am. J. Obstetrics & Gynecology* 447 (2018), <https://doi.org/10.1016/j.ajog.2018.08.044>. Irving Selikoff, in his seminal study of asbestotic disease in insulation workers, included several hundred workers who had died before he began the study. Selikoff was able to obtain information about exposure from union records and information about disease from hospital and autopsy records. Irving J. Selikoff et al., *The Occurrence of Asbestosis Among Insulation Workers in the United States*, 132 *Ann. N.Y. Acad. Sci.* 139, 143 (1965), <https://doi.org/10.1111/j.1749-6632.1965.tb41097.x>.

disease.²⁸ If the exposure causes the disease, the researcher would expect a greater proportion of the exposed individuals to develop the disease than the unexposed individuals.²⁹ For a health outcome that is measured continuously, such as intelligence quotient (IQ) or blood pressure, the researcher could compare the average of these outcomes among the exposed and unexposed. If exposure is measured as a continuous rather than a dichotomous variable—for example, if all study subjects were exposed to some radiation from a nuclear accident but the degree of exposure was lower for those farther away from the accident—the researcher could examine the association between the extent of exposure and the health outcome.

One advantage of the cohort study design is that the temporal relationship between exposure and disease can often be established more readily than in other study designs. By tracking people who initially have not been diagnosed with the disease, the researcher can determine the time of disease onset (or diagnosis) and its relation to exposure. This temporal relationship is critical to the question of causation, because exposure must precede disease onset for exposure to have caused the disease.

As an example, in 1950 a cohort study was begun to determine whether uranium miners exposed to radon were at increased risk of death due to lung cancer as compared with nonminers. The study group (also referred to as the exposed cohort) consisted of 3,400 underground miners. The control group or unexposed cohort (which need not be the same size as the exposed cohort) comprised nonminers from the same geographic area. Members of the exposed cohort were examined every three years, and the degree of this cohort's exposure to radon was measured from samples taken in the mines. Ongoing testing for radioactivity and periodic medical monitoring of lungs permitted the researchers to examine whether disease was linked to prior work exposure to radiation and allowed them to discern the relationship between exposure to radiation and disease. Exposure to radiation was associated with the development of lung cancer in uranium miners.³⁰

The cohort design often is used in occupational studies such as the one just discussed. But because the design is not experimental, the investigator has no control over what other exposures a worker in the study may have had. Hence, an increased risk of disease among the exposed group may be caused by agents other than the exposure of interest. A researcher planning a study must attempt to

28. See Table 1, *infra*, in the section titled “Relative Risk.”

29. Researchers often examine the rate of disease or death in the exposed and control groups. The rate of disease or death entails consideration of the number developing disease within a specified period. All smokers and nonsmokers will, if followed for 100 years, die. Smokers will die at a greater rate than nonsmokers in the earlier years.

30. This example is based on a study description in Abraham M. Lilienfeld & David E. Lilienfeld, *Foundations of Epidemiology* 237–39 (2d ed. 1980). The original study is Joseph K. Wagoner et al., *Radiation as the Cause of Lung Cancer Among Uranium Miners*, 273 NEJM 181 (1965), <https://doi.org/10.1056/NEJM196507222730402>.

identify factors (called confounders) other than the exposure that may be related to exposure and may be responsible for the increased risk of disease. We discuss this problem (which is not limited to cohort studies) below in the “Confounding Bias” section. If data are gathered about potential confounders, the researcher generally uses statistical methods³¹ to estimate an association that is independent of these factors. Evaluating whether the association is causal involves additional analysis, as discussed below in the “General Causation” section.

Case-Control Studies

In case-control studies, the researcher begins with a group of individuals who have a disease (cases) and then selects a similar group of individuals who do not have the disease (controls). Controls should come from the same source population as the cases. The researcher then compares the extent of exposure in the two groups. For example, researchers might use employment records or questionnaire responses to determine whether and to what extent each study subject was exposed to the agent of interest, or researchers might measure biomarkers in the cases and controls to infer their exposure history. If a certain exposure is associated with the disease, a higher odds of exposure would be observed among the cases than among the controls (see Figure 2). Because researchers employing this research design often (though not always) gather historical information about exposure to an agent in the case and control groups, case-control studies have sometimes, but less precisely, been referred to as “retrospective studies.”³²

For example, in the late 1960s, doctors in Boston were confronted with an unusual number of young female patients with vaginal adenocarcinoma. Those

Figure 2. Design of a case-control study.

31. See generally Daniel L. Rubinfeld & David Card, *Reference Guide on Multiple Regression and Advanced Statistical Models*, in this manual; Kaye & Stern, *supra* note 16, “Statistical Models” (discussing difficulties of multiple regression).

32. As described, the design of a case-control study is inherently retrospective rather than prospective. But other types of epidemiologic studies, including some cohort studies, may also be retrospective. See Strom, *supra* note 25 and accompanying text.

patients became the cases in a case-control study (because they had the disease in question). Controls who did not have the disease were selected based on their being born in the same hospitals and at the same time as the cases. The cases and controls were compared for exposure to agents that might be responsible, and researchers found maternal ingestion of diethylstilbestrol (DES), a drug prescribed to prevent miscarriage and premature delivery, in all but one of the cases but none of the controls.³³

An advantage of the case-control study is that it usually can be completed in less time and with less expense than a cohort study. Case-control studies are also particularly useful in the study of rare diseases, because if a cohort study were conducted, a large group of individuals would have to be studied in order to observe the development of a sufficient number of cases for statistical analysis.³⁴ A number of potential limitations of case-control studies are discussed in the section below titled “Biases.”

Cross-Sectional Studies

A third type of observational study is a cross-sectional study. In this type of study, for each study participant the presence of both the exposure of interest and the health outcome of interest is assessed at a single point in time. Thus, cross-sectional studies reveal the prevalence (i.e., the presence at that particular time) of both exposure and disease but do not provide the disease incidence (i.e., the development of disease over time).³⁵ A researcher interested in the association between a health outcome (e.g., IQ) and an exposure that is relatively consistent over time (e.g., blood lead levels from living in contaminated housing) might use a cross-sectional study design. However, because a cross-sectional study determines both exposure and disease in an individual at the same point in time, it may be impossible to establish the temporal relation between exposure and disease—that is, whether the exposure preceded the disease, which is necessary for drawing any causal inference. Indeed, cross-sectional studies may be

33. See Arthur L. Herbst et al., *Adenocarcinoma of the Vagina: Association of Maternal Stilbestrol Therapy with Tumor Appearance in Young Women*, 284 NEJM 878 (1971), <https://doi.org/10.1056/NEJM197104222841604>.

34. For example, to detect a statistically significant doubling of disease caused by exposure to an agent where the incidence of disease is 1 in 100 in the unexposed population would require sample sizes of 3,100 for the exposed and nonexposed groups for a cohort study, but only 177 for the case and control groups in a case-control study (see section titled “Sampling Error” below for a discussion of statistical significance). Harold A. Kahn & Christopher T. Sempos, *Statistical Methods in Epidemiology* 66 (1989). See also Kaye & Stern, *supra* note 16, “What Is the Standard Error?” “What Is the Confidence Interval?” and “Tests or Interval Estimates?”

35. See *In re Deepwater Horizon Belo Cases*, No. 3:19CV963-MCR-HTC, 2022 WL 17721595, at *10 (N.D. Fla. Dec. 15, 2022) (criticizing failure of expert to identify a study on which she relied as a cross-sectional study).

affected by reverse causation, in which the health outcome under study actually causes a change in exposure.³⁶ Though more limited than cohort or case-control studies, cross-sectional studies can provide valuable leads to further directions for research, particularly when reverse causation can be ruled out based on other knowledge.³⁷

Ecological Studies

Up to now, we have discussed studies in which data on both exposure and health outcome are obtained for each individual included in the study, although individual data are sometimes augmented by group-level information, such as data from census tracts. Other studies, called ecological studies, collect only aggregate data on groups as a whole. In ecological studies, rather than gathering information about individuals, researchers obtain and compare overall rates of disease or death (or other summary measure for continuous health outcomes) for different exposure groups.³⁸

One type of ecological study compares exposure groups across geographic locations. For example, epidemiologists might compare disease rates among areas with more or less air pollution.³⁹ When making such comparisons, epidemiologists may overlay data on demographic factors obtained from sources such as the American Community Survey. Epidemiologists may look at geospatial or temporal trends (which may identify so-called “clusters” of disease) to form hypotheses and research questions.⁴⁰

Ecological studies may be useful to identify associations for further exploration, but they can rarely provide causal answers. We illustrate the difficulty of

36. For example, a cross-sectional study might find that disinfectant use is associated with greater odds of asthma, but could not distinguish whether disinfectants cause people to have asthma or whether having asthma causes people to use disinfectants.

37. For more information and references about cross-sectional studies, see David D. Celen-tano & Moyses Szklo, *Gordis Epidemiology* 154–57 (6th ed. 2018).

38. Studies may be conducted in which all members of a group or community are treated as exposed to an agent of interest (e.g., a contaminated water system) and disease status is determined individually. These studies should be distinguished from ecological studies.

39. See Jonah Lipsitt et al., *Spatial Analysis of COVID-19 and Traffic-Related Air Pollution in Los Angeles*, 153 *Env't Int'l* 106531 (2021), <https://doi.org/10.1016/j.envint.2021.106531>.

40. For example, the observed emergence of a cluster of adverse events associated with the use of heparin, a longtime and widely prescribed anticoagulant, led to suspicions that some specific lot of heparin was responsible. The observed pattern led the Centers for Disease Control and Prevention to conduct a case-control study, which concluded that contaminated heparin manufactured by Baxter was responsible for the outbreak of adverse events. See David B. Blossom et al., *Outbreak of Adverse Event Reactions Associated with Contaminated Heparin*, 359 *NEJM* 2674 (2008), <https://doi.org/10.1056/NEJMoa0806450>; *In re Heparin Prods. Liab. Litig.*, 803 F. Supp. 2d 712 (N.D. Ohio 2011).

using ecological studies to determine causality with the following hypothetical ecological study.

Suppose that researchers, interested in determining whether a high dietary-fat intake is associated with breast cancer, compared different countries in terms of their average fat intakes and their average rates of breast cancer. If countries with high average fat intake also tend to have high rates of breast cancer, the finding would suggest an association between dietary fat and breast cancer. However, such a finding would be far from conclusive, because it lacks particularized information about an individual's exposure and disease status (i.e., whether an individual with high fat intake is more likely to have breast cancer).⁴¹ In addition to the lack of information about an individual's intake of fat, the researcher does not know about the individual's exposures to other agents (or other factors, such as a woman's age when she first gave birth) that may also be responsible for the increased risk of breast cancer. This lack of information about each individual's exposure to an agent and disease status can lead to an erroneous inference about the relationship between fat intake and breast cancer, a problem known as the ecological fallacy. The fallacy is assuming that, on average, the individuals in the study who have suffered from breast cancer consumed more dietary fat than those who have not suffered from the disease. This assumption may not be true. Nevertheless, the study is useful in that it identifies an area for further research: the fat intake of individuals who have breast cancer as compared with the fat intake of those who do not. Researchers who identify a difference in disease or death in an ecological study may follow up with a study of individuals.⁴²

In another type of ecological study, epidemiologists may compare disease rates over time and focus on disease rates before and after a point in time when some event of interest took place. For example, after the once widely prescribed drug Bendectin was removed from the market, the rate of limb-reduction birth defects did not change, which suggested that Bendectin did not cause birth

41. For a discussion of the data on this question and what they might mean, see Kaye & Stern, *supra* note 16.

42. Some courts have admitted expert testimony that relied on the results of ecological studies. In *Cook v. Rockwell Int'l Corp.*, 580 F. Supp. 2d 1071, 1095–96 (D. Colo. 2006), the plaintiffs' expert conducted an ecological study in which he compared the incidence of two cancers among those living in a specified area adjacent to the Rocky Flats Nuclear Weapons Plant with other areas more distant. (The likely explanation for relying on this type of study is the time and expense of a study that gathered information about each individual in the affected area.) The court recognized that ecological studies are less probative than studies in which data are based on individuals but nevertheless held that this limitation went to the weight of the study. Plaintiffs' expert was permitted to testify to causation, relying on the ecological study he performed. See also *Mead v. Sec'y of Health & Hum. Servs.*, 2010 WL 892248, at *38 (Fed. Cl. Mar. 12, 2010) ("Because these studies examine trends in the aggregate rather than examining disease onset in exposed individuals, ecological studies are afforded less evidentiary weight in the medical community than controlled studies are.").

defects.⁴³ By contrast, researchers' discovery that the timing of a dramatic increase in limb-reduction birth defects followed widespread use of the drug thalidomide supported the conclusion that thalidomide caused those defects.⁴⁴

However, other than with such powerful agents as thalidomide, which increased the incidence of limb-reduction birth defects by several orders of magnitude, these secular-trend studies (also known as timeline studies) are less reliable and less able to detect modest causal effects than are the observational studies described above.⁴⁵ Other factors that affect the measurement or existence of the disease, such as improved diagnostic techniques and changes in lifestyle or age demographics, may change over time. If those factors can be identified and measured, it may be possible to control for them with statistical methods. Of course, unknown factors cannot be controlled for in these or any other kinds of epidemiologic studies.

Genetic and Molecular Epidemiologic Studies

Epidemiology, like other fields of biological and medical science, has in recent decades been touched powerfully by advances in scientists' ability to identify and study the molecular constituents of human cells, tissues, and organs. Perhaps the best-known of these advances is the development of genomics: the study of the human genome, the sequence of DNA bases arranged in chromosomes that form

43. See *Wilson v. Merrell Dow Pharms.*, 893 F.2d 1149 (10th Cir. 1990) (affirming judgment entered for defendant on a jury verdict). In *Wilson*, the defendant introduced evidence showing total sales of Bendectin and the incidence of limb-reduction birth defects during the 1970–1984 period. In 1983, Bendectin was removed from the market, but the rate of limb-reduction birth defects did not change. The Tenth Circuit held that the district court correctly determined that the timeline data were admissible and the defendant's expert witnesses could rely on those data in rendering their opinions. *Id.* at 1152–53. See also *Siharath v. Sandoz Pharms. Corp.*, 131 F. Supp. 2d 1347 (N.D. Ga. 2001). In *Siharath*, the court took note of the absence of secular trend data to support plaintiff's claim. After describing why several observational studies produced, at best, inconclusive results about any association between use of the lactation-suppressing drug Parlodel and the very rare complication of postpartum stroke, the court observed: "No evidence has been offered of an increase in postpartum strokes after the drug [Parlodel] was approved for suppression of lactation; no evidence has been offered of a decrease in postpartum strokes after the approval for suppression of lactation was withdrawn." *Id.* at 1358.

44. Michael D. Green, *Bendectin and Birth Defects* 70–71 (1996) (describing how thalidomide's teratogenicity was discovered after Dr. Widukind Lenz found a dramatic increase in the incidence of limb-reduction defects in Germany beginning in 1960).

45. See *Graddy v. Sec'y of Health & Hum. Servs.*, No. 08–416V, 2017 WL 11286536, at **18–22 (Fed. Cl. Aug. 31, 2017) (finding that the expert witness's ecological study on childhood autism prevalence and the introduction or increased doses of certain vaccines did not allow for a reliable evidentiary inference of causation regarding MMR II, varicella, and hepatitis A vaccines and autism).

the basis of heredity.⁴⁶ But genomics is just one of several fields of large-scale research on categories of biological molecules and features, such as epigenomics,⁴⁷ proteomics,⁴⁸ and others. Rapid technological and computational improvements have increasingly facilitated “omics” studies that can be performed on a larger scale, at a lower cost, and in a shorter time.⁴⁹

Variations in genes and other biochemical constituents across the population may be associated with the incidence of disease or the ability to metabolize an agent, and therefore can be subject to epidemiologic study. Genetic epidemiology assesses the genetic components that, perhaps in combination with environmental or other risk factors, contribute to the development or progression of disease in human populations.⁵⁰ More generally, molecular epidemiology “joins an understanding of disease at a molecular level with population-based study designs and approaches.”⁵¹ The number of epidemiologic studies that include molecular and genetic factors is quickly increasing.⁵²

Genetic and molecular epidemiologic studies add to epidemiology the ability to consider types of data that were previously unavailable. Where researchers previously could collect data only on the health outcome of interest, the exposure of interest, and relatively easily observed other potentially relevant traits

46. See Int’l Hum. Genome Sequencing Consortium, *Initial Sequencing and Analysis of the Human Genome*, 409 *Nature* 860 (2001), <https://doi.org/10.1038/35057062>. Genomics is contrasted to genetics by its scale: genetics is the study of the inheritance or effect of one gene or a relatively small number of genes; genomics is the study of the entire human genome or large portions of it.

47. Epigenetic factors are biochemical features or constituents that affect the extent to which genes are “turned on,” that is, expressed through synthesis of the proteins the genes encode. They have been described as an “extra layer of instructions that influences gene activity.” Gail P. A. Kauwell, *Epigenetics: What It Is and How It Can Affect Dietetics Practice*, 108 *J. Am. Dietetic Ass’n* 1056, 1056 (2008), <https://doi.org/10.1016/j.jada.2008.03.003>. Epigenomics has been defined as “[t]he study of epigenetic marks . . . on a genome-wide scale.” Pauline A. Callinan & Andrew P. Feinberg, *The Emerging Science of Epigenomics*, 15 *Hum. Molecular Genetics* R95, R96 (2006), <https://doi.org/10.1093/hmg/ddl095>.

48. Proteomics is the study of the proteome, the “complete set of proteins made by an organism.” Nat’l Cancer Inst., *Proteomics*, Dictionary of Cancer Terms, <https://perma.cc/74G5-ZWNB>; *Proteome*, *id.*, <https://perma.cc/ZQ79-HX5R>.

49. See, e.g., Matthew K. Sigurdson et al., *Redundant Meta-Analyses Are Common in Genetic Epidemiology*, 127 *J. Clinical Epidemiology* 40, 46 (2020), <https://doi.org/10.1016/j.jclinepi.2020.05.035> (“The advent of genomewide agnostic approaches and massive new biobanks and consortia has created a new paradigm for human genome epidemiology.”); Sara Goodwin et al., *Coming of Age: Ten Years of Next-Generation Sequencing Technologies*, 17 *Nature Rev. Genetics* 333, 333–37 (2016), <https://doi.org/10.1038/nrg.2016.49> (describing gene sequencing technologies and stating that cost of sequencing a single genome had been reduced to about \$1,000).

50. This description is closely paraphrased from John S. Witte & Duncan C. Thomas, *Genetic Epidemiology*, in Timothy L. Lash et al., *Modern Epidemiology* 963, 963 (4th ed. 2021), <https://doi.org/10.1093/aje/kwj102>.

51. Claire H. Pernar et al., *Molecular Epidemiology*, in Lash et al., *supra* note 50 at 935.

52. See, e.g., Muin J. Khoury et al., *Genetic Epidemiology with a Capital E, Ten Years After*, 35 *Genetic Epidemiology* 845 (2011), <https://doi.org/10.1002/gepi.20634>.

such as age or socioeconomic status, researchers may now also be able to collect information about the study subjects' genotype or relevant cellular or molecular components. But adding genetic or molecular information about the study subjects does not somehow turn epidemiology from a population-based science into the study of individuals, any more than including information about the study subjects' exposures and health outcomes did. Neither do genetic and molecular epidemiology constitute new types of epidemiologic study designs. Rather, they apply existing modes of epidemiologic study to genetic or molecular information. Thus, genetic and molecular epidemiologic studies employ various combinations of the study designs, such as cohort studies and case-control studies, described in the preceding subsection. Depending on the type of genetic or molecular data under study and the details of the study design, genetic and molecular epidemiologic studies are subject to the same sources of error that must be considered in designing and interpreting the results of any epidemiologic study.⁵³

As with other epidemiologic studies, genetic and molecular epidemiology studies may be used to support or undermine claims of disease causation in litigation. Although commentators have long forecast that the output of genetic and molecular epidemiology would revolutionize causal proof, as of this writing few judicial opinions have addressed these types of studies, and it is far from clear that a revolution is in the offing. Nevertheless, it is increasingly likely that expert witnesses will rely on such studies in forming their opinions presented in courts.

In particular, genetic epidemiology may provide additional evidence of whether there is a causal connection between an environmental exposure and a disease at issue in litigation—either in a general sense or in the plaintiff's specific instance. For example, a study found that maternal exposure to organophosphate insecticides was associated with shorter gestational duration only among infants who had a genetic variant that resulted in a slower elimination of these insecticides.⁵⁴ Alternatively, genetic epidemiology may reveal associations between genetic variations and a plaintiff's disease, raising the issue of whether or not a genetic variation may be a competing cause of the disease. This requires assessment of whether the gene-disease association is causal in a general sense, whether it acts independently of the exposure, and whether it is a competing cause in the plaintiff's specific instance. The extreme, though not typical, example would be

53. Pernar et al., *supra* note 51, at 936 (emphasizing that although molecular epidemiology involves new “omics” technologies, “molecular epidemiology can only contribute valid and reproducible findings if epidemiologists critically integrate core methodological concepts of epidemiology”); *id.* at 947–52 (discussing usefulness of various epidemiologic study designs in molecular epidemiology research).

54. Kim G. Harley et al., *Association of Organophosphate Pesticide Exposure and Paraoxonase with Birth Outcome in Mexican-American Women*, PLoS One 6(8):e23923 (2011), <https://doi.org/10.1371/journal.pone.0023923>.

a health outcome or disease entirely determined by genetics,⁵⁵ as is the case with sickle cell anemia.⁵⁶

Molecular epidemiology may also become relevant to causation disputes in ways that go beyond genetics. In molecular epidemiology studies, as one researcher described them, “risk factors, outcomes, confounders or effect modifiers are measured with biomarkers.”⁵⁷ Parties may use these types of studies to support or undermine claims that a plaintiff was exposed to an alleged toxicant, that an exposure caused a plaintiff’s disease or otherwise affected the plaintiff’s biochemistry or physiology, or that the plaintiff suffers from a particular condition or disease. In particular, parties may attempt to rely on research that seeks to identify “signature” molecular markers of disease etiology, with the validity, sensitivity, and specificity of the purported signatures likely to be in dispute.⁵⁸ For example, in several cases involving claims that exposure to benzene caused a plaintiff’s leukemia, courts have considered the significance of certain chromosome aberrations as possible biomarkers of exposure or effect.⁵⁹

55. *E.g.*, *Bowen v. E.I. Du Pont de Nemours & Co.*, No. CIV.A. 97C-06-194 CH, 2005 WL 1952859 (Del. Super. Ct. June 23, 2005), *aff’d*, 906 A.2d 787 (Del. 2006) (discussing how a newly discovered test for a newly discovered genetic variant established that a genetic mutation rather than a toxic exposure was “the cause of” plaintiff’s condition).

56. The sickle cell trait is a well-known example of a genetically determined condition. *See* Muin J. Khoury & Janice S. Dorman, *Genetic Disease*, in *Molecular Epidemiology* 365, 370 (Paul A. Schulte & Frederica P. Perera eds., 1993).

57. Paolo Boffetta, *Biomarkers in Cancer Epidemiology: An Integrative Approach*, 31 *Carcinogenesis* 121, 125 (2010), <https://doi.org/10.1093/carcin/bgp269>. Confounders are discussed in the section titled “Biases” below and effect modifiers are discussed in the section titled “Effect Modification” below.

58. Validity, in this context, refers to the degree to which the measurement of the “signature” marker measures what it purports to measure, as well as to whether the selected marker is generalizable from the study that derived it to the case in which it is being used. Sensitivity refers to the ability of an “etiologic signature” to identify true causal cases, i.e., to avoid false negatives. Specificity refers to the ability of an etiologic signature to identify false causal cases, i.e., to avoid false positives. The absence of a highly sensitive etiologic marker would be stronger evidence against causation than would be the absence of a less sensitive marker. The presence of a highly specific etiologic marker would be stronger evidence for causation than would be the presence of a less specific marker. *See* Steve C. Gold, *When Certainty Dissolves into Probability: A Legal Vision of Toxic Causation for the Post-Genomic Era*, 70 *Wash. & Lee L. Rev.* 237, 265–76 (2013) (discussing these concepts); *see also infra* Glossary of Terms.

59. *E.g.*, *Henricksen v. ConocoPhillips Co.*, 605 F. Supp. 2d 1142, 1149–50 (E.D. Wash. 2009) (noting absence in plaintiff of chromosomal aberrations found more frequently in toxicant-induced acute myelogenous leukemia than in idiopathic cases); *Hendrian v. Safety-Kleen Sys., Inc.*, No. 08-14371, 2014 WL 1464462, at *7 (E.D. Mich. Apr. 15, 2014) (describing plaintiff’s expert’s testimony that presence of chromosomal aberrations indicated prior exposure to benzene); *Harris v. KEM Corp.*, No. 85 CIV. 2127 (WK), 1989 WL 200446, at *3–*5 (S.D.N.Y. Dec. 2, 1989) (denying defendant’s motion for summary judgment where plaintiff’s expert testified that plaintiff’s leukemia had chromosomal aberrations consistent with benzene exposure).

Epidemiologic and Toxicologic Studies

In addition to observational epidemiology, toxicology models based on animal studies (in vivo) may be used to determine toxicity in humans.⁶⁰ Animal studies have a number of advantages. They can be conducted as true experiments by assigning exposure at random and carefully controlling and measuring exposure. Animal studies can avoid the other problems that human epidemiology studies confront such as confounding⁶¹ by, for example, genetics, social factors, or nutrition; participant refusal, non-compliance, or loss to follow-up; and certain ethical issues including those involving certain subpopulations, such as pregnant women and children. Test animals can be sacrificed and their tissues examined, which may improve the accuracy of disease assessment.⁶² Animal studies often provide useful information about pathological mechanisms and play a complementary role to epidemiology by assisting researchers in framing and assessing the plausibility of hypotheses.

Animal studies have two significant disadvantages, however. First, animal study results must be extrapolated to another species—human beings—and differences in absorption, metabolism, and other factors may result in interspecies variation in responses. For example, one powerful human teratogen, thalidomide, does not cause birth defects in most rodent species.⁶³ Similarly, some known teratogens in animals are not believed to be human teratogens.⁶⁴ The second difficulty with inferring causation in humans based on animal studies is that such studies often use doses that are substantially higher than concentrations to which humans are exposed. This may require the estimation of dose–response relationships for lower doses that have not been tested in order to establish a dose at which no effect is expected. For many agents, such no–effect thresholds may

60. For an in-depth discussion of toxicology, see David L. Eaton et al., *Reference Guide on Toxicology*, in this manual.

61. See section titled “Effect Modification” below.

62. Ethical considerations against deliberately exposing humans to agents thought harmful, see *supra* note 18, have in the past not been thought to prohibit animal experimentation. Contemporary concern for the ethical treatment of animals used in research is reflected in a number of statutory and regulatory provisions. See, e.g., 15 U.S.C. § 2603(h)(1) (2022) (amended Toxic Substances Control Act requires Environmental Protection Agency to “reduce and replace, to the extent practicable, scientifically justified, and consistent with the policies of [the Act], the use of vertebrate animals in the testing of chemical substances and mixtures”); Nat’l Insts. Health, *Animal Care & Use in the Intramural Research Program*, NIH Policy Manual § 3040-2 (Mar. 18, 2022), available at <https://perma.cc/9LW3-QJBQ>; *id.* Appendix 1 (listing applicable statutes, regulations, standards, and policies).

63. Phillip Knightley et al., *Suffer the Children: The Story of Thalidomide* 271–72 (1979).

64. In general, it is often difficult to confirm that an agent known to be toxic in animals is safe for human beings. See Ian C.T. Nisbet & Nathan J. Karch, *Chemical Hazards to Human Reproduction* 98–106 (1983); Int’l Agency for Research on Cancer, *Interpretation of Negative Epidemiological Evidence for Carcinogenicity* (Nicholas J. Wald & Richard Doll eds., 1985) [hereinafter IARC (Wald & Doll)].

not be known or may not exist.⁶⁵ Thus, inference conducted solely on the basis of animal studies is fraught with considerable uncertainty.⁶⁶

Toxicologists also use *in vitro* methods, in which human or animal tissue or cells are grown in laboratories and are exposed to certain substances. While useful, the problem with this approach is also extrapolation—whether one can generalize the findings from the artificial setting of tissues in laboratories to whole human beings.⁶⁷

Often toxicologic studies are the only or best available evidence of toxicity.⁶⁸ Epidemiologic studies are difficult, time-consuming, expensive, and

65. See *infra* text accompanying footnotes 235–37.

66. See *Soldo v. Sandoz Pharms. Corp.*, 244 F. Supp. 2d 434, 466 (W.D. Pa. 2003) (quoting the first edition of this reference guide); see also *Gen. Elec. Co. v. Joiner*, 522 U.S. 136, 143–45 (1997) (holding that the district court did not abuse its discretion in excluding expert testimony on causation based on expert’s failure to explain how animal studies supported expert’s opinion that agent caused disease in humans).

67. For a further discussion of these issues, see Eaton et al., *supra* note 60, “Extrapolation from Animal (In Vivo) and Cell (In Vitro) Research to Humans.” A number of courts have grappled with the role of animal studies in proving causation in a toxic substance case. One line of cases takes a very dim view of their probative value. For example, in *Johnson v. Arkema, Inc.*, 685 F.3d 452 (5th Cir. 2012), the appellate court concluded that the district court did not abuse its discretion in discounting an animal study because “studies of the effects of chemicals on animals must be carefully qualified in order to have explanatory potential for human beings.” *Id.* at 463 (quoting *Allen v. Pennsylvania Eng’g Corp.*, 102 F.3d 194, 197 (5th Cir. 1996)). See also *Becnel v. BP Expl. & Prod., Inc.*, No. CV 17-1758-SDD-EWD, 2021 WL 4444723, at *2 (M.D. La. Sept. 28, 2021) (noting that relying on animal studies, in the absence of epidemiologic studies, is . . . “of very limited usefulness”) (quoting *Brock v. Merrell Dow Pharms., Inc.*, 874 F.2d 307, 313 (5th Cir. 1989)); *In re Mirena IUD Prod. Liab. Litig.*, 169 F. Supp. 3d 396, 445 (S.D.N.Y. 2016) (holding that the expert’s reliance on animal studies, without a sound basis for extrapolating these studies to humans, is inadmissible). Other courts have been more amenable to the use of animal toxicology in proving causation. See *Metabolife Int’l, Inc. v. Wornick*, 264 F.3d 832, 842 (9th Cir. 2001) (holding that the lower court erred in *per se* dismissing animal studies, which must be examined to determine whether they are appropriate as a basis for causation determination); see also *In re Paoli R.R. Yard PCB Litig.*, 916 F.2d 829, 853–54 (3d Cir. 1990) (questioning the basis for the lower court’s exclusion of animal studies and remanding for further development of the record); *Drake v. Allergan, Inc.*, 2014 WL 12718976, at *1 (D. Vt. Oct. 23, 2014) (“The Court is mindful that animal studies present certain risks but these risks are not sufficient to exclude them categorically, especially where there is other evidence of causation as is the case here.”). The Third Circuit in a subsequent opinion in *Paoli* observed:

[I]n order for animal studies to be admissible to prove causation in humans, there must be good grounds to extrapolate from animals to humans, just as the methodology of the studies must constitute good grounds to reach conclusions about the animals themselves. Thus, the requirement of reliability, or “good grounds,” extends to each step in an expert’s analysis all the way through the step that connects the work of the expert to the particular case.

In re Paoli R.R. Yard PCB Litig., 35 F.3d 717, 743 (3d Cir. 1994); see also *Cavallo v. Star Enter.*, 892 F. Supp. 756, 761–63 (E.D. Va. 1995) (courts must examine each of the steps that lead to an expert’s opinion), *aff’d in part and rev’d in part*, 100 F.3d 1150 (4th Cir. 1996).

68. The International Association for Research on Cancer (IARC), a well-regarded international public health agency, evaluates the human carcinogenicity of various agents. In doing so,

sometimes—when it is difficult to accurately measure exposure, or when the exposure or the disease is extremely rare—virtually impossible to perform.⁶⁹ Consequently, epidemiologic studies do not exist for a large array of environmental agents. Where both toxicologic and epidemiologic studies are available, no universal rules exist for how to reconcile them.⁷⁰ Researchers often employ

IARC obtains, evaluates, and synthesizes all of the relevant evidence, including animal studies as well as any human studies. IARC then publishes a monograph containing that evidence, IARC's analysis, and a categorical assessment of the likelihood an agent is carcinogenic. In a preamble to each monograph, IARC explains what each of the categorical assessments means. IARC may classify a substance as “probably carcinogenic to humans” solely on the basis of the strength of animal studies. Int'l Agency for Research on Cancer, *Human Papillomaviruses*, 90 Monographs on Evaluation of Carcinogenic Risks to Humans 9–10 (2007), <https://perma.cc/J52S-ELWH> [hereinafter *IARC Papillomaviruses*]. When IARC monographs are available, courts generally recognize them as authoritative. See *Hardeman v. Monsanto Co.*, 997 F.3d 941, 967 (9th Cir. 2021) (affirming lower court's admission of IARC categorization of glyphosate as “a probable carcinogen”), *cert. denied*, 142 S. Ct. 2834 (2022). But IARC has only conducted evaluations of a fraction of potentially carcinogenic agents, and many suspected toxic agents cause effects other than cancer. See IARC, Revised Preamble for the IARC Monographs (2021), available at <https://perma.cc/XXY4-7DKF>.

69. Thus, in a series of cases involving Parlodel, a lactation suppressant for mothers of newborns, efforts to conduct an epidemiologic study of its effect on causing strokes were stymied by the infrequency of such strokes in women of child-bearing age. See, e.g., *Brasher v. Sandoz Pharms. Corp.*, 160 F. Supp. 2d 1291, 1297 (N.D. Ala. 2001); see also *In re Tylenol (Acetaminophen) Mktg., Sales Pracs. & Prods. Liab. Litig.*, No. 2:12-CV-07263, 2016 WL 3997046, at *7 (E.D. Pa. July 16, 2016) (in series of cases involving liver damage from use of acetaminophen (Tylenol) at or above the suggested dosage, efforts to conduct an epidemiological study of Tylenol's effect on causing acute liver failure (ALF) were stymied by the rarity of drug-induced ALF). In other cases, a plaintiff's exposure to an overdose of a drug may be unique or nearly so. See *Zuchowicz v. United States*, 140 F.3d 381 (2d Cir. 1998).

70. See IARC (Wald & Doll), *supra* note 64 (identifying several substances and comparing animal toxicology evidence with epidemiologic evidence). One explanation for the conflicting judicial treatment of toxicological studies of animals, see *supra* note 67, may be that when there is a substantial body of epidemiologic evidence that addresses the causal issue, courts find that animal toxicology has much less probative value. That was the case, for example, in several Bendectin cases. E.g., *Turpin v. Merrell Dow Pharms., Inc.*, 959 F.2d 1349, 1359 (6th Cir. 1992); *Brock v. Merrell Dow Pharms., Inc.*, 874 F.2d 307, 313; see also *In re Paoli R.R. Yard PCB Litig.*, No. 86-2229, 1992 U.S. Dist. LEXIS 16287, at *16 (E.D. Pa. 1992) (excluding evidence of or based on animal studies linking PCB exposure to various health effects). Where epidemiologic evidence is not available, animal toxicology may be thought to play a more prominent role in resolving a causal dispute. See Michael D. Green, *Expert Witnesses and Sufficiency of Evidence in Toxic Substances Litigation: The Legacy of Agent Orange and Bendectin Litigation*, 86 Nw. U. L. Rev. 643, 680–82 (1992) (arguing that plaintiffs should be required to prove causation by a preponderance of the available evidence). For another explanation of the Bendectin cases as well as other toxic tort case clusters, see Gerald W. Boston, *A Mass-Exposure Model of Toxic Causation: The Content of Scientific Proof and the Regulatory Experience*, 18 Colum. J. Env't L. 181 (1993) (arguing that epidemiologic evidence should be required in mass-exposure cases but not in isolated-exposure cases). See also IARC *Papillomaviruses*, *supra* note 68; Eaton et al., *supra* note 60, “Toxicology and Epidemiology.” The U.S. Supreme Court, in *General Electric Co. v. Joiner*, 522 U.S. 136, 144–45 (1997), suggested that there is no categorical rule for toxicologic studies, observing, “[W]hether animal studies can ever be a proper foundation for an expert's opinion [is] not the issue. . . . The [animal] studies were so dissimilar to

an approach that considers the overall weight of evidence, that is, all of the relevant scientific evidence that addresses the question of interest.⁷¹ This methodology entails making a judgment about causation after carefully assessing the results, validity, and consistency of each epidemiologic and toxicologic study.⁷²

Interpreting the Results of an Epidemiologic Study

Epidemiologists are ultimately interested in whether a causal link exists between an agent and a disease. However, the first question an epidemiologist generally addresses is whether an association is observed between exposure to the agent and disease. An association between exposure to an agent and disease is observed when disease occurs more frequently (or less frequently) when exposure exists than when exposure is absent.⁷³ Although a causal relation is one possible explanation for an observed association between an exposure and a disease, an association does not necessarily mean that there is a cause–effect relation. Interpreting the meaning of an observed association is discussed below.⁷⁴

the facts presented in this litigation that it was not an abuse of discretion for the District Court to have rejected the experts’ reliance on them.”

71. The methodology relies on expert scientific judgment to evaluate and weight the available evidence in order to reach the best conclusion. See Douglas L. Weed, *Weight of Evidence: A Review of Concept and Methods*, 25 Risk Analysis 1545 (2005), <https://doi.org/10.1111/j.1539-6924.2005.00699.x>. A number of courts have endorsed weight of evidence as a reliable methodology. See, e.g., *In re Deepwater Horizon Belo Cases*, No. 3:19CV963-MCR-HTC, 2022 WL 17721595, at *19 (N.D. Fla. Dec. 15, 2022) (stating that “weight of the evidence approach to analyzing causation can be considered reliable, provided the expert considers all available evidence carefully and explains how the relative weight of the various pieces of evidence led to his conclusion”) (quoting *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1311 (N.D. Fla. 2018)). As the court in *In re Zantac (Ranitidine) Prod. Liab. Litig.*, 644 F. Supp. 3d 1075, 1168 (S.D. Fla. 2022), cogently observed: “Due to the ‘substantial judgment’ required of an expert in following this approach, it is crucial that the expert describe each step in the process by which he gathered and assessed the relevant scientific evidence” (quoting *Abilify*, *supra*, 299 F. Supp. at 1311)). When weight of evidence methodology is employed by a testifying expert, a critical step is adequately taking into account evidence contrary to the expert’s opinion. See *Norris v. Baxter Healthcare Corp.*, 397 F.3d 878, 882 (10th Cir. 2005) (“We are simply holding that where there is a large body of contrary epidemiological evidence, it is necessary to at least address it with evidence that is based on medically reliable and scientifically valid methodology.”); *Zantac*, *supra*, at *129 (“a plaintiff’s expert must address epidemiological evidence that is inconsistent with his or her causation opinions”).

72. See sections titled “Statistical Power” and “General Causation” below.

73. A negative association implies that the agent has a protective or curative effect. Because the concern in toxic substances litigation is whether an agent caused disease, this reference guide focuses on positive associations.

74. See section titled “General Causation” below.

This section begins by describing the ways of expressing the existence and strength of an association between exposure and disease or health outcome. It then proceeds to address sources of error that may produce an incorrect or skewed association, including random chance (sampling error) and non-random or systematic error (bias). Systematic error may result, for example, from inaccuracies in ascertaining health and exposure, from the manner of selecting those studied and information about them, or from confounding bias. This section also describes the statistical methods epidemiologists use to evaluate the importance of, and to address, these potential sources of error with respect to whether an association is real.

The strength of an association between exposure and a health outcome can be stated in various ways. For categorical outcomes, such as the occurrence of a disease, measures often employed include relative risk, odds ratio, attributable risk, or standardized mortality (or morbidity) ratio.⁷⁵ For continuous outcomes, such as IQ, researchers use other measures to describe the relationship between exposure and outcome. For example, statistical methods can be used to estimate a regression coefficient (sometimes called a beta coefficient) that represents the mean change in an outcome for a unit change in the level of exposure.⁷⁶ Regardless of the type of health outcome studied or the particular measure of association used, each of these measurements of association examines the degree to which the risk of an adverse health outcome changes with exposure to an agent in a population of individuals.

75. These are the type of health outcomes, and thus the measures of association, most commonly at issue in litigation. See, e.g., *In re Roundup Prods. Liab. Litig.*, 390 F. Supp. 3d 1102, 1120 n.18 (N.D. Cal. 2018) (identifying, explaining, and comparing relative risk and odds ratio); *In re Lipitor (Atorvastatin Calcium) Mktg., Sales Pracs. & Prods. Liab. Litig.*, No. MDL214MN-02502RMG, 2016 WL 827067, at *3 (D.S.C. Feb. 29, 2016) (discussing expert's selection of method to express magnitude of association from among relative risk, odds ratio, and risk difference). The Glossary of Terms *infra* defines two additional measures of strength of association for categorical outcomes: hazard ratio (see *Cooper v. Takeda Pharms. Am., Inc.*, 191 Cal. Rptr. 3d 67, 73–74, 78–79 (Cal. App. 2015) (describing expert testimony that defined and gave examples of hazard ratios)) and risk difference. A risk difference is the difference between the proportion of disease in those exposed to the agent and the proportion of disease in those who were unexposed. Thus, in the example given in the section titled “Relative Risk” below, the proportion of disease in those exposed is 40/100, the proportion of disease in the unexposed is 20/100, and the risk difference is 20/100 (40/100 minus 20/100). The risk difference is related to the attributable proportion of risk, another measure of association that is addressed below in the section titled “Attributable Risk.”

76. To estimate the association between an exposure and a continuous outcome, researchers compute beta coefficients, which are derived from standard multiple regression statistical analysis. See *infra* Glossary of Terms (defining beta coefficient). For more information on beta coefficients, see Rubinfield & Card, *supra* note 31, “Appendix.” Court opinions discussing epidemiology have not, to date, addressed beta coefficients.

Relative Risk

A commonly used approach for expressing the association between an agent and disease in cohort studies is the relative risk (RR).⁷⁷ It is defined as the ratio of the probability of disease in a group of exposed individuals (R_e in Table 1 and the equation below) to the probability of disease in a group of unexposed individuals (R_u in Table 1 and the equation below). Consider the information a researcher would obtain in conducting a cohort study as depicted in Table 1.

Table 1. Cross Tabulation of Exposure by Disease Status

	No Disease	Disease	Totals	Risk of Disease
Not Exposed	<i>a</i>	<i>c</i>	<i>a + c</i>	$R_u = c/(a + c)$
Exposed	<i>b</i>	<i>d</i>	<i>b + d</i>	$R_e = d/(b + d)$

The risk of disease is defined as the number of cases of disease that develop divided by the number of persons in the cohort under study.⁷⁸ Thus, the risk expresses the probability that a member of the population will develop the disease.

$$RR = \frac{R_e}{R_u} = \frac{\frac{d}{b + d}}{\frac{c}{a + c}}$$

For example, a researcher studies 100 individuals who are exposed to an agent and 200 individuals who are not exposed. After one year, 40 of the exposed individuals are diagnosed as having a disease, and 20 of the unexposed individuals also are diagnosed as having the disease. The relative risk of contracting the disease is calculated as follows:

- The risk of disease in the exposed individuals is 40 cases per 100 persons (40/100), or 0.4.
- The risk of disease in the unexposed individuals is 20 cases per 200 persons (20/200), or 0.1.

77. A relative risk cannot be calculated for a case-control study. An odds ratio is used instead to express the magnitude of any association found in such studies. See section titled “Odds Ratio” below.

78. Epidemiologists also use the concept of prevalence, which measures the existence of disease in a population at a given point in time, regardless of when the disease developed. Prevalence is expressed as the proportion of the population with the disease at the chosen time. See Celentano & Szklo, *supra* note 37, at 51–55.

- The relative risk is calculated as the ratio of the risk in the exposed group (0.4) divided by the risk in the unexposed group (0.1), or 4.0.

A relative risk of 4.0 indicates that the risk of disease in the exposed group is four times as high as the risk of disease in the unexposed group.⁷⁹

Risk, as defined above (generally referred to as cumulative incidence), can only be estimated if all individuals are followed for an equal period of time. If the follow-up time period differs between individuals in a study, the incidence rate is used instead. Incidence rates account for the fact that individuals followed for a longer period of time have a greater opportunity to develop the disease under study than those followed for a shorter time. To compute an incidence rate, a researcher divides the number of observed cases by the cumulated person-time.⁸⁰

In general, the relative risk can be interpreted⁸¹ as follows:

- If the relative risk equals 1.0, the risk in the group of exposed individuals is the same as the risk in the group of unexposed individuals.⁸² There is no association between exposure to the agent and disease.
- If the relative risk is greater than 1.0, the risk in the group of exposed individuals is greater than the risk in the group of unexposed individuals. There is a positive association between exposure to the agent and the disease, which may reflect a harmful effect of the agent in increasing the extent of disease.
- If the relative risk is less than 1.0, the risk in exposed individuals is less than the risk in unexposed individuals. There is a negative (or inverse) association between exposure to the agent and the disease, which could

79. See Celentano & Szklo, *supra* note 37, at 242–45; *Magistrini v. One-Hour Martinizing Dry Cleaning*, 180 F. Supp. 2d 584, 591 (D.N.J. 2002) (explaining the relationship between relative risk and the increased incidence of disease in the exposed group).

80. Person-time weights study participants by the amount of time those participants were observed and at risk for the disease. For example, one participant observed for one year is one person-year; one participant observed for two years is two person-years, etc. Two participants observed for one year each is also two person-years. The incidence rate is computed as the number of new cases of disease divided by the total person-time observed. See Celentano & Szklo, *supra* note 37, at 46–49.

81. For the sake of simplicity, this description refers only to relative risk. As noted in the immediately preceding text, if a cohort study follows different participants for different periods of time, the researcher computes an incidence rate ratio to determine if an association is observed. If an epidemiologic study reports an incidence rate ratio rather than a relative risk, the same interpretations as described in the text for relative risk would apply.

82. See *Magistrini*, 180 F. Supp. 2d at 591.

reflect a protective or curative effect of the agent on risk of disease. For example, immunizations lower the risk of disease. Thus, immunizations are expected to be negatively associated with the diseases that they target.

Although relative risk is a straightforward concept, care must be taken in interpreting it. Whenever an association is uncovered, further analysis should be conducted to assess whether the association is causal or due to chance (random error) or bias (including confounding).⁸³ These sources of error may also mask or skew a true association, resulting in a study that erroneously finds no association or overstates or understates the true association.

Epidemiologists often use relative risk as a measure of association in cohort studies. But researchers performing case-control studies cannot calculate a relative risk.⁸⁴ Instead, epidemiologists conducting case-control studies compute a different measure of association: an odds ratio.

Odds Ratio

The odds ratio (OR) is similar to a relative risk in that it expresses in quantitative terms the association between exposure to an agent and a disease. It is a convenient way to estimate an association, most particularly in case-control studies, though it can also be calculated for a cohort study.⁸⁵ The odds ratio approximates the relative risk when the disease is rare.⁸⁶

In a case-control study, the odds ratio is the ratio of the odds⁸⁷ that a case (one with the disease) was exposed to the odds that a control (one without the

83. See sections titled “Biases” and “Sampling Error” below.

84. A case-control study begins by examining a group of persons who already have the disease and another group of persons who do not have the disease. See section titled “Case-Control Studies” above. Because the number of cases and the number of controls are predetermined, the researcher cannot calculate the rate at which exposed and unexposed individuals in the study develop the disease. Lacking a rate or incidence of disease for both those exposed and those not exposed to the agent, a researcher cannot calculate a relative risk.

85. In a cohort study, the odds ratio is the ratio of the odds of a disease occurring when exposed to a suspected agent to the odds of the disease occurring when not exposed. An odds ratio can also be calculated for a cross-sectional study.

86. See Marcello Pagano & Kimberlee Gauvreau, *Principles of Biostatistics* 123 (3d ed. 2022). If the disease is not rare, the odds ratio is still valid to determine whether an association exists, but interpretation of its magnitude is less intuitive. For further detail about the odds ratio and its calculation, see Kahn & Sempos, *supra* note 34, at 47–56.

87. The odds of exposure is the ratio of those who were exposed to those who were not. Thus, from Table 2 *infra*, we can calculate the odds of exposure among the cases as a/c , and the odds of exposure among the controls as b/d .

disease) was exposed. Consider a case-control study, with results as shown schematically in a 2×2 table (Table 2):

Table 2. Cross Tabulation of Cases and Controls by Exposure Status

	Cases (with disease)	Controls (no disease)
Exposed	<i>a</i>	<i>b</i>
Not exposed	<i>c</i>	<i>d</i>

In a case-control study, the odds ratio *OR* is the odds that a case was exposed divided by the odds that a control was exposed. Looking at Table 2, this ratio can be calculated as:

$$OR = \frac{a/c}{b/d} = \frac{ad}{bc}$$

Because we are multiplying two diagonal cells in the table and dividing by the product of the other two diagonal cells, the odds ratio is sometimes also called the cross-products ratio.

Consider the following hypothetical study: A researcher identifies 100 individuals with a disease who serve as cases and 100 people without the disease who serve as controls for her case-control study. Of the 100 cases (with disease), 40 were exposed to an agent under study and 60 were not. Among the control group, 20 people were exposed and 80 were not. The data can be presented in a 2×2 table (Table 3).

Table 3. Case-Control Study Outcome

	Cases (with disease)	Controls (no disease)
Exposed	40	20
Not exposed	60	80

The calculation of the odds ratio would be $OR = (40/60)/(20/80) = 2.67$.

If the disease is relatively rare in the general population (about 5% or less), the odds ratio is a good approximation of the relative risk. Thus, in our example, there is almost a tripling in the risk of the disease in those exposed to the agent relative to those who were not exposed.⁸⁸

88. The odds ratio is usually more extreme (farther away from the null of 1.0) compared to the relative risk. In other words, if a relative risk is above 1.0, the odds ratio will tend to be larger; if a relative risk is below 1.0, the odds ratio will tend to be smaller. As the disease in question becomes more common, the difference between the odds ratio and the relative risk grows.

Figure 3. Risks in exposed and unexposed groups.

Attributable Risk

A frequently used measurement of risk is the attributable risk (AR), also called the attributable proportion of risk, the etiologic fraction, or the attributable risk percent. This measure represents the proportion of disease among exposed individuals that can be attributed to the exposure⁸⁹ and therefore, if the association is causal, the proportion of disease that could potentially be prevented if exposure to the agent were eliminated (see Figure 3).⁹⁰

The reason the odds ratio approximates the relative risk when the incidence of disease is small can be demonstrated by comparing the relative risk of a cohort study with its odds ratio. Referring to Table 1, the odds that the exposed group developed the disease is d/b ; similarly, the odds that the unexposed group developed the disease is c/a ; thus the odds ratio is $(d/b)/(c/a) = ad/bc$. Recall the relative risk would be $[d/(b+d)] / [c/(a+c)] = [d(a+c)] / [c(b+d)]$. Thus, when the incidence of disease is low, i.e., c and d are small in relation to a and b , the relative risk will approximate the odds ratio of ad/bc . See Celentano & Szklo, *supra* note 37, at 248–50.

If the disease is not rare, the relative risk may be estimated from the odds ratio. The formula for this estimate takes into account the prevalence of the disease among the unexposed (P_0):

$$RR = OR / (1 - P_0 + (P_0 \times OR)).$$

In our example, if the disease had a 15% prevalence among the unexposed, the corresponding estimated relative risk would be $2.67 / (1 - 0.15 + (0.15 \times 2.67)) = 2.14$. Note that, as described above, with a relatively high prevalence the numerical value of the odds ratio is farther from the null—in this case, greater than—the numerical value of the estimated relative risk. See Robert L. Grant, *Converting an Odds Ratio to a Range of Plausible Relative Risks for Better Communication of Research Findings*, 348 Brit. Med. J. f7540 (2014), <https://doi.org/10.1136/bmj.f7450>.

89. Kenneth J. Rothman et al., *Measures of Effect and Measures of Association*, in Lash, *supra* note 50, at 79, 93–97; see also *Landrigan v. Celotex Corp.*, 605 A.2d 1079, 1086 (N.J. 1992) (illustrating that a relative risk of 1.55 corresponds to an attributable risk of approximately 35%).

90. Risk is not zero for the control group (those not exposed) when there are other causal chains that cause the disease that do not require exposure to the agent. For example, some birth defects are the result of genetic sources, which do not require the presence of any environmental agent. Also, some degree of risk in the control group may be the result of background exposure to

To determine the proportion of a disease that is attributable to an exposure, a researcher would need to know the risk of the disease in the exposed group and the risk of disease in the unexposed group. The attributable risk is

$$AR = \frac{(\text{risk in the exposed}) - (\text{risk in the unexposed})}{\text{risk in the exposed}}$$

The attributable risk can be calculated using the example described in the section titled “Relative Risk.” Suppose a researcher studies 100 individuals who are exposed to a substance and 200 who are not exposed. After one year, 40 of the exposed individuals are diagnosed as having a disease, and 20 of the unexposed individuals are also diagnosed as having the disease.

- The risk of disease in the exposed group is 0.4 (40 persons with the disease out of 100 who are exposed).
- The risk of disease in the unexposed group is 0.1 (20 persons with the disease out of 200 who are not exposed).
- The proportion of disease in the exposed group that is attributable to the exposure is $(0.4 - 0.1)/0.4 = 0.75$ or 75%.

This means that 75% of the disease in the exposed group is attributable to the exposure. We should emphasize here that attributable does not necessarily mean “caused by.” Up to this point, we have only addressed associations. Inferring causation from an association is addressed in the “General Causation” section below.

Internal and External Validity

Internal validity is concerned with whether the result of a study—an association, for example in an epidemiologic context—is an accurate assessment of the true association in the source population from which study participants were recruited. Various biases such as selection bias, confounding bias, and information bias (all discussed in the “Biases” section below) can affect internal validity. For example, if researchers interviewing participants in a case-control study know the participant’s disease status, they might subconsciously probe harder to find exposure to the agent in participants with the disease than in those without

the agent being studied. For example, nonsmokers in a control group may have been exposed to passive cigarette smoke, which is responsible for some cases of lung cancer and other diseases. *See Ethyl Corp. v. EPA*, 541 F.2d 1, 25 (D.C. Cir. 1976) (describing the difficulty of finding people without exposure to ubiquitously distributed agents). There are some diseases that do not occur without exposure to an agent; these are known as signature diseases.

disease. That would produce an inflated estimate of the real association and would compromise the study's internal validity.⁹¹

External validity concerns whether the study results can be generalized to a different population. In the multidistrict litigation involving the drug phenylpropanolamine (PPA) used as an appetite suppressant, an epidemiologic study found an odds ratio of 16.58 for hemorrhagic stroke.⁹² The study was limited to individuals between the ages of 18 and 49 and, because of the paucity of men who had used PPA-containing appetite suppressants, the analysis was limited to women. In the litigation that followed, the court was faced with whether the study could be used to support causation for those under the age of 18, those over the age of 49, or men.⁹³ That issue called into question the matter of external validity: the extrapolation of the study results to a population that was not a part of the study.

Sources of Error in Epidemiologic Studies

Incorrect study results can occur in a variety of ways. A study may find a positive association (relative risk greater than 1.0) when there is no true association. Or a study may erroneously find that there is no association when in reality there is one. A study may also find an association when one truly exists, but the association found may be greater or less than the real association.

Two general categories of phenomena can cause erroneous associations: chance and bias. Before any inferences about causation are drawn from a study, the possible impact of these phenomena must be examined.⁹⁴

The findings of a study may be the result of chance (also called sampling error or random error). In designing a study, the size of the sample can be

91. Any problem with a study's internal validity would also affect the validity of any attempt to extrapolate the study's results to a different population. As described in the next paragraph, this would create a problem of external validity in addition to the impact on internal validity.

92. See W.N. Kernan et al., *Phenylpropanolamine and the Risk of Hemorrhagic Stroke*, 343 NEJM 1826 (Dec. 21, 2000), <https://doi.org/10.1056/NEJM200012213432501>.

93. See *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1235 (W.D. Wash. 2003). There was additional evidence in the case that the court took into account; the description of the case in the text is a stylized one to concisely illustrate the idea of external validity.

94. See Philip Cole, *Causality in Epidemiology, Health Policy, and Law*, 27 Env't L. Rep. 10279, 10285 (1997); *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 955 (3d Cir. 1990) (recognizing and discussing random sampling error and then referring to other errors, such as systematic bias, that create as much or more error in the outcome of a study). See also *Daniels-Feasel v. Forest Pharms., Inc.*, No. 17 CV 4188-LTS-JLC, 2021 WL 4037820, at *2 (S.D.N.Y. Sept. 3, 2021) ("Where a positive association is observed, its validity is assessed by evaluating the role of possible alternative explanations, such as chance, bias, or confounding."). For a similar description of error in study procedure and random sampling, see Kaye & Stern, *supra* note 16, "What Inferences Can Be Drawn from the Data?"

increased to reduce (but not eliminate) the likelihood that a result may be due to chance. Statistical methods permit an assessment of the extent to which the results of a study may be due to chance, most often by computing a p -value and/or a confidence interval, which are closely related and are described in more detail in the “Sampling Error” section below.

Briefly, a calculated p -value is used to determine whether a study result is considered “statistically significant.” As described in more detail below, testing for statistical significance entails comparing the calculated p -value to a pre-selected threshold that enables an assessment of the role of random error in producing the study result. A result that is statistically significant is generally considered unlikely to be the result of chance, although any p -value threshold chosen is arbitrary.

A confidence interval provides information about the uncertainty (or precision) of an estimated measure of association (such as a relative risk or an odds ratio). A wide confidence interval suggests that chance is more likely to have an important impact on the estimate while a tight interval points to a likelihood of a smaller impact of chance and thus a more precise estimate.

We emphasize a point that those unfamiliar with statistical methodology frequently find confusing: That a study’s results are statistically significant says nothing about the magnitude of any association (i.e., the relative risk or odds ratio) or about the biological, clinical, or public health importance of the finding.⁹⁵ Significant, as used with the adjective statistically, does not mean “big” or “important.” A large study may find a statistically significant relationship that is quite modest in magnitude—for example, a relative risk of 1.05. Another study may find an association that is quite large—say, a relative risk of 10.0 or even higher—yet is not statistically significant because of the potential for random error due to a small sample size.⁹⁶ In short, *statistical significance is not about the size of the risk associated with an exposure.*⁹⁷

95. See Modern Scientific Evidence, *supra* note 3, § 5.36 at 435 (“Statisticians distinguish between ‘statistical’ and ‘practical’ significance. . . .”); Cole, *supra* note 94, at 10282. Suppose a study finds a statistically significant risk of 1.05. If that association applies to a rare, easily managed side effect of a medication prescribed to treat a common, debilitating illness, the finding might be more a reason for relief than for concern. But if 1.05 is the relative risk of a common, serious illness associated with ubiquitous exposure to an air pollutant, the finding might be cause for great concern despite the small magnitude of the relative risk. Alternatively, suppose a study finds a relative risk of 10.0 that is not statistically significant. If that relative risk applies to an invariably fatal condition associated with a small number of exposures to a new chemical that is poised to enter widespread use, the finding might suggest a need for caution or further investigation.

96. To find small effects that are statistically significant, larger sample sizes are required. When effects are larger, fewer subjects are required to produce statistically significant findings. For further explanation, see the section titled “Sampling Error” below.

97. Understandably, some courts have been confused about the relationship between statistical significance and the magnitude of the association. See, e.g., Hyman & Armstrong, P.S.C. v. Gunderson, 279 S.W.3d 93, 102 (Ky. 2008) (conflating the magnitude of the association with

Bias also can produce error in the outcome of a study. In epidemiology, as in science generally, bias refers to methodological issues that skew a study's results, with no connotation that a researcher has a subjective desire for, or interest in, a particular outcome. Bias encompasses any effect that tends to produce study results that differ from the true value in a systematic, rather than random, way. Thus, bias is also known as systematic error.

Epidemiologists attempt to minimize bias through their study designs, including data-collections protocols. Study designs are developed before researchers begin gathering data. However, some biases cannot be addressed at the design stage, and even the best-designed and conducted studies are likely to produce results that are biased to some extent. Consequently, after data collection is completed, statistical tools are often used to identify and correct for potential sources of bias. Epidemiologists may reanalyze a study's data to correct for a bias identified in a completed study or to validate the analytical methods used.⁹⁸ If correction (sometimes referred to as adjustment) for identified biases cannot be performed, epidemiologists can estimate whether the bias is likely to have inflated or diluted any association that may exist. Identification of uncorrected bias may enable an epidemiologist to make an assessment of the extent to which a study's conclusions are valid. Common biases and how they may produce invalid results are described in the "Biases" section.

Sampling Error⁹⁹

Before detailing the statistical methods used to assess sampling error (which we use synonymously with random error or chance), two concepts central to epidemiology and statistical analysis must be explained. Understanding these concepts should facilitate comprehension of the statistical methods. Epidemiologists often refer to true association (also called real association), which is the association that really exists between an agent and a disease in a given population and that might be found by a perfect (but nonexistent and impossible) study. The true association is a concept used in evaluating the results of a given study, even though its

whether it is statistically significant); *In re Pfizer Inc. Sec. Litig.*, 584 F. Supp. 2d 621, 634–35 (S.D.N.Y. 2008) (confusing the magnitude of the effect with whether the effect was statistically significant); *In re Joint E. & S. Dist. Asbestos Litig.*, 827 F. Supp. 1014, 1041 (S.D.N.Y. 1993) (concluding that any relative risk less than 1.50 is statistically insignificant), *rev'd on other grounds*, 52 F.3d 1124 (2d Cir. 1995). See generally Kaye & Stern, *supra* note 16, "Tests or Interval Estimates?"

98. E.g., Richard A. Kronmal et al., *The Intrauterine Device and Pelvic Inflammatory Disease: The Women's Health Study Reanalyzed*, 44 J. Clinical Epidemiology 109 (1991), [https://doi.org/10.1016/0895-4356\(91\)90259-C](https://doi.org/10.1016/0895-4356(91)90259-C) (a reanalysis of a study that found an association between the use of IUDs and pelvic inflammatory disease concluded that IUDs do not increase the risk of pelvic inflammatory disease).

99. For a bibliography on the role of statistical significance in legal proceedings, see Sanders, *supra* note 16, at 329 n.138.

value is unknown. By contrast, a study's outcome will produce an observed association, which is known.

Formal procedures for statistical testing begin with the null hypothesis, which posits that there is no true association (i.e., a relative risk of 1.0) between exposure to the agent and the disease under study. Data are gathered and analyzed to see whether they disprove the null hypothesis.¹⁰⁰ The data are subjected to statistical testing to assess the plausibility that any association found is a result of random error or whether, instead, the data support rejection of the null hypothesis.

The use of the null hypothesis for this testing should not be understood as the a priori belief of the investigator. When epidemiologists investigate an agent, it is usually because they hypothesize that the agent is a cause of some outcome. Nevertheless, in preparing their study designs, epidemiologists rely on the null hypothesis to test the plausibility that any association found in a study was the result of random error.¹⁰¹

False Positives and Statistical Significance

When a study results in a positive association (i.e., a relative risk greater than 1.0), epidemiologists try to determine whether that result represents a true association or is the result of random error. Random error can be illustrated by considering a fair coin (i.e., not modified to produce more heads than tails, or vice versa). On average, we would expect that coin tosses would yield half heads and half tails. But sometimes, a set of coin tosses might yield an unusual result—for example, six heads out of six tosses, an occurrence that, purely by chance, would result in less than 2% of a series of six tosses. In the world of epidemiology, sometimes the study findings, merely by chance, do not reflect the true relationships between an agent and outcome. Any single study—even a clinical trial—is in some ways analogous to a set of coin tosses, being subject to the play of chance. So, for example, even if the true relative risk (in the total population) were 1.0, an epidemiologic study might find an observed relative risk (in the study sample) greater than (or less than) 1.0 because of random error (i.e., chance).¹⁰² An erroneous conclusion that the null hypothesis is false (i.e., a conclusion that there is a different risk among those exposed to an agent relative to those that were

100. See, e.g., *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579, 593 (1993) (scientific methodology involves generating and testing hypotheses).

101. See *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 945 (3d Cir. 1990); *United States v. Philip Morris USA, Inc.*, 449 F. Supp. 2d 1, 706 n.29 (D.D.C. 2006); Stephen E. Fienberg et al., *Understanding and Evaluating Statistical Evidence in Litigation*, 36 *Jurimetrics J.* 1, 21–24 (1995), [https://doi.org/10.1016/S0015-7368\(91\)73152-6](https://doi.org/10.1016/S0015-7368(91)73152-6).

102. See *Magistrini v. One-Hour Martinizing Dry Cleaning*, 180 F. Supp. 2d 584, 592 (D.N.J. 2002) (citing the second edition of this reference guide).

unexposed when no difference actually exists) owing to random error is called a false-positive error (also called a Type I error or alpha error).

Common sense leads one to believe that a large enough sample of individuals must be studied if the study is to identify a relationship that truly exists between exposure to an agent and a disease. Common sense also suggests that by enlarging the sample size (the size of the study group), researchers can form a more accurate conclusion and reduce the chance of random error in their results. Both statements are correct and can be illustrated by a test to determine if a coin is fair. A test in which a fair coin is tossed 1,000 times is more likely to produce close to 50% heads than a test in which the coin is tossed only 10 times. By contrast, it is far more likely that a test of a fair coin with 10 tosses will by chance come up with (for example) 80% heads than will a test with 1,000 tosses. With large numbers, the outcome of the test is less likely to be influenced by random error, and the researcher would have greater confidence in the inferences drawn from the data.¹⁰³

Given a set of epidemiologic data, one might want to ask the straightforward, obvious question: What is the probability that an observed association reflects a real association that exists in the population from which the study subjects were drawn? But traditional statistical methods cannot answer this question.¹⁰⁴ Instead, researchers compute “*p*-values” that address a related but very different question: Assuming there really is no association in the population—referred to as the null hypothesis—how probable is it that one would find an association in the study sample at least as large as the observed association?¹⁰⁵

103. This explanation of numerical stability was drawn from Brief Amicus Curiae of Prof. Alvan R. Feinstein in Support of Respondent, *Daubert v. Merrell Dow Pharms., Inc.*, No. 92-102, 1993 WL 13006284, at *12–*13 (U.S. Jan. 19, 1993). See also *Allen v. United States*, 588 F. Supp. 247, 417–18 (D. Utah 1984), *rev’d on other grounds*, 816 F.2d 1417 (10th Cir. 1987) (observing that although “[s]mall communities or groups of people are deemed ‘statistically unstable’” and “data from small populations must be handled with care[, it] does not mean that [the data] cannot provide substantial evidence in aid of our effort to describe and understand events”); Shi En Kim, *Heads or Tails*, Sci. Am., Jan. 2024, at 12 (explaining that if a coin were tossed a million times, an observed deviation of even one percent, such as 510,000 heads and 490,000 tails, would very likely result from a small but real bias in the coin).

104. For a discussion of Bayesian statistics, which under certain conditions can provide information about this probability, see *infra* text accompanying footnotes 120 and 178 and the entry “Bayesian analysis” in the Glossary of Terms.

105. This methodology, known as hypothesis testing, is one of the most counterintuitive techniques in statistics. See *Modern Scientific Evidence*, *supra* note 3, § 5.36 at 359 (“it is easy to mistake the *p*-value for the probability that there is no difference”).

The *p*-value for a given study does not provide a rate of error or even a probability of error for an epidemiologic study. In *Daubert*, 509 U.S. at 593, the Court stated that “the known or potential rate of error” should ordinarily be considered in assessing scientific reliability. Epidemiology, however, unlike some other methodologies—fingerprint identification, for example—does not permit

A p -value represents the probability that an association equal to or more extreme than (i.e., greater for a positive association or smaller for an inverse association) the observed association could be found *if no association were in fact present*, that is, if the null hypothesis were true.¹⁰⁶ Thus, a p -value of 0.1 means that there is a 10% chance that, with no association being actually present in the population from which the study sample was drawn (i.e., under the null hypothesis), values at least as large as an observed relative risk above 1.0 could have occurred by random chance.¹⁰⁷

The smaller the p -value, the less likely it is that the null hypothesis is true. Epidemiologists use a convention that the p -value must fall below some specified threshold, known as alpha or the significance level, for the results of the study to be considered statistically significant.¹⁰⁸ Thus, an outcome is statistically significant when the observed p -value for the study falls below the preselected significance level.

Significance testing allows researchers to minimize false positive results. The most common significance level used in science is 0.05. As explained above, a p -value of 0.05 means that the probability of observing an association at least as large as that found in the study, when in truth there is no association, is

an assessment of its accuracy by testing against a known reference standard. A p -value provides information only about the plausibility of random Type I error given the study result, but the true relationship between agent and outcome remains unknown. A p -value provides no information about the plausibility of random Type II error (false negatives), which is discussed in the sections titled “False Negatives” and “Statistical Power” below. Moreover, a p -value provides no information about whether other sources of error exist and, if so, their magnitude. See sections titled “Biases” and “Conceptual Error” below. In short, for epidemiology, there is no way to determine a rate of error—even for the random error aspect of studies. See *Kumho Tire Co. v. Carmichael*, 526 U.S. 137, 151 (1999) (recognizing that for different scientific and technical inquiries, different considerations will be appropriate for assessing reliability); *Cook v. Rockwell Int’l Corp.*, 580 F. Supp. 2d 1071, 1100 (D. Colo. 2006) (“Defendants have not argued or presented evidence that . . . there is, in fact, a method by which an overall ‘rate of error’ can be calculated for an epidemiologic study.”).

106. See also Kaye & Stern, *supra* note 16, “ p -values, Significance Levels, and Hypothesis Tests” (the p -value reflects the implausibility of the null hypothesis).

107. Technically, a p -value of 0.1 means that if in fact there is no association, if the same study were to be repeated, 10% of such studies would be expected to yield an association the same as, or greater than, the one found in the study due to random error. The interpretation is similar for observed relative risks below 1.0: a p -value of 0.10 would represent a 10% chance that values equal or smaller would be due to random error. Note that the description here and in the text describes a “one-tailed” significance test. For an explanation of the distinction between one-tailed and two-tailed tests, see *infra* note 113.

108. *Cook*, 580 F. Supp. 2d at 1100–01 (discussing p -values and their relationship with statistical significance); *Allen v. United States*, 588 F. Supp. 247, 416–17 (D. Utah 1984), *rev’d on other grounds*, 816 F.2d 1417 (10th Cir. 1987) (discussing statistical significance and selection of a level of alpha); see also Sanders, *supra* note 16, at 343–44 (explaining alpha, beta, and their relationship to sample size); *Developments in the Law—Confronting the New Challenges of Scientific Evidence*, 108 Harv. L. Rev. 1481, 1535–36, 1540–46 (1995) [hereinafter *Developments in the Law*].

equal to 5%.¹⁰⁹ When examining effect modification¹¹⁰ (such as when an association may differ by sex, social class, or genetics), epidemiologists usually use a higher p -value, e.g., a p -value of 0.10. This helps compensate for the fact that statistical power¹¹¹ to detect effect modification is lower relative to that of the power to detect overall associations because stratifying by an effect modifier effectively reduces the sample size.¹¹²

Figure 4 presents a graphical depiction to assist understanding of significance testing. Under the null hypothesis, we assume that, if we performed many similar studies identical to the one for which we wish to estimate a p -value and graphed the frequency of their outcomes, we would expect to observe a normal (bell-shaped) distribution, with most results clustered near the null value (remember, we assume the null hypothesis) and only a few extreme results in the “tails,” far from the hypothesized null value, as depicted by the small shaded

109. This means that if one examined a large number of situations in which the true relative risk equals 1—meaning there is no association between any of the agents studied and the outcome of interest—on average 1 result in 20 nevertheless would show an association that is statistically significant at a .05 level. When researchers examine many possible associations that might exist in their data—known as data dredging—we should expect that even if there are no true causal relationships, those researchers will find statistically significant associations in 1 of every 20 associations examined. See Rachel Nowak, *Problems in Clinical Trials Go Far Beyond Misconduct*, 264 Sci. 1538, 1539 (1994), <https://doi.org/10.1126/science.8202708>. For an accessible discussion of this problem, see Andrew Gelman & Eric Loken, *The Statistical Crisis in Science*, 107 Am. Scientist (2014), <https://doi.org/10.1511/2014.111.460>.

In certain contexts, the sheer number of tests—and therefore the number of associations that would appear by chance—is so large that researchers apply much more stringent conventions for statistical significance. For example, researchers testing hundreds of thousands of genetic variations for association with disease typically accept as statistically significant only results that would appear by chance no more than once in every 20 million trials. See Laura Buzdugan et al., *Assessing Statistical Significance in Multivariable Genome Wide Association Analysis*, 32 Bioinformatics 1990, 1991 (2016) (“the multiple testing issue is resolved by applying a stringent significance threshold—most commonly 5×10^{-8} ”). Some researchers favor even greater stringency. Sara L. Pulit et al., *Resetting the Bar: Statistical Significance in Whole-Genome Sequencing-Based Association Studies of Global Populations*, 41 Genetic Epidemiology 145 (2016), <https://doi.org/10.1002/gepi.22032> (arguing for significance levels ten to fifty times more stringent). Even in this context, the “cut points” chosen for statistical significance “are somewhat arbitrary and do not reflect the potential clinical or biological importance of associations, nor do they account for the cost of false negatives.” John S. Witte & Duncan C. Thomas, *Genetic Epidemiology*, in Lash et al., *supra* note 50, at 963, 970. For discussion of false negatives, see section titled “False Negatives” below.

110. See the section titled “Effect Modification” below for further explanation.

111. See the section titled “Statistical Power” below.

112. As explained *infra* at text accompanying footnote 172, researchers study effect modification using stratification—separating the study participants into subgroups (strata). For example, 200 participants in a study might be stratified into two strata of 100 males and 100 females. Because the number of participants in each stratum is smaller than the size of the study as a whole, the study’s statistical power for each stratum is reduced. The effect is illustrated below in an example at the end of the section titled “Effect Modification.”

Figure 4. Hypothetical probability distribution under the null hypothesis for an estimated relative risk of 4.0.

ranges in Figure 4. A significance test is ordinarily two-tailed, as depicted in Figure 4.¹¹³

There is some controversy among epidemiologists and biostatisticians about the appropriate role of significance testing.¹¹⁴ To the strictest significance testers,

113. Two-tailed p -values assume that the direction of the association, either greater or less than the null of 1.0, is not known, and thus distribute the probabilities on both sides of the null. For example, if a study estimated a relative risk of 4.0, a two-tailed p -value would include the probability that, if the null hypothesis is true, the study would find a relative risk either equal to or larger than 4.0 (the observed value) or equal to or less than 0.25 (the inverse of the observed value, i.e., $1/4.0$). A one-tailed test, which is sometimes employed, considers only probabilities on the same side of the null as the study result. For a given alpha, a one-tailed test effectively doubles the probability of finding a significant effect in the hypothesized direction and is therefore controversial among epidemiologists and uncommon in epidemiologic studies. See *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1241 (W.D. Wash. 2003) (accepting the propriety of a one-tailed test for statistical significance in a toxic-substance case); *United States v. Philip Morris USA, Inc.*, 449 F. Supp. 2d 1, 701 (D.D.C. 2006) (explaining the basis for EPA's decision to use a one-tailed test in assessing whether secondhand smoke was a carcinogen). But see *Good v. Fluor Daniel Corp.*, 222 F. Supp. 2d 1236, 1243 (E.D. Wash. 2002) (concluding that, in the circumstances presented, a one-tailed test on which the expert relied was not valid). For more on the difference between one-tailed and two-tailed tests, see Kaye & Stern, *supra* note 16.

114. In 2019, *The American Statistician*, a journal of the American Statistical Society, published an editorial that contained numerous "don'ts" in using statistical significance that many had previously violated. R. Wasserstein et al., *Moving to a World Beyond $p < 0.05$* , 73 Am. Statistician 1 (Supp. 1, 2019). Some courts, contrary to the editorial's prescriptions, have used statistically significant results as a threshold for acceptability of a study. The leading case advocating statistically significant studies is *Brock v. Merrell Dow Pharms., Inc.*, 874 F.2d 307, 312 (5th Cir.), *amended*, 884 F.2d 167

any study whose p -value is greater than the level chosen for statistical significance should be rejected as inadequate to disprove the null hypothesis. However, the consensus among most epidemiologists is that conclusions about potential

(5th Cir. 1989). Overturning a jury verdict for the plaintiff in a Bendectin case, the court observed that no statistically significant study had been published that found an increased relative risk for birth defects in children whose mothers had taken Bendectin. A number of courts have followed the *Brock* decision or have indicated strong support for significance testing as a screening device. See, e.g., *In re Zolof* (Sertraline Hydrochloride) Prod. Liab. Litig., 26 F. Supp. 3d 449, 456, 465 (E.D. Pa. 2014) (ruling that an expert witness's reliance on non-statistically significant data was "not derived from principles and techniques of uncontroverted validity" and was a "departure from use of well-established epidemiological methods"); *Wagoner v. Exxon Mobil Corp.*, 813 F. Supp. 2d 771, 800 (E.D. La. 2011) ("An opinion on general causation is inadmissible if it rests entirely on studies that do not show statistically significant results.").

By contrast, a number of courts appear more cautious about using significance testing as a necessary condition, instead recognizing that assessing the likelihood of random error is important in determining the probative value of a study. In *Allen*, 588 F. Supp. at 417, the court stated, "The cold statement that a given relationship is not 'statistically significant' cannot be read to mean there is no probability of a relationship." The Third Circuit described confidence intervals (i.e., the range of values that would be found in similar studies as a result of chance, with a specified level of confidence) and their use as an alternative to statistical significance in *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 948–49 (3d Cir. 1990). See also, e.g., *In re Lipitor* (Atorvastatin Calcium) Mktg., Sales Prac. & Prods. Liab. Litig., 892 F.3d 624, 642 (4th Cir. 2018) ("[W]e decline to establish a bright-line rule requiring experts to rely only on evidence that is statistically significant or else have their opinions excluded."); *Milward v. Acuity Specialty Prod. Grp., Inc.*, 639 F.3d 11, 24–25 (1st Cir. 2011) ("the district court read too much into the paucity of statistically significant epidemiological studies" since it would be "very difficult to perform an epidemiological study of the causes of [the disease] that would yield statistically significant results").

In *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993), although the trial court had relied in part on the absence of statistically significant epidemiologic studies, the Supreme Court did not explicitly address the matter. One commentator concluded that "*Daubert* did not set a threshold level of statistical significance either for admissibility or for sufficiency of scientific evidence." *Developments in the Law*, *supra* note 108, at 1535–36, 1540–46. The Supreme Court in *General Electric Co.*, 522 U.S. at 145–47, adverted to the lack of statistical significance in one study relied on by an expert as a ground for ruling that the district court had not abused its discretion in excluding the expert's testimony. In a different context—securities fraud—the Supreme Court held that a lack of statistical significance in adverse event reports did not disqualify them from being "material and requiring disclosure." *Matrixx Initiatives, Inc. v. Siracusano*, 563 U.S. 27 (2011). In the course of its opinion, the Court explained:

A lack of statistically significant data does not mean that medical experts have no reliable basis for inferring a causal link between a drug and adverse events. As *Matrixx* itself concedes, medical experts rely on other evidence to establish an inference of causation. We note that courts frequently permit expert testimony on causation based on evidence other than statistical significance. We need not consider whether the expert testimony was properly admitted in those cases, and we do not attempt to define here what constitutes reliable evidence of causation. It suffices to note that, as these courts have recognized, "medical professionals and researchers do not limit the data they consider to the results of randomized clinical trials or to statistically significant evidence."

Matrixx, 563 U.S. at 40–41 (citations and footnote omitted).

associations should not rely on strict significance testing¹¹⁵ and that it is inappropriate either to reject all results that fail to meet the specified p -value or to accept all results that do meet this level.¹¹⁶ Epidemiologists have become increasingly sophisticated in addressing the issue of random error and examining the data from a study that may provide information about the relation between an agent and a disease, without the necessity of basing their conclusions solely on statistical significance.¹¹⁷ Meta-analysis, a method for pooling the results of multiple studies, sometimes can ameliorate concerns about random error present in a single study.¹¹⁸

Calculation of a confidence interval permits a more refined assessment of appropriate inferences about the association found in an epidemiologic study.¹¹⁹ A confidence interval represents a range of possible values calculated from the

115. In addition to criticism of significance testing, many lawyers, judges, and legal academics have incorrectly stated that using an alpha of 0.05 for statistical significance testing imposes a burden of proof on the plaintiff far higher than the civil burden of a preponderance of the evidence (i.e., greater than 50%). See Michael D. Green, *Science Is to Law as the Burden of Proof Is to Significance Testing*, 37 *Jurimetrics J.* 205, 221 n.67 (1997) (book review) (citing many examples).

To fully explain why this comparison is mistaken would require more space and detail than is feasible here. We sketch out a brief explanation. First, using an alpha of 0.50 would not be equivalent to saying that the probability that the association found is real is 50%, and the probability that it is a result of random error is 50%. Statistical methodology does not permit assessment of those probabilities. Second, significance testing only bears on whether the observed magnitude of association arose as a result of random chance, not on whether the null hypothesis is true. Third, using stringent significance testing to avoid false-positive error comes at a complementary cost of inducing false-negative error. Fourth, alpha does not address the likelihood that a plaintiff's disease was caused by exposure to the agent; the magnitude of the association bears on that question. See section titled "Specific Causation" below. See Green, *supra* note 70, at 686–89; see also David H. Kaye, *Apples and Oranges: Confidence Coefficients and the Burden of Persuasion*, 73 *Cornell L. Rev.* 54, 66 (1987); Kaye & Stern, *supra* note 16, "Evaluating Hypothesis Tests"; *Turpin v. Merrell Dow Pharms., Inc.*, 959 F.2d 1349, 1357 n.2 (6th Cir. 1992); *cf.* *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 959 n.24 (3d Cir. 1990) ("The relationship between confidence levels and the more likely than not standard of proof is a very complex one . . . and in the absence of more education than can be found in this record, we decline to comment further on it.").

116. For a hypercritical assessment of statistical significance testing by two economists that nevertheless identifies much inappropriate overreliance on it, see Stephen T. Ziliak & Deidre N. McCloskey, *The Cult of Statistical Significance* (2008).

117. See Sanders, *supra* note 16, at 342 (describing the improved handling and reporting of statistical analysis in studies of Bendectin after 1980).

118. See section titled "Methods for Synthesizing or Combining the Results of Multiple Studies" below.

119. Kenneth Rothman, Professor of Public Health at Boston University and Adjunct Professor of Epidemiology at the Harvard School of Public Health, is one of the leaders in advocating the use of confidence intervals and rejecting strict significance testing. See *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 947 (3d Cir. 1990) (discussing Rothman's views on the appropriate level of alpha and the use of confidence intervals); *Turpin v. Merrell Dow Pharms., Inc.*, 959 F.2d 1349, 1353–54 n.1 (6th Cir. 1992) (discussing the relationship among confidence intervals, alpha, and statistical power). See also *Cook v. Rockwell Int'l Corp.*, 580 F. Supp. 2d 1071, 1100–01 (D. Colo. 2006) (discussing confidence intervals, alpha, and significance testing). For a discussion of

results of a study. For example, a 95% confidence interval signifies that 95% of the confidence intervals generated by multiple identical studies would include the true value. The width of the interval reflects random error. The narrower the confidence interval, the more statistically stable the results of the study.

The advantage of a confidence interval is that it displays more information than significance testing. Statistically significant does not convey the magnitude of the association found in the study or reveal how statistically stable that association is. A confidence interval shows boundaries of the relative risk (or other measure of association) based on selected levels of alpha or statistical significance. Just as the p -value does not provide the probability that the risk estimate found in a study is correct, the confidence interval does not provide the range within which the true risk is likely to lie. In other words, it is a misconception to interpret a 95% confidence interval as representing an interval within which the true value has a 95% probability of being found. Though some types of statistical analyses (referred to as Bayesian statistics) can generate intervals with this interpretation (referred to as credible intervals), most published research does not.¹²⁰ An example of two confidence intervals that might be calculated for a given relative risk is displayed in Figure 5.

Figure 5. 90% and 95% confidence intervals for a hypothetical study with a relative risk of 1.5.

The confidence intervals shown in Figure 5 are for a hypothetical study that found a relative risk of 1.5, with boundaries of 0.8 to 3.4 when alpha is set to 0.05 (equivalently, a confidence level of 0.95), and with boundaries of 1.1 to 2.2 when alpha is set to 0.10 (equivalently, a confidence level of 0.90). The confidence interval for alpha equal to 0.10 is narrower because it encompasses only

the use of confidence intervals in evaluating sampling error more generally than in the epidemiologic context, see Kaye & Stern, *supra* note 16, “What Is the Confidence Interval?”

120. See Jonathan A.C. Sterne & George Davey Smith, *Sifting the Evidence: What’s Wrong with Significance Tests*, 322 *BMJ* 226, 228 (2001) (comparing frequentist significance testing with Bayesian statistical approaches).

90% of the expected intervals. By contrast, the confidence interval for alpha equal to 0.05 includes the expected outcomes for 95% of the intervals. To generalize this point, the lower the alpha chosen (and therefore the more stringent the exclusion of positive results as possible random error), the wider the confidence interval. At a given alpha, the width of the confidence interval is determined by sample size. All other things being equal, the larger the sample size, the narrower the confidence boundaries (indicating greater numerical stability or precision). For a given risk estimate, a narrower confidence interval reflects a decreased likelihood that an association found in a particular study would occur by chance if the true association is 1.0.¹²¹

For the example in Figure 5, the boundaries of the confidence interval with alpha set at 0.05 encompass a relative risk of 1.0, and the result would be said not to be statistically significant at the 0.05 level. Alternatively, if the confidence boundaries are defined as an alpha equal to 0.10, then the confidence interval no longer includes a relative risk of 1.0, and the result could be described as statistically significant at the 0.10 level. Common practice in epidemiologic studies is to estimate 95% confidence intervals.

False Negatives

As Figure 5 illustrates, false positives can be reduced by adopting more stringent values for alpha, which increases the likelihood that a result will fail the selected test of statistical significance. Using an alpha of 0.05 will result in fewer false positives than using an alpha of 0.10. An alpha of 0.01 or 0.001 would produce even fewer false positives.¹²² The tradeoff for reducing false positives is an increase in false-negative errors (also called beta errors or Type II errors¹²³). This concept reflects the possibility that a study will be interpreted as negative (providing no grounds to reject the null hypothesis), when in fact there is a true

121. Where multiple epidemiologic studies are available, a technique known as meta-analysis may be used to combine the results of the studies (*see* section titled “Methods for Synthesizing or Combining the Results of Multiple Studies” below), thereby reducing the numerical instability of all the studies. *See generally* Diana B. Petitti, *Meta-Analysis, Decision Analysis, and Cost-Effectiveness Analysis: Methods for Quantitative Synthesis in Medicine* (2d ed. 2000).

122. As described above, *supra* note 109, in genome-wide association studies, which search the entire human genome to see if variations in genes are associated with variable disease risk, alpha is commonly set at 5×10^{-8} , allowing one false positive per 20 million tests. Some researchers, worried that such stringent significance testing causes too many real associations to be rejected as potential chance results, have proposed ameliorative approaches. *See* Shrahyashi Biswas et al., *A Framework for Pathway Knowledge Driven Prioritization in Genome-wide Association Studies*, 44 *Genetic Epidemiology* 841 (2020), <https://doi.org/10.1002/gepi.22345>.

123. *See* A Dictionary of Epidemiology 99 (Miquel Porta et al. eds., 6th ed. 2014).

association of a specified magnitude.¹²⁴ The probability of such an error, commonly called beta in statistical analyses, can be calculated for any study.

Statistical Power

When a study fails to find a statistically significant association, an important question is whether the result tends to exonerate the agent's toxicity or is essentially inconclusive with regard to toxicity.¹²⁵ The concept of statistical power can be helpful in evaluating whether a study's results, if not statistically significant, are exonerative or inconclusive.¹²⁶

The power of a study is the probability of finding a statistically significant association of a given magnitude (if it exists). The power of a study depends on several factors: the sample size; the level of alpha (or statistical significance) specified; the background incidence of disease; and the specified magnitude of the association (i.e., the size of the relative risk) that the researcher would like to detect.¹²⁷ Power curves can be constructed that show the likelihood of finding

124. See also *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 947 (3d Cir. 1990); *In re Testosterone Replacement Therapy Prods. Liab. Litig. Coordinated Pretrial Proc.*, No. 14 C 1748, 2017 WL 1833173, at *12 n.12 (N.D. Ill. May 8, 2017) (concluding expert's testimony comparing likelihood of Type I and Type II errors "will be helpful to the jury").

125. Even when a study or body of studies tends to exonerate an agent, that does not establish that the agent is absolutely safe. See *Cooley v. Lincoln Elec. Co.*, 693 F. Supp. 2d 767 (N.D. Ohio 2010). Epidemiology is not able to provide such evidence.

126. See Fienberg et al., *supra* note 101, at 22–23; Sander Greenland, *Null Misinterpretation in Statistical Testing and Its Impact on Health Risk Assessment*, 53 Preventative Med. 225 (2011), <https://doi.org/10.1016/j.jymed.2011.08.010> (explaining that statistical nonsignificance does not necessarily provide evidence for the null hypothesis and identifying such errors in reasoning). Thus, in *Smith v. Wyeth-Ayerst Labs. Co.*, 278 F. Supp. 2d 684, 693 (W.D.N.C. 2003) and *Cooley v. Lincoln Elec. Co.*, 693 F. Supp. 2d 767, 773 (N.D. Ohio 2010), the courts recognized that the power of a study was critical to assessing whether the failure of the study to find a statistically significant association was exonerative of the agent or inconclusive. See also *Procter & Gamble Pharms., Inc. v. Hoffmann-LaRoche Inc.*, No. 06 CIV. 0034 (PAC), 2006 WL 2588002, at *32 n.16 (S.D.N.Y. Sept. 6, 2006) (discussing power curves and quoting the second edition of this reference guide); *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1243–44 (W.D. Wash. 2003) (explaining expert's testimony that "statistical reassurance as to lack of an effect would require an upper bound of a reasonable confidence interval close to the null value"); *Ruff v. Ensign-Bickford Indus., Inc.*, 168 F. Supp. 2d 1271, 1281 (D. Utah 2001) (explaining why study should be treated as inconclusive rather than exonerative based on small number of subjects in the study).

127. See Malcolm Gladwell, *How Safe Are Your Breasts?*, New Republic, Oct. 24, 1994, at 22, 26, <https://perma.cc/83AP-4AGM>; Kenneth J. Rothman & Timothy L. Lash, *Precision and Study Size*, in Lash et al., *supra* note 50, at 333, 354–55. For continuous health outcomes such as child IQ, the magnitude of the association is measured differently (see *supra* text accompanying footnotes 75–76 and *infra* entry "beta coefficient" in the Glossary of Terms), and instead of background incidence the statistical power would depend in part on the background variability of the outcome.

any given relative risk in light of these factors. Often, power curves are used in the design of a study to determine what size a study population should be.¹²⁸

The power of a study is the complement of beta ($1-\beta$). Thus, a study with a likelihood of 0.25 of failing to detect a true relative risk of 2.0¹²⁹ or greater has a power of 0.75. This means the study has a 75% chance of detecting a true relative risk of 2.0. If the power of a null study to find a relative risk of 2.0 or greater is low, it has substantially less probative value than a study with similar results but a higher power.¹³⁰

Choosing the sample size is the main way in which a researcher can affect the power of the study. Because studies with larger sample sizes are more powerful than studies with smaller sample sizes (everything else being equal), a null study with a large sample size is given more credence than a similar null study with a smaller sample size.¹³¹

Biases

Other than sampling error, another reason an epidemiologic study might find an invalid or inaccurate association is systematic error or bias, as distinguished from random error. Bias may arise in the design or conduct of a study, data collection, or data analysis. Some biases (such as confounding, described below) may also be inherent to the natural relation between the agent of interest and the disease under study.

The meaning of scientific bias differs from conventional (and legal) usage, in which bias refers to a partisan point of view.¹³² When scientists use the term *bias*, they refer to anything that results in a systematic (nonrandom) error in a study result and thereby compromises the study's validity. The statistical measures that address possible sampling error—significance tests, confidence intervals, and power—do not address systematic error (bias), because bias does not result from random chance in the selection of study subjects.¹³³

128. For examples of power curves, see Kenneth J. Rothman, *Modern Epidemiology* 80 (1986); Pagano & Gauvreau, *supra* note 86, at 239. For a different graphical presentation showing how a smaller study size results in a wider 95% confidence interval for a given level of absolute and relative risk, see Rothman & Lash, *supra* note 127, at 360.

129. We use a relative risk of 2.0 for illustrative purposes because of the legal significance courts have attributed to this magnitude of association. See section titled “Specific Causation” below.

130. See also Kaye & Stern, *supra* note 16; section titled “Effect Modification” below.

131. See *id.* for a more detailed discussion of statistical power.

132. See A Dictionary of Epidemiology, *supra* note 123, at 21; Edmond A. Murphy, *The Logic of Medicine* 239–62 (1976).

133. See Green, *supra* note 70, at 667–68; Vincent M. Brannigan et al., *Risk, Statistical Inference, and the Law of Evidence: The Use of Epidemiological Data in Toxic Tort Cases*, 12 *Risk Analysis* 343, 344–45 (1992), <https://doi.org/10.1111/j.1539-6924.1992.tb00686.x>. Contrary to the statement in

Most epidemiologic studies have some degree of bias that may affect the outcome. If major bias is present, it may invalidate the study results. Identifying biases, however, can be challenging and requires expertise in both epidemiologic methods as well as the subject matter at hand. In reviewing the validity of an epidemiologic study, the epidemiologist should identify potential biases and analyze the amount or kind of error that might have been induced by the bias. In some cases, the potential direction of the bias can be determined and, depending on the specific type of bias, it may exaggerate the real association, dilute it, completely mask it, or even reverse its direction.

Biases are generally classified in three categories: selection bias, information bias, and confounding bias. Selection bias can result from differences between individuals selected for a study and the larger population about which researchers want to make inferences based on the study results. Information bias can arise from errors in measuring exposure, disease, or other relevant variables. Confounding bias can occur if other causal factors influence the association between exposure to an agent and a disease.

Selection Bias

Selection bias refers to the error in an observed association that results from the method of selection of study participants, such as cases and controls (in a case-control study) or exposed and unexposed individuals (in a cohort study). Selection bias can occur in several ways. One common source of selection bias is the existence of non-random differences between individuals who are selected as study participants and those who are not.¹³⁴

The selection of an appropriate control group has been described as the Achilles' heel of a case-control study.¹³⁵ Controls should be drawn from the same

at least one early toxic tort case, *see, e.g., Brock v. Merrell Dow Pharms., Inc.*, 874 F.2d 307, 312 (5th Cir. 1989), a study's use of confidence intervals cannot "incorporate the possibility" of bias in the data. A statistically significant result with a narrow 95% confidence interval could be incorrect if bias exists. *See In re Zolof (Sertraline Hydrochloride) Prods. Liab. Litig.*, 858 F.3d 787, 793 (3d Cir. 2017) ("If a causal connection does not actually exist, significant findings can still occur due to, *inter alia*, inability to control for a confounding effect or detection bias.").

134. In *In re "Agent Orange" Prod. Liab. Litig.*, 597 F. Supp. 740, 783 (E.D.N.Y. 1985), *aff'd*, 818 F.2d 145 (2d Cir. 1987), the court expressed concern about selection bias. The exposed cohort consisted of young, healthy men who served in Vietnam. Comparing the mortality rate of the exposed cohort and that of a control group made up of civilians might have resulted in error that was a result of selection bias. Failing to account for health status as an independent variable tends to understate any association between exposure and disease in studies in which the exposed cohort is healthier. *See also In re Baycol Prods. Litig.*, 532 F. Supp. 2d 1029, 1043 (D. Minn. 2007) (upholding admissibility of testimony by expert witness who criticized study based on selection bias).

135. William B. Kannel & Thomas R. Dawber, *Coffee and Coronary Disease*, 289 NEJM 100 (1973) (editorial), <https://doi/full/10.1056/NEJM197410242911703>.

source population (a concept often referred to as the study base) that produced the cases. Doing so avoids the possibility that the controls will have different risk factors for the disease than the cases. Selecting control participants becomes problematic if the control participants are selected for reasons that are related to their exposure (or lack thereof) to the agent being studied. For example, a study of the effect of smoking on heart disease will suffer selection bias if subjects of the study are volunteers and the decision to volunteer is affected by both being a smoker (perhaps smokers are more likely to choose to participate in a study due to concerns about their health) and having a family history of heart disease (which increases the probability that they will suffer from the disease due to genetics). In this case, the association will be biased upward because smokers with higher probabilities of heart disease will be more likely to self-select for the study.

Hospital-based studies, which are relatively common among researchers located in medical centers, illustrate the problem. Suppose an association is found between coffee drinking and coronary heart disease in a study using hospital patients as controls. The problem is that the hospitalized control group may include individuals who had been advised against drinking coffee for medical reasons, such as to prevent the aggravation of a peptic ulcer. In other words, the controls may become eligible for the study because of their medical condition, which is in turn related to their exposure status—their likelihood of avoiding coffee. If this is true, the amount of coffee drinking in the control group would understate the extent of coffee drinking expected in people who do not have the disease and thus would bias upwardly (i.e., exaggerate) any odds ratio observed.¹³⁶ Bias in hospital studies may also understate the true odds ratio when the exposures at issue increase the likelihood of cases being hospitalized and also contribute to the controls' chances of hospitalization.

Just as cases and controls in case-control studies should be selected independently of their exposure status, the exposed and unexposed participants in cohort studies should be selected independently of their disease risk.¹³⁷ For example, if women with hysterectomies are overrepresented among exposed (smoking) women in a cohort study of the connection between smoking and cervical

136. Hershel Jick et al., *Coffee and Myocardial Infarction*, 289 NEJM 63 (1973), <https://doi.org/10.1056/NEJM197307122890203> (finding an association between coffee drinking and coronary heart disease using hospital patients for controls).

137. Selection bias can introduce confounding factors (see section titled “Effect Modification” below) when unexposed controls may differ from the exposed cohort because exposure is associated with other risk (or protective) factors. Investigators can attempt to measure and adjust for those differences, as explained in the section titled “Effect Modification” below. See also Martha J. Radford & JoAnne M. Foody, *How Do Observational Studies Expand the Evidence Base for Therapy?*, 286 JAMA 1228 (2001), <https://doi.org/10.1001/jama.286.10.1228> (discussing the use of propensity analysis to adjust for potential confounding and selection biases that may occur from nonrandomization in observational epidemiology).

cancer, this could understate the association between the exposure and the disease. This is so because women who have a hysterectomy cannot develop cervical cancer so the overrepresentation of women with hysterectomies would reduce the number of smoking women who develop cervical cancer in the study. If exposure to the agent is also related to participation in the study, selection bias could occur. For example, if women who are more health-conscious (and therefore are less likely to smoke) were also more likely to enroll in the study, a spurious association would be created between smoking and cervical cancer.

A further source of selection bias occurs when those selected to participate decline to participate or drop out before the study is completed. Many studies have shown that individuals who choose to participate or remain in studies over time differ substantially from those who do not. If a substantial portion of individuals declines to participate, the researcher should investigate whether those who declined are different from those who agreed. If data are available on non-participants, the researcher can compare relevant characteristics of those who participate with those who do not, to show the extent to which the two groups are comparable. Similarly, if a significant number of subjects drop out of a study before completion, the remaining subjects may not be representative of the original study populations. The researcher should examine whether that is the case.

The fact that a study may suffer from selection bias does not necessarily invalidate its results. A number of factors may suggest that a bias, if present, had only a limited effect. If the association is particularly strong, for example, bias is less likely to account for all of it. In addition, a consistent association across different control groups suggests that possible biases applicable to a particular control group are not invalidating. Similarly, a dose-response relationship (see section titled “Dose-Response Relationship” below) found among multiple groups exposed to different doses of the agent may provide additional evidence that biases applicable to the exposed group are not a major problem. However, the converse may not necessarily be true as the risk of disease associated with some agents may not consistently increase with exposure level, a concept referred to as nonlinearity.¹³⁸ Finally, it is important to note that if data are available about nonparticipants or those lost to follow-up, statistical methods can be applied to mitigate selection bias.

Information Bias

Information bias is a result of inaccurate information primarily about either the disease or the exposure status of the study participants.¹³⁹ In assessing whether the data may reflect inaccurate information, one must assess whether the data

138. See *infra* notes 237–41 and accompanying text.

139. Incorrect information about potential confounders can also bias the results of a study.

were collected from objective and reliable sources. Medical records, government documents, employment records, death certificates, and interviews are examples of data sources that are used by epidemiologists to measure either exposure or disease status. The accuracy of a particular source may affect the validity of a research finding. For example, using employment records to gather information about exposure to narcotics probably would lead to inaccurate results, because employees tend to keep such information private. If the researcher uses an unreliable source of data, the study may not be useful.

The kinds of quality-control procedures used may affect the accuracy of the data. For data collected by interview, quality-control procedures should probe the reliability of the individual and whether the information is verified by other sources whenever possible. For data collected and analyzed in the laboratory, quality-control procedures should assess the validity and reliability of the laboratory tests.

Exposure information bias

Though information bias may affect the results of a study of any study design, this category of bias (exposure information bias) is an important consideration for retrospective studies, such as case-control studies, where researchers depend on information from the past to determine exposure.¹⁴⁰ In some situations, the researcher may be required to interview the subjects to determine past exposures, thus relying on the subjects' memories. Research has shown that individuals with disease (cases) tend to recall past exposures more readily than individuals with no disease (controls);¹⁴¹ this creates a potential for a type of information bias called recall bias.

For example, consider a case-control study conducted to examine the cause of congenital malformations. The epidemiologist is interested in whether the malformations were caused by an infection during the mother's pregnancy. A group of mothers of infants with malformations (cases) and a group of mothers of infants with no malformation (controls) are interviewed regarding infections

140. Information bias can be a problem in cohort studies as well. When exposure is determined retrospectively, there can be a variety of impediments to obtaining accurate information. Similarly, when disease status is determined retrospectively, bias is a concern. The determination that asbestos is a cause of mesothelioma was hampered by inaccurate death certificates that identified lung cancer rather than mesothelioma, a rare form of cancer, as the cause of death. See I.J. Selikoff et al., *Mortality Experience of Insulation Workers in the United States and Canada*, 220 *Annals N.Y. Acad. Sci.* 91, 110–11 (1979), <https://doi.org/10.1111/j.1749-6632.1979.tb18711.x>; David E. Lilienfeld & Paul D. Gunderson, *The "Missing Cases" of Pleural Malignant Mesothelioma in Minnesota, 1979–81: Preliminary Report*, 101 *Pub. Health Rep.* 395, 397–98 (1986).

141. Steven S. Coughlin, *Recall Bias in Epidemiological Studies*, 43 *J. Clinical Epidemiology* 87 (1990).

during pregnancy. Mothers of children with malformations may recall an inconsequential fever or runny nose during pregnancy that readily would be forgotten by a mother who had a normal infant.¹⁴² Even if in reality the infection rate in mothers of children with malformations is no different from the rate in mothers of normal children, the result in this study would be an apparently higher rate of infection in the mothers of the children with the malformations solely on the basis of recall differences between the two groups.¹⁴³

The issue of recall bias can sometimes be addressed by finding a second source of data to validate the subject's response (e.g., blood-test results from pre-natal visits or medical records that document symptoms of infection).¹⁴⁴ Alternatively, the mothers' responses to questions about other exposures that were not

142. Recall bias among parents whose babies had birth defects was a prominent issue in Bendectin cases. See, e.g., *Brock*, 874 F.2d at 311–12 (discussing recall bias among women who bear children with birth defects); *Lynch v. Merrell-National Labs.*, 830 F.2d 1190, 1195 (1st Cir. 1987) (discussing a study's attempt to “wash out ‘maternal-recall bias’”).

143. In a case similar to this hypothetical, *Newman v. Motorola, Inc.*, 218 F. Supp. 2d 769, 778 (D. Md. 2002), the court considered a study of the effect of cell phone use on brain cancer and concluded that there was good reason to suspect that recall bias affected the results of the study, which found an association between cell phone use and cancers on the side of the head where the cell phone was used but no association between cell phone use and overall brain tumors. The court excluded plaintiff's proposed expert testimony on causation. *Id.* at 783.

144. Two researchers who used a case-control study to examine the association between congenital heart disease and the mother's use of drugs during pregnancy corroborated interview data with the mother's medical records. See Sally Zierler & Kenneth J. Rothman, *Congenital Heart Disease in Relation to Maternal Use of Bendectin and Other Drugs in Early Pregnancy*, 313 NEJM 347, 347–48 (1985). Courts have considered researchers' varied efforts to determine the extent to which recall bias affected study results. For example, in one case plaintiffs' experts “pointed to studies that sought to validate self-reports of pesticide exposure and that found similar recall accuracy between cases and controls.” *In re Roundup Prods. Liab. Litig.*, 390 F. Supp. 3d 1102, 1121 (N.D. Cal. 2018). In multidistrict litigation alleging that prolonged perineal use of talcum powder products caused ovarian cancer, an expert witness for plaintiffs acknowledged the possibility that recall bias affected the results of case-control studies, but opined that the possibility could be discounted because similar results were found in data collected both before and after widespread media coverage of the purported causal link. *In re Johnson & Johnson Talcum Powder Mktg., Sales Pracs., & Prods. Litig.*, 509 F. Supp. 3d 116, 167 (D.N.J. 2020). The court concluded that “Defendants and their experts may disagree with Plaintiffs' general causation experts' assessment of recall bias in the case-control studies, but that does not render their opinions unreliable under *Daubert*.” *Id.* at 168. In another talcum powder case, plaintiffs relied on a case-control study in which the researchers lacked an independent source of data on the study subjects' talcum powder use. But the researchers relied on a study of a different exposure, “in which retrospective recall could be compared to verifiable prospective data,” to provide a surrogate baseline measurement of inaccurate recall. *Carl v. Johnson & Johnson*, 237 A.3d 308, 327 (N.J. Super. Ct. App. Div. 2020). The researchers performed a sensitivity analysis that showed that even if their study suffered from twice as much recall bias, their result would still be statistically significant. *Id.* The court reversed the trial judge's exclusion of plaintiffs' expert testimony. *Id.* at 344.

expected to cause the disease may shed light on whether bias affected the recall of the relevant exposures.¹⁴⁵

Bias may also result from reliance on interviews with surrogates who are individuals other than the study subjects. This is often necessary when, for example, a subject (in a case-control study) has died of the disease under investigation or may be too ill to be interviewed.

The quality of a study's assessment of participants' exposure can affect the credibility of an association with a health outcome.¹⁴⁶ The extent of exposure¹⁴⁷ can be obtained from a number of different sources, each of which has limitations and strengths.¹⁴⁸

For estimating past exposures, epidemiologists often use indirect measures of exposure, such as interviewing workers and reviewing employment records. For

145. Analogously, an expert testified that because recall bias would be expected to affect reported exposures for people with any type of cancer, concerns about recall bias were diminished where "epidemiology studies on the whole observed associations only between" exposure to an herbicide and a particular type of cancer, rather than with "the other cancers about which participants were asked." *In re Roundup Prods. Liab. Litig.*, 390 F. Supp. 3d 1102, 1121 (N.D. Cal. 2018). The court concluded that "concerns about recall bias in these studies do not demand that a reliable expert opinion meaningfully discount the body of case-control studies when assessing causation." *Id.*

146. The quality of exposure assessment in an epidemiologic study should be distinguished from the issue of the quality of the evidence of the extent of the plaintiff's exposure, an issue that often arises in environmental-exposure cases. *See infra* note 150.

147. The exposure "dose" is defined in various ways, but dose often refers to the intensity or magnitude of exposure multiplied by the time exposed. *See* Bernard D. Goldstein, *Toxic Torts: The Devil Is in the Dose*, 15 J.L. & Pol'y 551, 554 (2008) ("Dose is defined as concentration multiplied by frequency or duration—it is not just the exposure level at any one point in time."). Other definitions of dose may be more appropriate in light of the biological mechanism of the disease. *See* Emily White et al., *Principles of Exposure Measurement in Epidemiology: Collecting, Evaluating, and Improving Measures of Disease Risk Factors* (2d ed. 2008); National Research Council, *Exposure Science in the 21st Century* (2012). *See also* *Gates v. Rohm & Haas Co.*, 655 F.3d 255, 260 (3d Cir. 2011) (affirming district court decision that an expert report that assumed a constant and average value of air pollutant exposure during lengthy time periods, which is considered "overly simplistic," was insufficient evidence to establish dose). For a discussion of the difficulties of determining dose from atomic fallout, *see Allen*, 588 F. Supp. 247, 425–26, *rev'd on other grounds*, 816 F.2d 1417 (10th Cir. 1987).

The timing of exposure in relation to the life course may also be critical, especially if the disease of interest is a birth defect. In *Smith v. Ortho Pharm. Corp.*, 770 F. Supp. 1561, 1577 (N.D. Ga. 1991), the court criticized a study for its inadequate measure of exposure to spermicides. The researchers had defined exposure as receipt of a prescription for spermicide within 600 days of delivery, but this definition of exposure is too broad because environmental agents are likely to cause birth defects only during a narrow band of time.

148. *See In re Paoli R.R. Yard PCB Litig.*, No. 86-2229, 1992 U.S. Dist. LEXIS 18430, at *9–*11 (E.D. Pa. Oct. 21, 1992) (discussing valid methods of determining exposure to chemicals). Exposure science is a discipline that assesses exposure and its extent and is addressed in another reference guide in this manual. *See* M. Elizabeth Marder & Joseph V. Rodricks, *Reference Guide on Exposure Science and Exposure Assessment*, "Understanding Human Exposure: Key Concepts," in this manual.

example, a study might treat all those employed to install asbestos insulation as having been exposed to asbestos during the period that they were so employed. However, there may be a wide variation of exposure within any job, and therefore this job-classification measure may not accurately determine individual levels of exposure.¹⁴⁹ If the agent of interest is a drug, medical or hospital records often can be used to determine past exposure. Retrospective studies that determine past exposures indirectly are usually less accurate than prospective studies or follow-up studies, including ones in which a drug or medical intervention is the agent of interest.

Exposure to the agent can also be measured directly. To directly determine an individual's level, duration, and timing of exposure to an agent, researchers can use biological markers, or biomarkers, when they are available.¹⁵⁰ A biomarker

149. Occupational epidemiologists frequently employ study designs that consider all agents to which workers in a particular occupation are exposed because they seek to determine the hazards associated with that occupation. Isolating one of the agents for examination would be difficult if not impossible. These studies, then, present difficulties when used in court in support of a claim by a plaintiff who was exposed to only one or some of the agents that were present at the worksite that was the subject of the study. See, e.g., *Knight v. Kirby Inland Marine Inc.*, 482 F.3d 347, 352–53 (5th Cir. 2007) (concluding that case-control studies of cancer that entailed exposure to a variety of organic solvents at job sites did not support claims of plaintiffs who claimed exposure to benzene caused their cancers).

150. A different, but related, problem often arises in court. Determining the plaintiff's exposure to the alleged toxic substance always involves a retrospective determination and may involve difficulties similar to those faced by an epidemiologist planning a study. Thus, in *John's Heating Serv. v. Lamb*, 46 P.3d 1024 (Alaska 2002), plaintiffs were exposed to carbon monoxide because of defendants' negligence with respect to a home furnace. The court observed: "[W]hile precise information concerning the exposure necessary to cause specific harm to humans and exact details pertaining to the plaintiff's exposure are beneficial, such evidence is not always available, or necessary, to demonstrate that a substance is toxic to humans given substantial exposure and need not invariably provide the basis for an expert's opinion on causation." *Id.* at 1035 (quoting *Westberry v. Gislaved Gummi AB*, 178 F.3d 257, 264 (4th Cir. 1999)). See generally Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 cmt. c(2) & rptrs. note (2010).

Even if a biomarker exists for exposure to a particular agent, it may be problematic to attempt to use that biomarker as a measure of a plaintiff's past exposure to that agent. As described in the next paragraph, the persistence of biomarkers in the body following an exposure varies. Because of the long latency period between exposure and the manifestation of disease that is characteristic of many toxic tort cases, biomarker measurements that are available at the time of litigation may not accurately reflect a plaintiff's much earlier exposure to a toxicant.

To address the problem of determining a plaintiff's exposure in asbestos cases, a number of courts have adopted a requirement that the plaintiff demonstrate (1) regular use by an employer of the defendant's asbestos-containing product; (2) the plaintiff's proximity to that product; and (3) exposure over an extended period of time. See, e.g., *Lohrmann v. Pittsburgh Corning Corp.*, 782 F.2d 1156, 1162–64 (4th Cir. 1986); *Gregg v. V-J Auto Parts, Inc.*, 943 A.2d 216, 226 (Pa. 2007); see also *James v. Bessemer Processing Co.*, 714 A.2d 898, 911–14 (N.J. 1998) (applying same standard to a claim involving substances other than asbestos and holding that plaintiff presented sufficient evidence of exposure to certain substances in particular manufacturers' products to withstand summary judgment). Other courts have imposed more stringent requirements. E.g., *Bostic v. Georgia-Pacific Corp.*, 439 S.W.3d 332, 353 (Tex. 2014) (holding that "the dose must be quantified but need not be established with mathematical precision," although "the plaintiff must prove with

may be the actual parent compound to which an individual is exposed, a metabolite of the parent compound, or some other measure that reflects an exposure-induced alteration in biologic systems at the functional or molecular level.¹⁵¹ Measurements can be made in various biologic materials, including blood, urine, amniotic fluid, breast milk, seminal fluid, fecal material, hair, and nails. The appropriate matrix for measuring exposure is determined by the chemical agent and its properties.

Measurements in bodily fluids of chemicals with long half-lives (in the order of years), such as lead or DDT, are more likely to reflect exposure preceding a health outcome.¹⁵² Other chemical agents have short half-lives in the human body (e.g., bisphenol A, phenols), and thus the level of exposure indicated by a biomarker may not accurately reflect exposure during a critical window but may only reflect a very recent exposure (e.g., the last meal).¹⁵³ Appropriate biological markers, however, are available only for a small number of toxicants.¹⁵⁴

scientifically reliable expert testimony that the plaintiff's exposure to the defendant's product more than doubled the plaintiff's risk of contracting the disease"). For criticism of Bostic's requirement of a risk-doubling dose from each defendant's product, see Steve C. Gold, *Drywall Mud and Muddy Doctrine: How Not to Decide a Multiple-Exposure Mesothelioma Case*, 49 Ind. L. Rev. 117 (2015).

151. Courts occasionally have noted the use of biomarkers to classify study subjects' exposure levels. See, e.g., *Nat'l Bank of Commerce (of El Dorado, Ark.) v. Dow Chem. Co.*, 965 F. Supp. 1490, 1553–54 (E.D. Ark. 1996) (favorably citing defendant's expert's testimony that praised a study in which low levels of cholinesterase in blood were used as a biomarker for exposure to cholinesterase-inhibiting pesticides). More often, courts must resolve disputes about whether a particular plaintiff displays a putative biomarker of exposure and the significance of the putative biomarker's presence or absence. See, e.g., *In re TMI Litig.*, 193 F.3d 613, 690–93 (3d Cir. 1999) (affirming exclusion of expert's estimates of radiation doses plaintiffs received during nuclear accident fifteen years earlier because another methodology would provide more accurate estimates after such a long lapse of time); *In re Flint Water Cases*, 2021 WL 5356295, at *3 (E.D. Mich. Nov. 17, 2021) (denying motion to exclude testimony of plaintiff's expert that measurement of lead levels in bone, rather than in blood, provided more accurate exposure assessment); *Barlow v. Gen. Motors Corp.*, 595 F. Supp. 2d 929, 944 n.6 (S.D. Ind. 2009) (rejecting plaintiffs' suggestion that body fat measurements would provide better marker of PCB exposure than blood measurements, where plaintiffs failed to produce evidence to that effect); *Young v. Burton*, 567 F. Supp. 2d 121, 136 (D.D.C. 2008) (excluding plaintiff's expert testimony that certain biomarkers indicated exposure to mold five years earlier, where defense experts testified that the markers' response to exposure lasts only minutes or hours).

152. If such a biomarker exists, retrospective studies may be able accurately to capture the exposure during critical biological windows depending on the half-life of the chemical and the time since that window.

153. In cases where the exposure has a short half-life, multiple measurements may be needed to accurately assess the level of exposure, unless they are reflective of typical exposure or if a single exposure can have a biologic effect. To use a biomarker to obtain an accurate assessment of exposure to such an agent, it may be necessary to measure the biomarker at multiple times, unless it is shown that a single measurement is representative of a longer-term exposure or that a single exposure could cause the health outcome at issue.

154. See Jessie P. Buckley et al., *Exposure to Contemporary and Emerging Chemicals in Commerce Among Pregnant Women in the United States: The Environmental Influences on Child Health Outcome*

In addition to biomarkers, epidemiologists may use measurements of non-biologic matrices such as water, dust, and air to assess exposure to agents found in those media.¹⁵⁵ Sometimes monitoring devices can be used to measure such environmental exposures directly, but monitoring data often are not available for exposures that have occurred in the past unless they are routinely collected, such as through governmental air or water monitoring.

The route (e.g., inhalation or absorption), duration, and intensity of exposure also are important factors. Even with environmental monitoring, the dose measured in the environment generally is not the same as the dose that reaches internal target organs. If the researcher has calculated the internal dose of exposure, the scientific basis for this calculation should be examined for soundness.¹⁵⁶

Disease information bias

Information bias may also result from inaccurate measurement of disease status. The quality and sophistication of the diagnostic methods used to detect a disease should be assessed.¹⁵⁷ The proportion of subjects eligible for study who were

(ECHO) Program, 56 Env't Sci. & Tech. 6560, 6560 (2022), <https://doi.org/10.1021/acs.est.1c08942> (National Health and Nutrition Examination Survey (NHANES) provides data on exposure to 350 chemicals, a small fraction of the number of chemicals in use); Angela N.H. Creager, *Human Bodies as Chemical Sensors: A History of Biomonitoring for Environmental Health and Regulation*, 70 Stud. Hist. & Phil. Sci. 70, 76 (2018), <https://doi.org/10.1016/j.shpsa.2018.05.010> ("For the past quarter century, research on biomarkers and genetic dosimetry has seemed poised to change environmental public health by offering more sensitive tools for measuring chemical exposure. Yet so far these tools have not displaced the widespread reliance on methods of chemical analysis."); Steve C. Gold, *The More We Know, The Less Intelligent We Are?—How Genomic Information Should, And Should Not, Change Toxic Tort Causation Doctrine*, 34 Harv. Env't L. Rev. 370 (2010) (describing circumstances where courts can improve their ability to link toxic substances to human illness by properly understanding and utilizing genomic information and analyzing biomarkers); Gary E. Marchant, *Genetic Data in Toxic Tort Litigation*, 14 J. L. & Pol'y 7, 18–32 (2006) (explaining concept of biomarkers and how they might be used to provide evidence of: (1) exposure or dose, (2) general and specific causation, and (3) identifying those with greater risks of future disease; discussing cases in which biomarkers were employed; and concluding, "genomic data [like biomarkers] have enormous potential to make toxic tort litigation more informed, consistent and fair").

155. For example, concentrations of perfluorooctanoic acid (PFOA, a so-called "forever chemical") found in a drinking water supply, levels of lead in dust in a home, or levels of polycyclic aromatic hydrocarbons (PAHs) or fine particulate matter (PM_{2.5}) in the ambient air may be used to estimate exposures of the people who drink the water, live in the home, or breathe the air.

156. See also Eaton et al., *supra* note 60.

157. The hazards of adversarial review of epidemiologic studies to determine bias are highlighted by *O'Neill v. Novartis Consumer Health, Inc.*, 55 Cal. Rptr. 3d 551, 558–60 (Ct. App. 2007). Defendant's experts criticized a case-control study relied on by plaintiff on the ground that there was misclassification of exposure status among the cases. Plaintiff objected to this criticism because defendant's experts had only examined the cases for exposure misclassification, which would tend

actually examined should be determined. If, for example, many of the subjects refused to be tested, the fact that the test used was of high quality may be of relatively little value given the potential for selection bias.

The scientific validity of the research findings is influenced by the accuracy of the diagnosis of disease or health status under study.¹⁵⁸ The disease must be one that is recognized and defined to enable accurate diagnoses. To ensure that the diagnoses of study subjects are in fact accurate, diagnostic criteria accepted by the medical community should be used.¹⁵⁹ For example, a researcher

to exaggerate any association by providing an inaccurately inflated measure of exposure in the cases. The experts failed to examine whether there was misclassification in the controls, which, if it existed, would tend to incorrectly diminish any association.

158. In *In re Swine Flu Immunization Prods. Liab. Litig.*, 508 F. Supp. 897, 903 (D. Colo. 1981), *aff'd sub nom. Lima v. United States*, 708 F.2d 502 (10th Cir. 1983), the court critically evaluated a study relied on by an expert whose testimony was stricken. In that study, determination of whether a patient had Guillain-Barré syndrome was made by medical clerks, not physicians who were familiar with diagnostic criteria.

159. See generally Robert H. Friis & Thomas A. Sellers, *Epidemiology for Public Health Practice* 494 (6th ed. 2021) (in a case-control study, “the definition of a case is influenced by a number of factors, including whether there are standard diagnostic criteria . . . and whether the criteria to diagnose the disease are subjective or objective”).

Classification problems have affected the study of agent-disease links that later became the subject of litigation, for example the under-reporting of deaths due to mesothelioma. See *supra* note 140. Few court opinions, however, have addressed misclassification bias as the basis of a challenge to the validity of epidemiologic studies. See, e.g., *In re Lipitor (Atorvastatin Calcium) Mktg., Sales Pracs., & Prods. Liab. Litig.* (No. II) MDL 2502, 892 F.3d 624, 635–38 (4th Cir. 2018) (affirming exclusion of expert testimony where expert based opinion on reanalysis of epidemiologic study data using a different disease definition); *Rochkind v. Stevenson*, 164 A.3d 254, 261–62 (Md. 2017) (reversing admission of expert testimony opining that exposure to lead can cause attention deficit-hyperactivity disorder (ADHD) where expert relied on epidemiologic studies showing association with attention decrements in general but not with ADHD as defined by diagnostic criteria); *In re Lipitor (Atorvastatin Calcium) Mktg., Sales Pracs., & Prods. Liab. Litig.*, 174 F. Supp. 3d 911, 917 n.5 (D.S.C. 2016) (noting that where one study found a statistically significant association, but another did not, the difference could be explained by the latter study’s use of a more restrictive disease definition but making “no value judgments” with respect to either study’s quality).

A related but subtly different issue arises more frequently: disputes about whether a plaintiff has been diagnosed accurately with a disease that has been (or could be) the subject of epidemiologic study. See, e.g., *Grant v. Bristol-Myers Squibb*, 97 F. Supp. 2d 986, 992 (D. Ariz. 2000) (“where experts propose that breast implants cause a disease but cannot specify the criteria for diagnosing the disease, it is incapable of epidemiologic testing[, rendering] the experts’ methods insufficiently reliable to help the jury”); *Burton v. Wyeth-Ayerst Labs.*, 513 F. Supp. 2d 719, 722–24 (N.D. Tex. 2007) (parties disputed whether cardiology problem involved two separate diseases or only one; court concluded that all experts in the case reflected a view that there was but a single disease); *Nat’l Bank of Commerce (of El Dorado, Ark.) v. Dow Chem. Co.*, 965 F. Supp. 1490 (E.D. Ark. 1996) (where children exposed *in utero* to pesticides suffered from birth defects, parties disputed whether children’s symptoms supported diagnosis of inherited syndromes); *In re Breast Implant Cases*, 942 F. Supp. 958, 961 (E.D.N.Y. & S.D.N.Y. 1996) (rejecting plaintiffs’ experts’ testimony that breast implants caused a “new undifferentiated atypical disease” with “hundreds of symptoms”).

interested in studying spontaneous abortion in the first trimester must determine that study subjects are pregnant. If that determination were made based on the results of home pregnancy tests at a time when home pregnancy tests were known to have a high rate of false-positive results (indicating pregnancy when the woman is not pregnant), the study will overestimate the number of spontaneous abortions.

Information bias due to misclassification

Misclassification is a consequence of information bias in which, because of problems with the information available, individuals in the study may be misclassified as to exposure status or disease status. Bias due to exposure misclassification can be differential or nondifferential. In nondifferential misclassification (also called random misclassification), the inaccuracies in determining exposure are independent of disease status, or the inaccuracies in diagnoses are independent of exposure status—in other words, the data are crude and contain some level of random error. This is a common problem.

Generally, nondifferential misclassification shifts the study's result toward a finding of no effect.¹⁶⁰ Thus, if errors are nondifferential, an apparent association between an exposure and disease would not be a product of incorrect classification. Instead, nondifferential misclassification generally underestimates the true size of the association. Studies that find no association and are likely affected by a fair amount of nondifferential misclassification should therefore be regarded with suspicion. In fact, it has been shown that under some conditions, severe nondifferential misclassification could result in an association that suggests that an agent reduces the risk of disease, when in fact exposure to the agent increases the risk. However, it is important to note that nondifferential misclassification on its own does not guarantee a bias towards the null. Bias away from the null, resulting in a larger estimated association than the truth, can occur if the exposure or the health outcome has more than two levels (i.e., present versus absent)¹⁶¹ or if misclassification is related to errors made on other variables.¹⁶²

160. Toxic tort cases are typically concerned with the association of an exposure with disease, a dichotomous outcome that is either present or absent. In studies of dichotomous outcomes, nondifferential misclassification generally shifts the observed value of the relative risk, odds ratio, or other measure of association toward one. In studies between exposures and continuous variables such as IQ, which measure associations differently, nondifferential misclassification generally shifts the observed value of the study's measure of association toward zero.

161. See Alexander Walker et al., *Comparing Imperfect Measures of Exposure*, 121 Am. J. Epidemiology 783 (1985), <https://doi.org/10.1093/oxfordjournals.aje.a114049>; Mustafa Dosemeci et al., *Does Nondifferential Misclassification of Exposure Always Bias a True Effect Toward the Null Value?*, 132 Am. J. Epidemiology 746 (1990), <https://doi.org/10.1093/oxfordjournals.aje.a115716>.

162. See Michael Chavance et al., *Correlated Nondifferential Misclassifications of Disease and Exposure: Application to a Cross-Sectional Study of the Relation Between Handedness and Immune Disorders*, 21

Differential misclassification is caused by a systematic error in determining exposure in cases as compared with controls, or disease status in unexposed cohorts relative to exposed cohorts. For example, in a case-control study this would occur if, in the process of anguishing over the possible causes of the disease, parents of ill children recalled more exposures to a particular agent than actually occurred, or if parents of the controls, for whom the issue was less emotionally charged, recalled fewer. This can also occur in a cohort study in which, for example, birth-control users (the exposed individuals) are monitored more closely for potential side effects, leading to a higher rate of disease identification in that cohort than in the unexposed cohort. Depending on how the misclassification occurs, a differential bias can produce an error in either direction—the exaggeration or understatement of a true association.

Confounding Bias

Confounding is another important potential source of error in epidemiologic studies.¹⁶³ Confounding occurs when another causal factor (the confounder) confuses the relationship between the agent and the outcome of interest.¹⁶⁴ Confounding can bias a study result by either exaggerating or diluting an association.¹⁶⁵ One instance of confounding is when a factor is causally related to both the agent and disease of interest. For example, researchers may conduct a study that finds individuals with gray hair have a higher rate of death than those with hair of another color. Instead of hair color having an effect on death, the results might be explained by the confounding factor of age. If old age causes gray hair (those who are older have a greater probability of having gray hair than those who are younger), old age may be responsible for the association found between hair color and death.¹⁶⁶ To negate the effect of confounding bias, researchers

Int'l J. Epidemiology 537 (1992), <https://doi.org/10.1093/ije/21.3.537>; P. Kristensen, *Bias from Nondifferential but Dependent Misclassification of Exposure and Outcome*, 3 Epidemiology 210 (1992), <https://doi.org/10.1097/00001648-199205000-00005>.

163. See *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1322–26 (N.D. Fla. 2018) (quoting this reference guide and discussing the evidence that negated the possibility of confounding in an epidemiologic study).

164. See Lash et al., *supra* note 50, at 263–64.

165. One example of a confounding factor that may result in a study's outcome understating an association is vaccination. Thus, if a group exposed to an agent has a higher rate of vaccination for the disease under study than the unexposed group, the vaccination may reduce the rate of disease in the exposed group, thereby producing an association that is less than the true association without the confounding of vaccination.

166. This example is drawn from Kahn & Sempos, *supra* note 34, at 63.

must separate the relationship between gray hair and risk of death from that of old age and risk of death.¹⁶⁷

Confounding can be further illustrated by a hypothetical prospective cohort study designed to investigate whether drinking alcohol is associated with emphysema. Participants are followed for a period of 20 years and the incidence of emphysema in the exposed (participants who consume more than 15 drinks per week) and the unexposed is compared. At the conclusion of the study, the relative risk of emphysema in the drinking group is found to be 2.0 (an association that suggests a possible effect). But does this association reflect a true causal relationship or might it be the product of confounding?

One possibility for a confounding factor is smoking, a known causal risk factor for emphysema. If those who drink alcohol are more likely to be smokers than those who do not drink, then smoking may be responsible for some or all of the higher risk of emphysema among those who drink.

A serious problem in observational studies such as this hypothetical study is that the individuals are not assigned randomly to the groups being compared as they might be in a clinical trial. As discussed above, randomization maximizes the possibility that factors other than the one under study are evenly distributed between the exposed and the unexposed groups.¹⁶⁸ In observational studies, by contrast, other forces determine who is exposed to other (possibly causal) factors. The lack of randomization leads to the potential problem of confounding. Thus, for example, the exposed group might consist of those who are exposed at work to an agent suspected of being an industrial toxicant. The members of this group may, however, differ from unexposed controls by residence, socioeconomic or health status, age, or other extraneous factors.¹⁶⁹ These other factors may be causing (or protecting against) the disease, but because of potential confounding,

167. *Schwab v. Philip Morris USA, Inc.*, 449 F. Supp. 2d 992, 1199–1200 (E.D.N.Y. 2006), *rev'd on other grounds*, 522 F.3d 215 (2d Cir. 2008), describes confounding that led to premature conclusions that low-tar cigarettes were safer than regular cigarettes. Smokers who chose to switch to low-tar cigarettes were different from other smokers in that they were more health conscious in other aspects of their lifestyles. Failure to account for that confounding—and measuring a healthy lifestyle is difficult even if it is identified as a potential confounder—biased the results of those studies.

168. Randomization attempts to ensure that the presence of a potentially confounding risk factor (such as smoking in the preceding paragraph's example), is governed by chance, as opposed to being affected or determined by the presence of the potential risk factor under study (such as drinking in the preceding paragraph's example) or the underlying medical condition being studied (such as emphysema in the preceding paragraph). See Kenneth J. Rothman & Timothy L. Lash, *Epidemiologic Study Design with Validity and Efficiency Considerations*, in Lash et al., *supra* note 50, at 105, 109, 121–22; see also section titled “Experimental and Observational Studies of Suspected Toxic Agents” above.

169. See, e.g., *In re “Agent Orange” Prod. Liab. Litig.*, 597 F. Supp. 740, 783 (E.D.N.Y. 1984) (discussing the problem of confounding that might result in a study of the effect of exposure to Agent Orange on Vietnam servicemen), *aff'd*, 818 F.2d 145 (2d Cir. 1987).

an association of the disease with exposure to the agent may appear when one does not exist or may be masked when one exists. Confounders, like smoking in the alcohol-drinking study, do not reflect an error made by the investigators; rather, they reflect the inherently “uncontrolled” nature of exposure designations in observational studies. When they can be identified, confounders should be taken into account.

To evaluate whether smoking is a confounding factor in a study of alcohol consumption and emphysema, the researcher would stratify the data into smoking and nonsmoking subgroups, would compute associations within each subgroup, and would average these results. If the average of the stratified associations was the same as that in the all-subjects group, then smoking would not be a confounding factor. But if these values differed, this would provide evidence that smoking is a confounder of the observed association between drinking and emphysema. If the stratified results showed no association (e.g., a relative risk of 1), this would indicate that the confounding factor (smoking) fully accounts for the apparent association of drinking with emphysema.

Table 4 reveals our hypothetical study’s results, with smoking being a confounding factor, which, when accounted for, eliminates the association. As the table shows, in the full cohort, drinkers have twice the risk of emphysema compared with nondrinkers. When the relationship between drinking and emphysema is examined separately in smokers and in nonsmokers, the risk of emphysema in drinkers compared with nondrinkers is not elevated in smokers or in nonsmokers. This is because smokers are disproportionately drinkers and have a higher rate of emphysema than nonsmokers. Thus, the relationship between drinking and emphysema in the full cohort is distorted by failing to take into account the relationship between being a drinker and being a smoker.

Even after accounting for the effect of known suspected confounders (such as smoking in our example), there is always a risk that an undiscovered or unrecognized confounding factor may contribute to a study’s findings, by either magnifying or reducing the observed association.¹⁷⁰ It is, however, necessary to keep that risk in perspective. Often the mere possibility of uncontrolled confounding is used to call into question the results of a study. This was certainly the strategy of some who sought, or unwittingly helped, to undermine the implications of the studies persuasively linking cigarette smoking to lung cancer. The critical question is whether it is plausible that the findings of a given study could indeed be due to unrecognized confounders.

170. Tyler J. VanderWeele & Kenneth J. Rothman, *Formal Causal Models*, in Lash et al., *supra* note 50, at 33; *see also* section titled “Experimental and Observational Studies of Suspected Toxic Agents” above.

Table 4. Hypothetical Emphysema Study Data^a

	Total Cohort				Smokers				Nonsmokers			
	Total	Cases	Incidence ^a	RR ^b	Total	Cases	Incidence ^a	RR	Total	Cases	Incidence ^a	RR
Drinking Status												
Nondrinkers	471	16	0.034	—	111	9	0.081	—	360	7	0.019	—
Drinkers	739	51	0.069	2.0	592	48	0.081	1.0	147	3	0.020	1.0

^a The incidence of disease is not normally presented in an epidemiologic study, but we include it here to aid in comprehension of the ideas discussed in the text.

^b RR = relative risk. The relative risk for the drinkers in each of the cohorts is determined based on reference to the risk among nondrinkers; that is, the risk of disease among drinkers is compared with nondrinkers for each of the three cohorts separately.

Techniques to identify confounding factors

Epidemiologic theory has evolved over recent years and so has the understanding of confounding. Directed acyclic graphs (DAGs), a form of causal diagram, are now considered to be the tool of choice to identify which factors should be addressed as potential confounders. These graphs reflect the understanding of the researcher regarding the causal relation among factors (shown as nodes) by linking them with arrows pointing from causes to effects. Any path from exposure to the health outcome under study that does not follow the direction of arrows can generate statistical associations that are not causal. Examination of this graph will thus allow the researcher to determine which factors to adjust for to block noncausal associations.

Figure 6 illustrates how epidemiologists can use DAGs to identify confounders. For the hypothetical study depicted in Figure 6, the research question is whether exposure A to the herbicide glyphosate increases the risk of outcome Y, non-Hodgkin lymphoma. But suppose some potential confounding factors C, such as age, race, and sex, affect both the exposure A and the outcome Y. Focusing for simplicity on just one of these factors, age, suppose that older people had higher exposure to glyphosate and also had higher risk of non-Hodgkin lymphoma. This would create a noncausal association between exposure and disease. The DAG in Figure 6 reveals that a noncausal path—one that does not follow the causal direction indicated by arrows—can be drawn between exposure A and outcome Y by passing through confounder C. If this hypothetical study finds an association between exposure to glyphosate and non-Hodgkin lymphoma risk, at least part of that observed association could be due to the fact that older people, because of their age, experience both higher exposure and greater risk of the disease.

DAGs can also allow investigators to determine which factors should not be adjusted for in order to avoid blocking a causal path.

Figure 6. Directed acyclic graph (DAG) for a hypothetical study of glyphosate and non-Hodgkin lymphoma.

Figure 7. Directed acyclic graph for a hypothetical study of air pollution and heart disease.

For instance, imagine a hypothetical study of a possible association between exposure to air pollution and risk of heart disease. Based on a review of prior research, the epidemiologist suspects that air pollution may cause heart disease, at least in part, by affecting blood pressure. In this causal model, depicted in a DAG in Figure 7, blood pressure is assumed to mediate, rather than to confound, any causal connection between air pollution and heart disease. The DAG shows that it would be inappropriate to adjust for blood pressure, as this would block the portion of the effect of air pollution that occurs through blood pressure. This example illustrates that adjusting for factors can either remove or introduce bias. Careful examination of the causal relation among factors is necessary to determine the appropriate approach to apply.

Techniques to prevent or limit confounding

Choices in the design of a research project (e.g., methods for selecting the subjects) can prevent or limit confounding. In designing a study, the researcher must determine other risk factors for the disease under study, such as age, sex, or genotype, that may be related to exposure to the agent under study. Investigators can limit the differential distribution of these factors in the study groups by selecting unexposed subjects to “match” exposed subjects in terms of these variables. If the two groups are matched (for example, by age), then any association observed in the study cannot be the result of age, the matched variable.¹⁷¹ Often

171. Selecting a control population based on matched variables necessarily affects the representativeness of the selected controls and may affect how generalizable the study results are to the

investigators frequency-match groups so that the distribution (for example, of age) is similar in the two groups. This reduces the potential for confounding by age but may still require adjustment.

Restricting the persons who are included as subjects in a study is another method to control for confounders. If age or sex is suspected as a confounder, then the subjects enrolled in a study can be limited to those of one sex or those who are within a specified age range. When there is no variance among subjects in a study with regard to a potential confounder, confounding as a result of that variable is eliminated.

In most observational studies, many factors could potentially confound associations. This makes it challenging to apply the matching or restriction methods. Indeed, if age, socioeconomic status, smoking, and race are identified as potential confounders, finding matches or restricting participation to individuals with very precise characteristics may be impractical and make it difficult to generalize findings to individuals with other characteristics than those included in the study. For this reason, most studies use statistical models to control for multiple confounders.

Techniques to control for confounding factors

A good study design will consider potential confounders and obtain data about these variables. There are several analytic approaches to account for the distorting effects of a potential confounder, including stratification or multivariable regression analysis. Stratification permits an investigator to evaluate the effect of a suspected confounder by subdividing the study groups based on a confounding factor. For example, in Table 4, alcohol drinkers have been stratified based on whether they smoke (the suspected confounder).

To take another example that entails a continuous rather than dichotomous potential confounder, let us say we are interested in the relationship between smoking and lung cancer but suspect that air pollution or urbanization may confound the relationship. An observed relationship between smoking and lung cancer could then theoretically be due in part to pollution, if smoking were more common in polluted areas. One could investigate this issue by stratifying the data by degree of urbanization and looking at the relationship between smoking and lung cancer in each urbanization stratum. Figure 8 shows actual

population at large. However, for a study to have merit, it must first be internally valid; that is, it must not be subject to unreasonable sources of bias or confounding. Only after a study has been shown to meet this standard does its universal applicability or generalizability to the population at large become an issue. When a study population is not representative of the general or target population, existing scientific knowledge may permit reasonable inferences about the study's broader applicability, or additional confirmatory studies of other populations may be necessary.

Figure 8. Age-adjusted lung-cancer mortality rates per 100,000 person-years by urban-rural classification and smoking category.

Source: Adapted from E. Cuyler Hammond & Daniel Horn, *Smoking and Death Rates: Report on Forty-Four Months of Follow-Up of 187,783 Men: II, Death Rates by Cause*, 166 JAMA 1294 (1958).

age-adjusted lung-cancer mortality rates per 100,000 person-years by urban or rural classification and smoking category.¹⁷²

For each degree of urbanization, lung cancer mortality rates in smokers are shown by the darker bars, and nonsmoker mortality rates are indicated by lighter bars. From these data we see that in every level (or stratum) of urbanization, lung cancer mortality is higher in smokers than in nonsmokers. Therefore, the observed association of smoking and lung cancer cannot be attributed to the level of urbanization. By examining each stratum separately, we, in effect, hold urbanization constant and still find much higher lung cancer mortality in smokers than in nonsmokers.

The standardization method was historically used primarily to control for the effect of age in mortality studies. Two types of standardizations are used—direct and indirect. In direct standardization (e.g., when based on age), overall disease or death rates are calculated for each population as though each had the age distribution of another standard or reference population, using the age-specific disease or death rates for each study population. We can then compare these overall rates, called age-adjusted rates, knowing that any difference

172. This example and Figure 8 (including the source credit in Figure 8) are from Celentano & Szklo, *supra* note 37, at 294–99.

between these rates cannot be attributed to differences in age, since both age-adjusted rates were generated using the same standard population.

Indirect standardization is used when the age-specific rates for a study population are not known. In that case, the overall disease/death rate for the standard/reference population is recalculated based on the age distribution of the population of interest using the age-specific rates of the standard population. Then, the actual number of disease cases/deaths in the population of interest can be compared with the number in the reference population that would be expected if the reference population had the age distribution of the population of interest.

This ratio is called the standardized mortality ratio (SMR). When the outcome of interest is disease rather than death, it is called the standardized morbidity ratio¹⁷³ (and the discussion below of standardized mortality rate is equally applicable to a standardized morbidity rate). If the ratio equals 1.0, the observed number of deaths equals the expected number of deaths, and the mortality rate of the population of interest is no different from that of the reference population. If the SMR is greater than 1.0, the population of interest has a higher mortality risk than that of the reference population, and if the SMR is less than 1.0, the population of interest has a lower mortality rate than that of the reference population.

Thus, age adjustment provides a way to compare populations while in effect holding age constant. Adjustment is used not only for comparing mortality rates in different populations but also for comparing rates in different groups of subjects selected for study in epidemiologic investigations. Although this discussion has focused on adjusting for age, it is also possible to adjust for other variables, such as sex, race, genetic variability, occupation, and socioeconomic status.¹⁷⁴ However, because this method is based on stratifying study data into groups that will become smaller as the number of variables considered increases, the standardization method can only be used to account for a small number of potential confounders without reducing the numbers in each category to the point at which they are not statistically stable.

As stated above, most studies use statistical models to address multiple confounders at once. Multivariable regression analysis, a technique that relates an outcome to multiple explanatory factors, is most commonly used for this

173. See *Burst v. Shell Oil Co.*, No. CIV.A. 14-109, 2015 WL 3755953, at *6 n.15 (E.D. La. June 16, 2015) (explaining SMR and its relationship with relative risk), *aff'd*, 650 F. App'x 170 (5th Cir. 2016) (quoting *Taylor v. Airco, Inc.*, 494 F. Supp. 2d 21, 25 n.4 (D. Mass. 2007)). For an example of adjustment used to calculate an SMR for workers exposed to benzene, see Robert A. Rinsky et al., *Benzene and Leukemia: An Epidemiologic Risk Assessment*, 316 NEJM 1044 (1987), <http://doi.org/10.1289/ehp.8982189>.

174. For further elaboration on adjustment, see Celentano & Szklo, *supra* note 37, at 82–85; Cole, *supra* note 94, at 10,281.

purpose.¹⁷⁵ For example, Narayan and colleagues used logistic regression to estimate whether occupational exposure to pesticides was associated with the risk of Parkinson's disease in central California while controlling for multiple potential confounders including age, sex, smoking, education, race, and frequency of household pesticide use, as well as ambient residential- and work-address pesticide exposures. In this case-control study, they found that self-reported occupational use of herbicides for a duration exceeding 10 years was associated with a doubling in the risk (i.e., an odds ratio of 2.1 and 95% confidence interval of 1.1 to 3.9) of being diagnosed with Parkinson's disease.¹⁷⁶

However, because there is no free lunch, the use of such methods to address confounding comes at a cost, as they require making a number of assumptions about the characteristics of the data and of the relation among the variables.¹⁷⁷ In addition, the larger the number of confounders one wants to control for, the less precise the association between an agent and a disease generally becomes. This is referred to as the bias–variance tradeoff.

The type of multivariable regression model that is used is primarily determined by the form of the outcome data under study. For example, logistic regression (generating odds ratios) is often used for dichotomous outcome data (e.g., presence versus absence of disease); linear regression (generating differences in means) is generally used for continuous outcome data (e.g., blood pressure or IQ); and Cox proportional hazards models (generating hazard ratios) tend to be the method of choice for survival data (e.g., time to death for a given cancer).

Regression analysis was originally developed in the nineteenth century. Statistical methods have evolved, and researchers sometimes use more sophisticated approaches. For example, Bayesian analyses (named after the statistician Thomas Bayes) allow for the integration of prior knowledge in the statistical analysis.¹⁷⁸ In a combination between the exposure-matching and the regression

175. For a more complete discussion of multivariable analysis, see Rubinfeld & Card, *supra* note 31.

176. See Shilpa Narayan et al., *Occupational Pesticide Use and Parkinson's Disease in the Parkinson Environment Gene (PEG) Study*, 107 *Env't Int'l* 266 (2017), <http://doi.org/10.1016/j.envint.2017.04.010>.

177. For more details, see Rubinfeld & Card, *supra* note 31, “What Model Should Be Used to Evaluate the Question at Issue?”

178. Epidemiologic studies assessed by Bayesian statistical analyses have begun to gain a foothold in litigation, although court opinions are still dominated by discussion of traditional significance testing. See *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, No. 3:16MD2734, 2021 WL 4951944, at *5 (N.D. Fla. July 15, 2021) (“Numerous federal courts have found Dr. Madigan’s methodology of detecting safety signals using a combination of frequentist and Bayesian algorithms to be reliable under Rule 702 and *Daubert*.”); *Langrell v. Union Pac. R. Co.*, No. 8:18CV57, 2020 WL 3037271, at *3 (D. Neb. June 5, 2020) (admitting testimony of specific causation expert who testified “he used a Bayesian approach” to assess causation of a cancer so rare that it was “unlikely or impossible for epidemiological studies to be performed”); *In re Testosterone Replacement Therapy Prods. Liab. Litig.*, No. 14 C 1748, 2018 WL 4030585, at *8 (N.D. Ill. Aug. 23, 2018) (denying motion to exclude testimony of expert “whose Bayesian critiques of epidemiological studies” were similar to those of another expert whose testimony “the Court has previously found admissible”). For a description of

approaches, propensity score matching allows researchers to match study subjects based on their probability of exposure given the value of potential confounders.¹⁷⁹ The potential outcome (or counterfactual) approach aims to simulate randomized-controlled trials by estimating outcomes under different exposure scenarios in which measured confounders are not related to the exposure and/or the outcome. Methods applying this approach include inverse-probability weighting and the parametric g-formula.

The methods described above, through different means and under different assumptions, allow for adjustment of the effect of confounders on an association between an agent and a disease. They aim to estimate the association after having removed confounding by the measured variables. The details of these methods are too technical for discussion here. The crucial points to recognize are that using statistical models to address possible confounding is an accepted part of epidemiologic practice and that choosing the correct statistical model for a study is important to the validity of the study's results. If an association between an agent and a disease remains after accounting for selection, information, and confounding bias, a researcher must then assess whether an inference of causation is justified. This entails consideration of the *Hill* factors explained in the section below titled "General Causation."

Conceptual Error

In addition to the possibility of bias, a study may also be limited by flawed definitions or premises in its design. Consider, for example, a researcher who wishes to investigate whether a certain drug is teratogenic (causes birth defects). If the researcher defines the disease of interest as all birth defects, rather than a specific type of birth defect, there should be a scientific basis to hypothesize that the effects of the drug could be so broad. If the effect is in fact more limited, the result of this conceptualization error could be to dilute or mask any real effect that the agent might have on a specific type of birth defect.¹⁸⁰

Bayesian statistical methods, see Kaye & Stern, *supra* note 16, "Bayesian Statistical Methods and Posterior Probabilities" and "Appendix: Conditional Probability and Bayes' Rule."

179. "Propensity scoring is a system where researchers attempt to control for confounding by creating a comorbidity 'score' for a study participant; the more confounding comorbidities a participant has, the higher [the participant's] score and, through the score, the researchers estimate the propensity of the subject to contribute to confounding." *In re Zantac* (Ranitidine) Prods. Liab. Litig., 644 F. Supp. 3d 1075, 1260 (S.D. Fla. 2022). In *Zantac*, the court excluded proffered expert testimony in part because the court found that the experts testified inconsistently about the merits of propensity scoring. *Id.* at 1261.

180. In *Brock*, 874 F.2d at 312, the court discussed a reanalysis of a study in which the effect was narrowed from all congenital malformations to limb-reduction defects. The magnitude of the association changed by 50% when the effect was defined in this narrower fashion. See Timothy J. Lash et al., *Measurement and Measurement Error*, in Lash et al., *supra* note 50, at 287, 297

Similarly, if the researcher studies the connection between the drug and limb-reduction birth defects in particular, the researcher should consider that an exogenous agent can only cause such a defect during the period of limb organogenesis (weeks 5–9 of the pregnancy). If the researcher defines exposure as the mother taking the drug anytime during her pregnancy, conceptual bias is introduced. Classifying as exposed those pregnant women who took the drug outside the window when exposure could have caused the outcome of interest would tend to understate any association that might exist.

Biases That Affect a Body of Epidemiologic Evidence

Some biases go beyond errors in individual studies and affect the overall body of available evidence in a way that skews what appears to be the universe of evidence. Publication bias is the tendency for scientific journals to prefer to publish studies that find an association.¹⁸¹ If negative studies are never published, the published literature as a whole will be biased. These types of biases may present problems for researchers who attempt to synthesize or combine the results of multiple studies to assess the existence and magnitude of an association.¹⁸²

Financial conflicts of interest by researchers and the source of funding of studies have also been shown to have an effect on the outcomes of such studies.¹⁸³ As the former editor-in-chief of the *British Medical Journal* noted:

(“Unwarranted assurances of a lack of any effect can easily emerge from studies in which a wide range of etiologically unrelated outcomes are grouped.”). For a more general discussion of conceptualization and other types of errors and their relation to legal decision-making, see Vern R. Walker, *Theories of Uncertainty: Explaining the Possible Sources of Error in Inferences*, 22 *Cardozo L. Rev.* 1523, 1544–47, 1553–55 (2001).

181. Celentano & Szklo, *supra* note 37, at 234. Investigators may contribute to this effect by neglecting to submit negative studies for publication. Publication bias “can pose a serious problem when the results from all published clinical trials are reviewed.” *Id.* Publication bias can also affect systematic reviews or meta-analyses of observational studies on a given agent–disease relationship. For clinical trials, medical journals have attempted to minimize publication bias by requiring that before any study is considered for publication, it must have been registered in a public trial registry before any data is gathered. See Catherine D. DeAngelis et al., *Clinical Trial Registration: A Statement from the International Committee of Medical Journal Editors*, 292 *JAMA* 1363 (2004), <https://doi.org/10.1056/NEJMe048225>. The National Institutes of Health (NIH) requires that all NIH-funded clinical trials must be registered and the results reported. See Nat’l Insts. of Health, *NIH Policy on the Dissemination of NIH-Funded Clinical Trial Information*, NOT-OD-16-149, Sept. 16, 2016, <https://grants.nih.gov/grants/guide/notice-files/NOT-OD-16-149.html>.

182. See section titled “Methods for Synthesizing or Combining the Results of Multiple Studies” below.

183. See Jerome P. Kassirer, *On the Take: How Medicine’s Complicity with Big Business Can Endanger Your Health* 79–84 (2005); Deepa V. Cherla et al., *The Effect of Financial Conflict of Interest, Disclosure Status, and Relevance on Medical Research from the United States*, 34 *J. Gen. Internal Med.*

The major determinant of whether reviews of passive smoking concluded it was harmful was whether the authors had financial ties with tobacco manufacturers. In the disputed topic of whether third-generation contraceptive pills cause an increase in thromboembolic disease, studies funded by the pharmaceutical industry find that they don't and studies funded by public money find that they do.¹⁸⁴

Effect Modification

Populations and individuals with different characteristics may be more or less susceptible to the adverse health effects of an agent. Such characteristics are called effect modifiers.

For example, sex and gender are suspected to modify the effect of a number of associations. Stronger associations between exposure to air pollution and respiratory outcomes have been reported among women relative to men.¹⁸⁵ Biologic sex may also modify associations between exposure to agents, such as pesticides and hormones, and some health outcomes.¹⁸⁶ Age may also modify associations. For example, associations between an agent and age may occur if

Dunn et al., *Conflict of Interest Disclosure in Biomedical Research: A Review of Current Practices, Biases, and the Role of Public Registries in Improving Transparency*, 1 *Rsch. Integrity & Peer Rev.* 1 (2016), <https://doi.org/10.1186/s41073-016-0006-7>.

Epidemiologists, like other scientists, also may engage in scientific misconduct, even fraud. See generally James R. Wible, *The Economics of Scientific Misconduct* 24–38 (2023) (describing two “waves” of scientific misconduct in the late 20th and early 21st centuries and reviewing studies attempting to estimate how often misconduct occurs); Steven L. George, *Research Misconduct and Data Fraud in Clinical Trials: Prevalence and Causal Factors*, 21 *Int'l J. Clinical Oncology* 15, 16 (2016), <https://doi.org/10.1007/s10147-015-0887-3> (listing several instances of falsified or fabricated data in clinical trials); Steven S. Coughlin et al., *Ethics and Scientific Integrity in Public Health, Epidemiological and Clinical Research*, 34 *Pub. Health Rev.* 1, 6 (2012), <https://doi.org/10.1007/BF03391657> (providing example of published falsified epidemiologic data); Ferric Fang et al., *Misconduct Accounts for the Majority of Retracted Scientific Publications*, 42 *PNAS* 17028, 17029 (2012) (“nearly half of retractions are for fraud or suspected fraud”); Douglas L. Weed, *Preventing Scientific Misconduct*, 88 *Am. J. Pub. Health* 125, 126 (1998), <https://doi.org/10.2105/ajph.88.1.125> (noting that although the frequency of scientific misconduct is difficult to quantify, “big effects may arise from small numbers”). Courts should be aware of this possibility, although in an adversarial system, the opposing party has the primary role in identifying such misbehavior when it could have an impact on the case at hand. In-depth discussion of scientific misconduct is beyond the scope of this guide.

186. See Jonathan Chevrier et al., *Sex and Poverty Modify Associations Between Maternal Peripartum Concentrations of DDT/E and Pyrethroid Metabolites and Thyroid Hormone Levels in Neonates Participating in the VHEMBE Study*, 131 *Env't Int'l* 131 (2019), <https://doi.org/10.1016/j.envint.2019.104958>.

older individuals are more likely than younger individuals to develop a particular disease (such as cancer) after exposure to the agent.

Exogenous agents may serve as effect modifiers as well. One example involves warfarin, a drug used to prevent clotting in individuals at risk of strokes and other blood-mediated adverse outcomes. A case study reported on a woman whose measure of the effect of warfarin on her blood clotting, known as the international normalized ratio (INR), was stable but whose INR became doubled when she drank cranberry juice. Her INR returned to normal when she ceased drinking cranberry juice.¹⁸⁷ Cranberry juice thus appears to be an effect modifier for the anti-coagulation effects of warfarin.

Susceptibility to a given exposure may also be modified by genetic factors, a concept known as gene–environment interaction. For example, while smoking is a known risk factor for bladder cancer, a meta-analysis¹⁸⁸ found that the relative risk was 40% greater among individuals who eliminate some chemicals more slowly owing to a particular variant of the gene NAT2, relative to those with other variants of the gene who eliminate chemicals faster.¹⁸⁹

Genetic variations¹⁹⁰ that affect how toxicants are metabolized, and therefore affect the effects of exposures on disease risks, may be common.¹⁹¹ To the

187. See Gale L. Hamann et al., *Warfarin-cranberry juice interaction*, 45(3) Ann. Pharmacotherapy e17 (2011), <https://doi.org/10.1345/aph.1P451>.

188. See section titled “Methods for Synthesizing or Combining the Results of Multiple Studies” below.

189. See Montserrat García-Closas et al., *NAT2 Slow Acetylation, GSTM1 Null Genotype, and Risk of Bladder Cancer: Results from the Spanish Bladder Cancer Study and Meta-Analyses*, 366 Lancet 649 (2005), [https://doi.org/10.1016/S0140-6736\(05\)67137-1](https://doi.org/10.1016/S0140-6736(05)67137-1).

190. A gene is a segment of DNA that, through its sequence of components called bases, codes for the production of a protein or part of a protein. Genetic variations are alterations in the sequence of bases that constitute a person’s DNA. These variations may be present in the sperm and egg cells that join to form an embryo (germline mutations), in which case they affect all of a person’s cells, or they may arise at some point during life (somatic mutations), in which case they affect only cells descended from cells in which the change occurred. DNA may vary in many different ways. A frequently studied type of genetic variation is a polymorphism—a segment of DNA that occurs in multiple forms (alleles) in the population as a result of inherited mutations in some portion of the base sequence. Polymorphisms may affect the structure or function of the protein encoded by a gene and may therefore affect health. In addition to changes in the genetic structure itself, epigenetic changes—alterations in the molecules that control the extent of gene expression (protein production)—may affect how the body interacts with potential toxicants. See, e.g., *McMillan v. Togus Regional Off., Dep’t of Veterans Affs.*, 294 F. Supp. 2d 305, 312 (E.D.N.Y. 2003) (“It is generally accepted that genetic susceptibility plays a key role in determining the adverse effects of environmental chemicals. . . . [I]f polymorphisms of the gene encoding the AhR [protein] exist in humans as they do in laboratory animals, some people would be at greater risk or at lesser risk for the toxic and carcinogenic effects of TCDD [dioxin].”)

191. See Ebony B. Bookman et al., *Gene–Environment Interplay in Common Complex Diseases: Forging an Integrative Model: Recommendations from an NIH Workshop*, 35 Genetic Epidemiology 217, 218–19 (2011), <https://doi.org/10.1002/gepi.20571> (stating that susceptibility to most human diseases “is complex and multifactorial” and describing the difficulty of assessing risk contribution in

extent that genetic variability is reflected in risk heterogeneity, an epidemiologic study that does not consider its subjects' genotypes in addition to their exposure status may produce results that are not entirely valid with respect to some portion of the study participants, even if the study validly reports the relative risk of exposure for the study sample as a whole.¹⁹² The study might understate the relative risk for people whose genetics make them more vulnerable to the effects of the exposure (perhaps even to the point of finding no association at all in the sample as a whole) and overstate the relative risk for people whose genetics protect them from the effects of the exposure. This does not mean that epidemiologic studies must consider genetic variability in order to provide useful causal evidence. Currently, most epidemiologic studies do not gather detailed genetic information on the study participants¹⁹³ for various reasons, including incomplete current scientific understanding of genetic differences in susceptibility to exposure.¹⁹⁴

gene-environment interactions); Frederica P. Perera, *Molecular Epidemiology: On the Path to Prevention?*, 92 J. Nat'l Cancer Inst. 602, 608 (2000), <https://doi.org/10.1093/jnci/92.8.602> ("new molecular epidemiologic and other data invalidate the assumption of population homogeneity"); see also, e.g., Brenda Eskenazi et al., *Organophosphate Pesticide Exposure, PON1, and Neurodevelopment in School-Age Children from the CHAMACOS Study*, 134 Env't Rsch. 149, 156 (2014), <https://doi.org/10.1016/j.envres.2014.07.001> ("Future policies regarding protection from [organophosphate] pesticide exposure should consider that some children may be more vulnerable to early life exposures by virtue of their or their mother's genetic predispositions. . . .").

192. The relative risk for the population as a whole will depend on the relative risk of exposure for each relevant genotype and the frequency of each relevant genotype in the population. Either of these values might be inaccurately measured in a study, either because of random error or because of some type of bias (e.g., a sample of people of one ancestry might not accurately reflect the genotype frequencies in a more diverse population).

193. See Witte & Thomas, *supra* note 50, at 964 ("The incorporation of environmental factors into studies of genetics has been slower moving. While some complex diseases have long been recognized as having both environmental and familial components, our understanding of their interaction is only in its infancy. . . . much remains to be understood.").

194. Even if, for instance, a study shows that the relative risk associated with an exposure varies with different variants of a particular gene, variants affecting the relative risk could also exist in other genes. The study might or might not assess what those other genes are and how differences in the various involved genes interact with each other. The biological effects of exposure to benzene, for example, appear to be influenced by variations in at least five genes. See Diana Dougherty et al., *NQO1, MPO, CYP2E1, GSTT1 and GSTM1 Polymorphisms and Biological Effects of Benzene Exposure—A Literature Review*, 182 Toxicology Letters 7, 15 (2008) ("this review shows that multiple genetic polymorphisms on the benzene metabolism pathway should be taken into account when studying the biological effects of benzene exposure"). Studies have also identified several genes with variants that are associated with different relative risks for tobacco smokers of both lung cancer, see Boffetta, *supra* note 57, at 124, and chronic obstructive pulmonary disease, see Chime-dikhamsuren Ganbold et al., *The Cumulative Effect of Gene-Gene Interactions Between GSTM1, CHRNA3, CHRNA5 and SOD3 Gene Polymorphisms Combined with Smoking on COPD Risk*, 16 Int'l J. Chronic Obstructive Pulmonary Disease 2857, 2866 (2021), <https://doi.org/10.2147/COPD>

Although some courts have considered general claims of differential susceptibility to toxic exposures,¹⁹⁵ few have been confronted with epidemiologic studies that quantitatively assess the degree to which an association between disease risk and exposure status appears to have been modified by genetic variability.¹⁹⁶ It is reasonable to believe that courts will see more such studies¹⁹⁷ offered as evidence on the issue of general causation.¹⁹⁸ If that occurs, knowledge of the plaintiff's genotype could be relevant,¹⁹⁹ although not necessarily essential, evidence on the issue of specific causation.²⁰⁰

.S320841/ ("few studies consider gene-gene or gene-environment interaction with the genetic factors in COPD susceptibility").

195. See, e.g., *In re Asbestos Prods. Liab. Litig.*, No. 10-CV-61118, 2011 WL 605801 (E.D. Pa. Feb. 16, 2011) (denying motion to exclude testimony of expert witness who opined "that susceptibility to asbestos-related disease varies within the population and the dose of asbestos necessary to cause the disease is different for each individual, and largely dependent upon genetic predisposition"); *Young v. Burton*, 567 F. Supp. 2d 121, 137 (D.D.C. 2008) (rejecting plaintiff's expert's claim that variations in HLA-DR gene affected susceptibility to illness resulting from exposure to mold); *Blackwell v. Wyeth*, 971 A.2d 235, 252–53 (Md. 2009) (affirming exclusion of expert testimony that mercury in vaccine caused autism in genetically susceptible plaintiff where trial judge found no evidence that the genetic variants about which the expert testified were associated with autism or affected mercury excretion).

196. Genetic variation in susceptibility to the toxic effects of beryllium was central to *Sheridan v. NGK Metals Corp.*, 609 F.3d 239, 244 (3d Cir. 2010), "because only persons who have a particular genetic 'marker'—the Human Leukocyte Antigen (HLA)-DPB1 allele—can potentially recognize beryllium in the lungs as an antigen." The court observed that "[m]ultiple studies have attempted to determine the percentage of the population that is genetically predisposed, or 'susceptible,' to [chronic beryllium disease]. The results so far are inconclusive and disputed." *Id.* at 245; see also *Paz v. Brush Engineered Metals, Inc.*, 555 F.3d 383, 396 n.22 (5th Cir. 2009) (quoting an expert witness's article stating that from 1% to 16% of individuals exposed to beryllium develop disease, depending on genetic susceptibility and nature of exposure).

197. See generally, e.g., Cosetta Minelli et al., *Interactive Effects of Antioxidant Genes and Air Pollution on Respiratory Function and Airway Disease: A HuGE Review*, 173 Am. J. Epidemiology 603, 618 (2011), <https://doi.org/10.1093/aje/kwq403> ("The study of genetic susceptibility can greatly improve our understanding of air pollution pathophysiologic mechanisms of action and allow identification of those pollution components with the highest potential for harm.").

198. See section titled "General Causation" below for a discussion of general causation.

199. See *Spahn v. Sec'y of Health & Hum. Servs.*, 133 Fed. Cl. 588, 593, 600 (Fed. Cl. 2017) (sustaining special master's rejection of claim for compensation for vaccine injury where claimant's expert opined that CPOX4 mutation rendered claimant ultra-susceptible to neurotoxic effects of mercury in the vaccine but claimant did not undergo genetic testing to determine whether he had the mutation).

200. Consider, hypothetically, a gene that occurs in two forms (alleles), *A* and *a*; people with at least one *A* allele (genotype *AA* or *Aa*) who are exposed to toxicant *T* have a relative risk of 10 for a particular disease, but exposed people without an *A* allele (genotype *aa*) are protected from the toxicity and have a relative risk of 1 (no association). An exposed *AA* or *Aa* plaintiff would have a different case from an exposed *aa* plaintiff. But suppose that *a* alleles are rare, so that *aa* genotypes account for only 1% of the population. It might be reasonable to permit the factfinder to draw the inference that a sick, exposed plaintiff was not *aa*, even if the plaintiff's actual

To illustrate effect modification, below are hypothetical data from a case-control study for the relationship of a dichotomous exposure, such as smoking (ever vs. never), and a dichotomous outcome, such as the existence of a disease. The data reveal effect modification by sex.

TOTAL

	Diseased	Not diseased	Total
Exposed	300	250	550
Not Exposed	200	250	450

The odds ratio for the association between exposure and disease for the total sample (males and females together) is 1.50; statistical analysis reveals a 95% confidence interval (CI) bounded by 1.20 and 1.90 and a p -value equaling 0.002 (often abbreviated as “95% CI = 1.20, 1.90; $p = 0.002$ ”). The low p -value means that this association is statistically significant for the entire study sample. However, we may have reason to believe that the exposure may differentially affect males and females. To examine this possibility, we stratify the data by sex.

MALES

	Diseased	Not diseased	Total
Exposed	80	50	130
Not Exposed	45	75	120

The odds ratio for the association between exposure and disease in the males is 2.70 (95% CI = 1.60, 4.60, $p < 0.001$). The low p -value means that this association is statistically significant, but the relatively wide confidence interval reflects the moderate size of the subsample of males ($n = 250$).

FEMALES

	Diseased	Not diseased	Total
Exposed	220	200	420
Not Exposed	155	175	330

genotype for some reason cannot be ascertained. Alternatively, limitations of the genetic epidemiology studies themselves, *see supra* note 53 and accompanying text, might affect the probative value of evidence of the plaintiff’s genotype. Specific causation is discussed in the section titled “Specific Causation” below.

The odds ratio for the association between exposure and disease in the females is 1.20 (95% CI = 0.90, 1.70, $p = 0.14$). The higher p -value means that this association is not statistically significant and the narrower confidence interval relative to males reflects the larger size of the subsample of females ($n = 750$).

We can test for whether the association between exposure and outcome is statistically different among males ($OR = 2.70$) relative to females ($OR = 1.20$). The p -value for the interaction is small (0.01), i.e., the interaction is statistically significant, suggesting that the finding that sex modifies the association between the exposure and the disease is not likely the result of random error.²⁰¹

General Causation

Once epidemiologists conclude that an association exists, the next question is whether an inference of causation is appropriate.²⁰² To make a judgment about causation, a knowledgeable expert considers the available studies and evaluates the body of evidence using the criteria described below.²⁰³

201. One court quoted an expert witness who explained the importance of effect modification thusly: “If, for example, the association between an exposure and an outcome is different for men than for women, sex modifies the relationship between the exposure and the outcome.” . . . When effect modification is present, “[c]ombining the two groups to create a summary measure of association is meaningless: it is not true for men and it is not true for women.” *Ohio Valley Envt Coal. v. Fola Coal Co.*, 120 F. Supp. 3d 509, 520–21 (S.D. W. Va. 2015) (quoting epidemiologist David Garabrandt; citations omitted).

Effect modification can coexist with confounding (see the section titled “Confounding Bias” above). Using slightly different terminology, one epidemiology textbook explained:

Effect-measure modification differs from confounding in several important ways. The most salient difference is that, whereas confounding is a bias that the investigator hopes to prevent or remove from the effect estimate, effect-measure modification is a property of the effect under study. Thus, effect-measure modification is a finding to be reported rather than a bias to be avoided or removed. Moreover, in epidemiologic analysis, one tries to eliminate confounding, but one may be interested in describing effect-measure modification.

Sebastien Haneuse & Kenneth J. Rothman, *Stratification and Standardization*, in Lash et al., *supra* note 50, at 609, 610.

202. For an excellent example of the authors of a study analyzing whether an inference of causation is appropriate in a case-control study examining whether bromocriptine (Parlodel) (a lactation suppressant) causes seizures in postpartum women, see Kenneth J. Rothman et al., *Bromocriptine and Puerperal Seizures*, 1 *Epidemiology* 232, 236–38 (1990), <https://doi.org/10.1097/00001648-199005000-00009>.

203. In a lawsuit, this would be done by an expert witness. In science, the effort is usually conducted by a panel of experts. See Douglas L. Weed, *Epidemiologic Evidence and Causal Inference*, 14 *Hematology/Oncology Clinics N. Am.* 797 (2000) (discussing judgment involved in selecting criteria and assigning rules of evidence to them in the process of judging whether an association is causal); Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 cmt. c (2010) (“[A]n evaluation of data and scientific evidence to determine whether an inference of causation is appropriate requires judgment and interpretation.”).

When epidemiologists evaluate whether a cause–effect relationship exists between an agent and a health outcome, they are using the term causation in a way similar, but not identical, to the way that the familiar but-for, or sine qua non, test is used in law for cause in fact. “Conduct is a factual cause of [harm] when the harm would not have occurred absent the conduct.”²⁰⁴ This is equivalent to describing the act or occurrence as a necessary link in a chain of events that results in the particular outcome.²⁰⁵ Epidemiologists use causation to mean that an increase in the incidence of disease or an adverse health outcome among the group of exposed subjects would not have occurred had they not been exposed to the agent.²⁰⁶ Thus, exposure is a necessary condition for the increase in the incidence of disease among those exposed.²⁰⁷ The relationship between the epidemiologic concept of cause and the legal question of whether exposure to an agent caused an individual’s disease is addressed in the section below titled “Specific Causation.”

Data from epidemiologic studies, as well as from toxicology and in vitro studies, are also considered in an approach termed weight of evidence.²⁰⁸ In the landmark 1964 Surgeon General’s report on smoking and health, smoking was determined to be a causal agent in lung cancer based on the consistency, strength,

More generally, causation always requires an inference from circumstantial evidence because causation cannot be perceived directly with any of the five senses. Epidemiologic evidence is one form of circumstantial evidence that informs the inferential process when the causal question involves agents and disease.

204. Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 26 (2010); *see also* Dan B. Dobbs et al., *Dobbs’ Law of Torts* § 189 (updated 2024). When multiple causes are each operating and each is independently capable of causing an event, the but-for, or necessary-condition, concept for causation is problematic. This is the familiar two-fires scenario, in which two independent fires simultaneously burn down a house and is sometimes referred to as overdetermined outcomes. Neither fire is a but-for, or necessary condition, for the destruction of the house, because either fire would have destroyed the house. *See* Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 (2010). This two-fires situation is analogous to an individual being exposed to two agents, each of which is capable of causing the disease contracted by the individual. *See* *Basko v. Sterling Drug, Inc.*, 416 F.2d 417 (2d Cir. 1969).

205. *See supra* note 10; *see also* Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 26 cmt. c (2010) (employing a “causal set” model to explain multiple elements, each of which is required for an outcome).

206. Bruce G. Charlton, *Attribution of Causation in Epidemiology: Chain or Mosaic?*, 49 J. Clinical Epidemiology 105, 105 (1999), [https://doi.org/10.1016/0895-4356\(95\)00030-5](https://doi.org/10.1016/0895-4356(95)00030-5) (“The imputed causal association is at the group level, and does not indicate the cause of disease in individual subjects.”).

207. *See* Lash et al., *supra* note 50, at 8 (“We can define a cause of a specific disease event as an antecedent event, condition, or characteristic that was necessary for the occurrence of the disease at the moment it occurred, given that other conditions are fixed.”); *Allen v. United States*, 588 F. Supp. 247, 405 (D. Utah 1984) (quoting a physician on the meaning of the statement that radiation causes cancer), *rev’d on other grounds*, 816 F.2d 1417 (10th Cir. 1987).

208. *See supra* note 71 and accompanying text.

specificity, temporal relationship, and coherence of the association.²⁰⁹ A year later, Sir Austin Bradford Hill published a list of elements to consider for inferring causation from an association that partially overlapped with those applied in the Surgeon General's report.²¹⁰ The items Hill identified are sometimes erroneously presented as mandatory "criteria" rather than as factors or considerations, but Hill himself acknowledged that they could only serve to assist in the inferential process: "None of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a *sine qua non*."²¹¹ Yet it is imperative to note that epidemiologists employ these guidelines only after a study finds an association, to determine whether that association reflects a true causal relationship.²¹² These guidelines consist of several key inquiries that assist researchers in making a judgment about causation.²¹³ Generally, researchers are conservative when it comes to assessing causal relationships, often calling for stronger evidence and more research before a conclusion of causation is drawn.²¹⁴

209. U.S. Dep't Health, Educ. & Welfare, Pub. Health Serv., *Smoking and Health: Report of the Advisory Committee to the Surgeon General of the Public Health Service* 26–32 (1964) (describing the types of evidence considered in reaching the report's conclusion), <https://perma.cc/9TH2-JP7B>.

210. See Austin Bradford Hill, *The Environment and Disease: Association or Causation?*, 58 *Proc. Royal Soc'y Med.* 295 (1965). For discussion of these considerations and their respective strengths in informing a causal inference, see Celentano & Szklo, *supra* note 37, at 236–39; David E. Lilienfeld & Paul D. Stolley, *Foundations of Epidemiology* 276–80 (3d ed. 2019); Weed, *supra* note 203.

211. See Hill, *supra* note 210, at 36.

212. In a number of cases, experts attempted to use these guidelines to support the existence of causation in the absence of any epidemiologic studies finding an association. *Compare* *Rains v. PPG Indus.*, 361 F. Supp. 2d 829, 836–37 (S.D. Ill. 2004) (explaining Hill factors and proceeding to apply them even though there was no epidemiologic study that found an association) *and* *Wendell v. GlaxoSmithKline LLC*, 858 F.3d 1227, 1235–36 (9th Cir. 2017) (reversing exclusion of testimony of plaintiff's expert who "used the Bradford Hill methodology" but "did not rely on animal or epidemiological studies") *with* *Hoeffling v. U.S. Smokeless Tobacco Co.*, 576 F. Supp. 3d 262, 273 (E.D. Pa. 2021) (finding an expert's general causation opinion based on the Hill factor of "biological plausibility" unreliable because there was no epidemiologic evidence supporting an association), *In re Roundup Prods. Liab. Litig.*, 390 F.3d 1102, 1131 (N.D. Cal. 2018) ("identifying an association . . . is a necessary predicate to reliable application of the Bradford Hill criteria"), *and* *Jones v. Novartis Pharms. Corp.*, 235 F. Supp. 3d 1244, 1268 (N.D. Ala. 2017) (inability to point to a study showing an association between exposure and disease was "fatal flaw" of expert's reliance on Hill factors (citing the third edition of this reference guide)).

213. See Mervyn Susser, *Causal Thinking in the Health Sciences: Concepts and Strategies in Epidemiology* (1973); *Gannon v. United States*, 571 F. Supp. 2d 615, 624 (E.D. Pa. 2007) (quoting expert who testified that the Hill factors are "'well-recognized' and widely used in the science community to assess general causation"); *Chapin v. A & L Parts, Inc.*, 732 N.W.2d 578, 584 (Mich. Ct. App. 2007) (expert testified that Hill factors are the most well-utilized method for determining if an association is causal).

214. *Berry v. CSX Transp., Inc.*, 709 So. 2d 552, 568 n.12 (Fla. Dist. Ct. App. 1998) ("Almost all genres of research articles in the medical and behavioral sciences conclude their discussion with qualifying statements such as 'there is still much to be learned.' This is not, as might be assumed, an expression of ignorance, but rather an expression that all scientific fields are open-ended and can

Some regulatory agencies have modified the Hill factors in a number of ways and used them as a guide. The United States Environmental Protection Agency (EPA) has employed a system called the Causal Analysis/Diagnosis Decision Information System, or CADDIS, a weight-of-evidence approach to identify causal agents.²¹⁵ The International Agency for Research on Cancer (IARC) also relies on a weight-of-evidence approach that considers epidemiologic studies, animal experiments, and mechanistic information.²¹⁶ The IARC convenes groups of experts in various fields who are asked to reach consensus and to collectively consider the strength of the association, consistency across studies and diverse populations, dose–response relationships, biological plausibility, and temporal relationships observed in epidemiologic studies, as well as the results of animal and mechanistic studies.²¹⁷

The following is a modified list of the Hill considerations²¹⁸ that inform epidemiologists in making judgments about causation (there is no threshold number that must exist²¹⁹):

1. Temporal relationship
2. Strength of the association

progress from their present state. . . .”); *Hall v. Baxter Healthcare Corp.*, 947 F. Supp. 1387, 1446–51 (D. Or. 1996) (report of Merwyn R. Greenlick, court-appointed epidemiologist). In *Cadarian v. Merrell Dow Pharms., Inc.*, 745 F. Supp. 409 (E.D. Mich. 1989), the court refused to permit an expert to rely on a study that the authors had concluded should not be used to support an inference of causation in the absence of independent confirmatory studies. The court did not address the question whether the degree of certainty used by epidemiologists before making a conclusion of cause was consistent with the legal standard. See *DeLuca*, 911 F.2d at 957 (standard of proof for scientific community is not necessarily appropriate standard for expert opinion in civil litigation); *Wells v. Ortho Pharm. Corp.*, 788 F.2d 741, 745 (11th Cir. 1986).

215. U.S. Env’t Prot. Agency, *Causal Analysis/Diagnostic Decision Information System (CADDIS)*, <https://perma.cc/2L4R-58T8> (last visited Aug. 5, 2024); see U.S. Env’t Prot. Agency, *CADDIS Volume 1: Stressor Identification—About Causal Assessment*, “An Approach to Causal Inference,” <https://perma.cc/T52H-X84S> (“We accept multiple causation concepts and all relevant evidence and methods for turning data into evidence.”).

216. For a discussion of mechanistic data, see Eaton et al., *supra* note 60, “Toxicological Processes and Target Organ Toxicity.”

217. See generally, e.g., Int’l Agency for Rsch. on Cancer, 96 IARC Monographs on the Evaluation of Carcinogenic Risks to Humans: Alcohol Consumption and Ethyl Carbamate 7–33 (2010) (describing IARC approach).

218. This list was developed by Leon Gordis, the epidemiologist coauthor of the first three editions of this reference guide. See Celentano & Szklo, *supra* note 37, at 276–79. The original Hill considerations were: 1) consistency; 2) strength; 3) specificity; 4) dose–response; 5) temporal relationship; 6) biological plausibility; 7) coherence; and 8) experiment. See Hill, *supra* note 210. These considerations are largely congruent with the factors listed in the text, although with some wording differences and the addition of the “consideration of alternative explanations” item in the text.

219. See *Cook v. Rockwell Int’l Corp.*, 580 F. Supp. 2d 1071, 1098 (D. Colo. 2006) (“Defendants cite no authority, scientific or legal, that compliance with all, or even one, of these factors is required. . . . The scientific consensus is, in fact, to the contrary. It identifies Defendants’ list of factors as some of the nine factors or lenses that guide epidemiologists in making judgments about causation. . . . These factors are not tests for determining the reliability of any study or the causal inferences drawn from it.”).

3. Dose–response relationship
4. Replication of the findings
5. Biological plausibility
6. Consideration of alternative explanations
7. Cessation of exposure
8. Specificity of the association
9. Consistency with other relevant knowledge

There is no formula or algorithm that can be used to assess whether a causal inference is appropriate based on these guidelines.²²⁰ One or more factors may be absent even when a true causal relationship exists.²²¹ Similarly, the existence of some factors does not ensure that a causal relationship exists. Drawing causal inferences after finding an association and considering these factors requires judgment and searching analysis, based on biology, of why a factor or factors may be absent despite a causal relationship, and vice versa. Although the drawing of causal inferences is informed by scientific expertise, it is not a determination that is made by using an objective or algorithmic methodology.²²²

Temporal Relationship

A temporal, or chronological, relationship must exist for causation to exist. If an exposure causes disease, the exposure must occur before the disease develops.²²³ If the exposure occurs after the disease develops, it cannot have caused the disease. Although temporal relationship is often listed as one of many factors in assessing whether an inference of causation is justified, this aspect of a temporal relationship is a necessary factor: Without exposure before the disease, causation cannot exist.²²⁴

220. See Douglas L. Weed, *Epidemiologic Evidence and Causal Inference*, 14 *Hematology/Oncology Clinics N. Am.* 797 (2000), [https://doi.org/10.1016/s0889-8588\(05\)70312-9](https://doi.org/10.1016/s0889-8588(05)70312-9).

221. See *Cook v. Rockwell Int'l Corp.*, 580 F. Supp. 2d 1071, 1098 (D. Colo. 2006) (rejecting argument that plaintiff failed to provide sufficient evidence of causation based on failing to meet four of the Hill factors).

222. See David A. Savitz & Gregory Wellenius, *Interpreting Epidemiologic Evidence: Study Design and Analysis* 199–210 (2d ed. 2016).

223. See *McClain v. Metabolife Int'l, Inc.*, 401 F.3d 1233, 1243 (11th Cir. 2005) (“[T]he chronological relationship between exposure and effect must be biologically plausible . . . [thus], if a disease or illness in an individual preceded the established period of exposure, then it cannot be concluded that the chemical caused the disease, although it may be possible to establish that the chemical aggravated a pre-existing condition or disease.”) (quoting David L. Eaton, *Scientific Judgment and Toxic Torts: A Primer in Toxicology for Judges and Lawyers*, 12 J. L. & Pol’y 5 (2003)).

224. However, exposure during the disease initiation process may cause the disease to be more severe than it otherwise would have been without the additional dose.

With specific causation, a subject dealt with in detail in the section below titled “Specific Causation,” there may be circumstances in which a temporal relationship supports the existence of a causal relationship.

If the latency period between exposure and outcome is known,²²⁵ then exposure consistent with that information may lend credence to a causal relationship. This is particularly true when the latency period is short and competing causes are known and can be ruled out. Thus, if an individual suffers an acute respiratory response shortly after exposure to a suspected agent, and other causes of that respiratory problem are known and can be ruled out, the temporal relationship strongly supports the conclusion that a causal relationship exists.²²⁶ By contrast, exposure outside a known latency period, such as an exposure very quickly followed by development of cancer, constitutes evidence against the existence of causation.²²⁷ When latency periods are lengthy, variable, or not known, and a substantial proportion of the disease is due to unknown causes, temporal relationship provides little beyond satisfying the requirement that cause precede effect.²²⁸

225. When the latency period is known—or is known to be limited to a specific time period—as is the case with the adverse effects of some vaccines—the time frame from exposure to manifestation of disease can be critical to determining causation. Thus, epidemiologic evidence identified the swine flu vaccine as a cause of Guillain-Barre syndrome (GBS) but the peak latency period was two to three weeks after vaccination and the excess risk disappeared after 10 weeks. That evidence was critical in denying recovery to a swine flu vaccinee who developed GBS 17 weeks after vaccination. See *Robinson v. United States*, 533 F. Supp. 320, 328 (E.D. Mich. 1982).

226. For courts that have relied on temporal relationships of the sort described, see *Bonner v. ISP Technologies, Inc.*, 259 F.3d 924, 930–31 (8th Cir. 2001) (giving more credence to the expert’s opinion on causation for acute response based on temporal relationship than for chronic disease that plaintiff also developed); *Heller v. Shaw Indus., Inc.*, 167 F.3d 146 (3d Cir. 1999); *Westberry v. Gislaved Gummi AB*, 178 F.3d 257 (4th Cir. 1999); *Zuchowicz v. United States*, 140 F.3d 381 (2d Cir. 1998); *Creanga v. Jarda*, 886 A.2d 633, 641 (N.J. 2005); *Alder v. Bayer Corp., AGFA Div.*, 61 P.3d 1068, 1090 (Utah 2002) (“If a bicyclist falls and breaks his arm, causation is assumed without argument because of the temporal relationship between the accident and the injury [and, the court might have added, the absence of any plausible competing causes that might instead be responsible for the broken arm].”).

227. See *De Bazan v. Sec’y of Health & Hum. Servs.*, 539 F.3d 1347, 1352 (Fed. Cir. 2008) (plaintiff’s disease occurred too soon after vaccination for it to have been causal); *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1238 (W.D. Wash. 2003) (determining that expert testimony on causation for plaintiffs whose exposure was beyond known latency period was inadmissible).

228. These distinctions provide a framework for distinguishing between cases that are largely dismissive of temporal relationships as supporting causation and others that find it of significant persuasiveness. Compare cited cases, *supra* note 226, with *Moore v. Ashland Chem. Inc.*, 151 F.3d 269, 278 (5th Cir. 1998) (giving little weight to temporal relationship in case in which there were several plausible competing causes that may have been responsible for plaintiff’s disease) and *Glastetter v. Novartis Pharms. Corp.*, 252 F.3d 986, 990 (8th Cir. 2001) (giving little weight to temporal relationship in case reports involving drug and stroke).

Strength of the Association

The relative risk is a commonly used measure of association that represents the strength of an association.²²⁹ Larger relative risks (or stronger associations using other statistical measures) are often believed to be more likely to be causal than smaller ones.²³⁰ For cigarette smoking, for example, the estimated relative risk for lung cancer is very high, about 10.²³¹ That is, the risk of lung cancer in smokers is approximately 10 times the risk in nonsmokers.

A relative risk of 10, as seen with smoking and lung cancer, is so large that, aside from causality, only very strong uncontrolled bias or large random error could account for it. Although smaller relative risks can also reflect causality, epidemiologists scrutinize such associations more closely because weaker biases (which may have been ignored or are unknown) or smaller random error could account for them.

Dose–Response Relationship

If exposure to an agent causes a disease, higher exposures would generally be expected to increase the incidence or severity of that disease.²³² Therefore, whether a dose–response relationship exists is a factor epidemiologists consider in assessing whether an association is causal.²³³ This subsection describes several possible forms

229. See section titled “Relative Risk” above.

230. See Celentano & Szklo, *supra* note 37, at 277 (“The stronger the association, the more it is that the relation is causal.”); *In re Johnson & Johnson Talcum Powder Prods. Mktg., Sales Pracs. & Prods. Litig.*, 509 F. Supp. 3d 116, 162 (D.N.J. 2020) (citing the second edition of this reference guide). The use of the strength of the association as a factor, however, does not reflect a belief that weaker causal effects occur less frequently than stronger ones. See Green, *supra* note 70, at 652–53 n.39; Tyler J. VanderWeele et al., *Causal Inference and Scientific Reasoning*, in Lash et al., *supra* note 50, at 17, 18–19 (“the stronger an association, the harder it is to explain away as artifacts of biases” but “there are many weaker associations that are generally agreed to reflect causal effects”). Indeed, the apparent strength of a given agent is dependent on the prevalence of the other necessary elements that must occur with the agent to produce the disease, rather than on some inherent characteristic of the agent itself. See Lash et al., *supra* note 50, at 87–91.

231. See Doll & Hill, *supra* note 9. The relative risk of lung cancer from smoking is a function of intensity and duration of dose (and perhaps other factors). See Karen Leffondré et al., *Modeling Smoking History: A Comparison of Different Approaches*, 156 Am. J. Epidemiology 813 (2002), <https://doi.org/10.1093/aje/kwf122>. The relative risk provided in the text is based on a specified magnitude of cigarette exposure. There is evidence that the relative risk has increased over time even though smokers in more recent studies smoked fewer cigarettes per day. Pub. Health Servs., U.S. Dep’t of Health & Hum. Servs., *The Health Consequences of Smoking: 50 Years of Progress: A Report of the Surgeon General* 158–86, 293 (2014).

232. Exceptions to this general proposition exist. See *infra* Figure 13, depicting a non-monotonic dose–response curve, and accompanying text.

233. See *Newman v. Motorola, Inc.*, 218 F. Supp. 2d 769, 778 (D. Md. 2002) (recognizing importance of dose–response relationship in assessing causation).

of dose–response relationships. The descriptions are of adverse responses (such as the development of a disease after exposure to an agent) although some responses may be beneficial (such as the therapeutic effect of a medication).

A linear dose response exists when the response increases proportionally to increasing dose, as depicted in the graph in Figure 9. The adverse response (the dependent variable) reflected in the y axis is the incidence of disease in the population and the x axis represents the dose of the agent of interest (the independent variable).²³⁴

Figure 9. Linear dose response.

Some causal agents do not exhibit a linear dose–response relationship. For example, some agents may not cause disease until the exposure exceeds a certain threshold dose. Figure 10 depicts a dose–response relationship with a threshold, with a linear dose–response relationship for doses above the threshold.

Figure 10. Linear threshold dose response.

There may be a no–effect threshold dose for some toxic substances, reflecting, for example, defense mechanisms and repair processes.²³⁵ However, for

234. Another dose–response relationship that may be of interest to researchers is the relationship of the severity of disease with increasing dose.

235. The idea that the “dose makes the poison” is a central tenet of toxicology, attributed to Paracelsus in the sixteenth century. See Eaton et al., *supra* note 60, “Introduction” section, in this

others such as carcinogens, it is commonly assumed that no threshold dose exists on a group basis.²³⁶ It is unlikely that researchers will find good evidence to support or refute the threshold–dose hypothesis because of the inability of epidemiology or animal toxicology to ascertain the effects of very small doses.²³⁷

Even if the incidence of disease increases with increasing dose, that dose–response relationship may not be linear. Supra-linear responses reflect a response that increases with increasing dose, but for which the rate of increase is smaller at higher doses than at lower doses, as depicted in Figure 11.²³⁸ Sub-linear responses reflect a response that increases with increasing dose, but for which the rate of increase is larger at higher doses than at lower doses, as depicted in Figure 12.²³⁹ Particularly for low-dose exposures, the shape of the dose–response curve—whether linear or curvilinear (and if the latter, the shape of the curve)—is a matter of hypothesis and speculation.²⁴⁰

manual. This dictum does not mean that any agent is capable of causing any disease if an individual is exposed to a sufficient dose. Rather, it reflects only the idea that there is a safe dose below which an agent does not cause any toxic effect. See Philip Wexler & Antoinette N. Hayes, *The Evolving Journey of Toxicology: A Historical Glimpse*, in Casarett and Doull's *Toxicology: The Basic Science of Poisons* 3 (Curtis D. Klaassen ed., 9th ed. 2019); see also *Alder v. Bayer Corp., AGFA Division*, 61 P.3d 1068, 1088 (Utah 2002) (illustrating misunderstanding of the concept that “the dose makes the poison”). Toxic agents tend to cause specific harmful effects, an idea that also originated with Paracelsus. See section titled “Specificity of the Association” below.

236. See, e.g., Edward J. Calabrese et al., *Ethical Challenges of the Linear Non-Threshold (LNT) Cancer Risk Assessment Revolution: History, Insights, and Lessons To Be Learned*, 2022 Sci. Total Env't 832, <https://doi.org/10.1016/j.scitotenv.2022.155054>; Bernd Kaina et al., *Do Carcinogens Have a Threshold Dose? The Pros and Cons*, in *Regulatory Toxicology* 397 (Franz-Xaver Reichl & Michael Schwenk eds., 2014). See also Irving J. Selikoff, *Disability Compensation for Asbestos-Associated Disease in the United States: Report to the U.S. Department of Labor* 181–220 (1981); *Ferebee v. Chevron Chem. Co.*, 736 F.2d 1529, 1536 (D.C. Cir. 1984) (dose–response relationship for low doses is “one of the most sharply contested questions currently being debated in the medical community”); *In re TMI Litig. Consol. Proc.*, 927 F. Supp. 834, 844–45 (M.D. Pa. 1996) (discussing low-dose extrapolation and the possibility of no-effect doses for radiation exposure and cancer).

237. Cf. Arnold L. Brown, *The Meaning of Risk Assessment*, 37 *Oncology* 302, 303 (1980); see also Advisory Comm. on Childhood Lead Poisoning Prevention, *Ctrs. for Disease Control & Prevention*, *Low Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention* 7 (2012) (“new studies and re-interpretation of past studies have demonstrated that it is not possible to determine a threshold below which [blood lead level] is not inversely related to IQ”), <https://stacks.cdc.gov/view/cdc/11859>.

238. A supra-linear dose–response curve reveals a greater rate of response to increasing dose than would exist if the response rate were linear. A linear curve for the same dose and endpoint, see *supra* Figure 9, would be below the supra-linear curve depicted in Figure 11.

239. In contrast to a supra-linear curve, the responses in a sub-linear dose–response curve are lower than would exist if the response were linear. A linear curve for the same dose and endpoint, see *supra* Figure 9, would be above the sub-linear curve depicted in Figure 12.

240. See *Allen v. United States*, 588 F. Supp. 247, 419–24 (D. Utah 1984) (describing uncertainties about dose–response relationship at low levels of radiation exposure), *rev'd on other grounds*, 816 F.2d 1417 (10th Cir. 1987); *In re Bextra & Celebrex Mktg. Sales Pracs. & Prod. Liab. Litig.*, 524 F. Supp. 2d 1166, 1180 (N.D. Cal. 2007) (criticizing expert for “primitive” extrapolation of

Figure 11. Supra-linear dose response.

Figure 12. Sub-linear dose response.

Finally, some agents may have a greater adverse effect on health outcomes at lower doses than at higher doses. Figure 13 depicts such a non-monotonic dose-response curve.²⁴¹

Evidence for non-monotonic dose response has been presented for chemicals that affect hormones (termed endocrine disruptors) as well as for essential nutrients. In such cases, an association may be observed at lower doses and perhaps not at moderate or high doses. For example, while there is a range of manganese intake that contributes to normal child development, low manganese intake could impair normal bone formation, reproduction, and immune response;²⁴² conversely, high exposure of pregnant women to manganese in

risk based on assumption of linear relationship of risk to dose); Troyen A. Brennan & Robert F. Carter, *Legal and Scientific Probability of Causation for Cancer and Other Environmental Disease in Individuals*, 10 J. Health Pol'y & L. 33, 43–44 (1985).

241. A non-monotonic effect is one in which the relationship between the response of the dependent variable does not continually proceed in the same direction as the independent variable, as shown in the dose-response curve in Figure 13.

242. See Longman Li & Xiaobo Yang, *The Essential Element Manganese, Oxidative Stress, and Metabolic Diseases: Links and Interactions*, *Oxidative Med. Cell Longevity*, Apr. 5, 2018, <https://doi.org/10.1155/2018/7580707>; Food & Nutrition Bd., Inst. Med., Dietary Reference Intakes for

Figure 13. Non-monotonic dose response.

drinking water may impair cognition among their children.²⁴³ Thus, a dose-response relationship is supportive, but not essential, evidence that the relationship between an agent and disease is causal.²⁴⁴

Replication of the Findings

Rarely, if ever, does a single study persuasively demonstrate a cause-effect relationship.²⁴⁵ It is important that a study be repeated in different populations and by different investigators before a causal relationship is accepted by epidemiologists and other scientists.²⁴⁶

Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc (2001); Judy L. Aschner & Michael Aschner, *Nutritional Aspects of Manganese Homeostasis*, 26 *Molecular Aspects Med.* 353 (2005), <https://doi.org/10.1016/j.mam.2005.07.003>; Pan Chen et al., *Manganese Metabolism in Humans*, 23 *Frontiers Bioscience-Landmark* 1655 (2018), <https://doi.org/10.2741/4665>.

243. See Kaitlin Vollet, *Manganese Exposure and Cognition Across the Lifespan: Contemporary Review and Argument for Biphasic Dose-Response Health Effects*, 3 *Current Env't Health Reps.* 392 (2016), <https://doi.org/10.1007/s40572-016-0108-x>.

244. Evidence of a dose-response relationship as bearing on whether an inference of general causation is justified is analytically distinct from determining whether evidence of the dose to which a plaintiff was exposed is required in order to establish specific causation. On the latter matter, see section titled “Specific Causation” below; Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 cmt. c(2) & rptrs. note (2010).

245. In *Kehm v. Procter & Gamble Co.*, 580 F. Supp. 890, 901 (N.D. Iowa 1982), *aff'd*, 724 F.2d 613 (8th Cir. 1983), the court remarked on the persuasive power of multiple independent studies, each of which reached the same finding of an association between toxic shock syndrome and tampon use.

246. See Celentano & Szklo, *supra* note 37, at 277 (“Replication of findings is particularly important in epidemiology.”); *In re Mirena IUS Levonorgestrel-Related Prods. Liab. Litig.* (No. II), 341 F. Supp. 3d 213, 250 (S.D.N.Y. 2018) (citing the third edition of this reference guide), *aff'd*, 982 F.3d 113 (2d Cir. 2020). *But see* *Smith v. Wyeth-Ayerst Labs. Co.*, 278 F. Supp. 2d 684, 710 n.55 (W.D.N.C. 2003) (observing that replication is difficult to establish when there is only one study that has been performed at the time of trial).

The importance of replicating research findings permeates most fields of science. In epidemiology, research, if repeated, often is repeated in different populations. Consistency of the findings of multiple investigations is an important factor in making a judgment about causation. Different studies that examine the same exposure–disease relationship generally should yield qualitatively similar, but likely not quantitatively identical, results.²⁴⁷ However, it is important to keep in mind that relations between exposures and outcomes may actually differ between populations because of differences in other factors (e.g., genetics, sociodemographic characteristics, nutrition).

Biological Plausibility

Biological plausibility is not an easy criterion to use and depends upon existing knowledge about the mechanisms by which the disease develops. When biological plausibility exists, it lends credence to an inference of causality.²⁴⁸ For example, the conclusion that high cholesterol is a cause of coronary heart disease is made more plausible because cholesterol is found in atherosclerotic plaques.²⁴⁹ However, observations have been made in epidemiologic studies that were not

247. See Valentin Amrhein et al., *Inferential Statistics as Descriptive Statistics: There Is No Replication Crisis if We Don't Expect Replication*, 73 Am. Statistician 262 (2019), <https://doi.org/10.1080/00031305.2018.1543137>.

248. A number of courts have adverted to this criterion in the course of their discussions of causation in toxic substances cases. *E.g.*, *In re Phenylpropanolamine (PPA) Prods. Liab. Litig.*, 289 F. Supp. 2d 1230, 1247–48 (W.D. Wash. 2003); *Cook v. United States*, 545 F. Supp. 306, 314–15 (N.D. Cal. 1982) (discussing biological implausibility of a two-peak increase of disease when plotted against time); *Landrigan v. Celotex Corp.*, 605 A.2d 1079, 1085–86 (N.J. 1992) (discussing the existence vel non of biological plausibility); see also Eaton et al., *supra* note 60, “Demonstrating an Association Between Exposure and Risk of Disease.”

249. High LDL cholesterol levels are associated with higher rates of coronary heart disease. The physical presence of cholesterol in plaques found in blood vessels lends credence—biological plausibility—to the idea that this association is causal. The causal relation has been confirmed by randomized clinical trials of statin drugs, which reduce blood levels of LDL cholesterol and have a protective effect against heart disease.

Epidemiologists have also used another approach to help rule out the possibility that the association resulted from the effects of some unknown confounder (a factor causing both high LDL cholesterol and coronary heart disease) or even the possibility that coronary heart disease causes LDL cholesterol to collect in plaques (i.e., so-called reverse causation). This approach relies on genetic variability to provide information about the causal role of cholesterol levels.

Some people have genetic variations that affect their metabolism of fats and reduce their LDL cholesterol levels. People with these cholesterol-lowering genes have reduced risk of coronary heart disease. The observation that an inherited genetic variation is associated with both lower LDL cholesterol levels and reduced risk of coronary heart disease strongly supports the inference that cholesterol levels affect the disease risk rather than heart disease causing cholesterol or confounding. Because the presence or absence of coronary heart disease does not affect an individual's inherited genes, there is no possibility of reverse causation. Because some unknown factor does not alter both

biologically plausible at the time but that were subsequently shown to be correct.²⁵⁰ When an observation is inconsistent with current biological knowledge, it should not be discarded, but the observation should be confirmed before it is given credence. The salience of this factor varies depending on the extent of scientific knowledge about the toxicology as well as cellular and subcellular mechanisms through which the disease process works. The mechanisms of some diseases are understood quite well based on evidence, including from toxicologic research, whereas other mechanism explanations are merely hypothesized—although hypotheses are sometimes accepted under this factor.²⁵¹

a person's inherited genes and a person's coronary heart disease risk, the possibility of confounding is greatly reduced (see section titled "Effect Modification" above).

This epidemiologic method—known as Mendelian randomization (named after Gregor Mendel, the pioneering researcher of the laws of heredity)—uses genetic variation (in the example, the cholesterol-lowering variant) as a proxy for an exposure of interest (in the example, LDL cholesterol levels), to help clarify whether the exposure is causally associated with a health outcome of interest (in the example, coronary heart disease). As vast genomic datasets are increasingly available, the number of studies applying Mendelian randomization is increasing rapidly.

Mendelian randomization can be applied when genetic variations are associated with the exposure of interest and certain other assumptions are satisfied. It might seem implausible that a genetic variation is associated with the likelihood that someone is exposed to a potentially toxic substance. But genetic variation could affect how a person metabolizes a substance, which in turn could affect the substance's toxicity in that person. In such a situation, Mendelian randomization could be useful for the causal issues discussed in this reference guide; we thus provide this brief introduction to the methodology. As of the date of publication of this reference guide, however, Mendelian randomization has not been prominent in research on the types of causal issues addressed here and has not figured at all in court opinions concerning those issues. For short introductions to the methodology, see Gemma Sharp, *Introduction to Mendelian Randomization*, youtube.com/watch?v=isMZhasFc4M (Mar. 10, 2020) (last visited November 13, 2024); Connor A. Emdin et al., *Mendelian Randomization*, 318 JAMA 1925 (2017), <https://doi.org/10.1001/jama.2017.17219>. For a more mathematical introduction, see E. Sanderson et al., *Mendelian Randomization*, 2 Nature Rev. Methods Primers [6] (2022), <https://doi.org/10.1038/s43586-021-00092-5>.

250. For example, Sir Norman Gregg connected German measles in pregnant women with congenital cataracts before there was understanding of the role of viruses as teratogens. See Celenzano & Szklo, *supra* note 37, at 277; N. McAllister Gregg, *Congenital Cataract Following German Measles in the Mother*, 107 Epidemiology & Infection iii (1991), <https://doi.org/10.1017/s0950268800048627>.

251. See Douglas L. Weed & Stephen D. Hursting, *Biologic Plausibility in Causal Inference: Current Methods and Practice*, 147 Am. J. Epidemiology 415 (1998), <https://doi.org/10.1093/oxfordjournals.aje.a009466> (examining use of this criterion in contemporary epidemiologic research and distinguishing between alternative explanations of what constitutes biological plausibility, ranging from mere hypotheses to "sufficient evidence to show how the factor influences a known disease mechanism"); David A. Savitz, *Epidemiology and Biological Plausibility in Assessing Causality*, 5 Env't Epidemiology e177 (2021), <https://doi.org/10.1097/EE9.0000000000000177>. For a discussion of the role of mechanistic research in toxicology, see Eaton et al., *supra* note 60, "Toxicological Processes and Target Organ Toxicity."

Consideration of Alternative Explanations

This consideration refers to the possibility that an observed association is caused by something other than the exposure under study. The importance of considering the possibility of bias and confounding and ruling out those possibilities is discussed above.²⁵²

Cessation of Exposure

If an agent is a cause of a disease, then one would expect that cessation of exposure to that agent ordinarily would reduce the risk of the disease.²⁵³ This has been the case, for example, with cigarette smoking and lung cancer. In many situations, however, relevant data are simply not available regarding the possible effects of ending the exposure. But when such data are available, and eliminating exposure reduces the incidence of disease, this factor strongly supports a causal relationship.

Specificity of the Association

An association exhibits specificity if the exposure is associated only with a single disease or type of disease. This criterion reflects the fact that although an agent causes one disease, it does not necessarily cause other diseases.²⁵⁴ This

252. See sections titled “Biases” and “Effect Modification” above.

253. In his speech, Hill labeled this consideration “Experiment” because, as compared to other types of observational studies, the ability to observe what happens when an exposure ceases is more closely akin to a controlled experiment.

254. See, e.g., *Nelson v. Am. Sterilizer Co.*, 566 N.W.2d 671, 676–77 (Mich. Ct. App. 1997) (affirming dismissal of plaintiff’s claims that chemical exposure caused her liver disorder, but recognizing that evidence supported claims for neuropathy and other illnesses); *Sanderson v. Int’l Flavors & Fragrances, Inc.*, 950 F. Supp. 981, 996–98 (C.D. Cal. 1996); see also *Taylor v. Airco, Inc.*, 494 F. Supp. 2d 21, 27 (D. Mass. 2007) (holding that plaintiff’s expert could testify to causal relationship between vinyl chloride and one type of liver cancer for which there was only modest support given strong causal evidence for vinyl chloride and another type of liver cancer).

When a party claims that evidence of a causal relationship between an agent and one disease is relevant to whether the agent caused another disease, courts have required the party to show that the mechanisms involved in development of the disease are similar. For example, in *Milward v. Acuity Specialty Products*, 639 F.3d 11, 19–20 (1st Cir. 2011), the court accepted the plaintiff’s expert’s testimony that benzene caused a rare form of leukemia based on studies supporting the proposition that benzene was a cause of the general form of leukemia and testimony about the common causal mechanism for all types of leukemia. *Accord In re Bextra & Celebrex Mktg. Sales Pracs. & Prod. Liab. Litig.*, 524 F. Supp. 2d 1166, 1183 (N.D. Cal. 2007); *Magistrini v. One-Hour Martinizing Dry Cleaning*, 180 F. Supp. 2d 584, 603 (D.N.J. 2002).

consideration is highly debatable. Evidence amassed since the publication of Hill's paper runs contrary to this. For example, cigarette manufacturers have long claimed that because cigarettes have been linked to multiple adverse health outcomes including lung cancer, emphysema, bladder cancer, heart disease, pancreatic cancer, and other conditions, there is no specificity and the relationships are not causal. There is, however, at least one good reason why inferences about the health consequences of tobacco do not require specificity: Because tobacco and cigarette smoke are not in fact single agents but consist of numerous harmful agents, smoking represents exposure to multiple agents, with multiple potential effects. However, even a single chemical can increase risk for multiple disease endpoints, e.g., multiple cancers.²⁵⁵ For example, asbestos causes both lung cancer and mesothelioma.

Consistency with Other Relevant Knowledge

In addressing the causal relationship of lung cancer to cigarette smoking, researchers examined trends over time for lung cancer and for cigarette sales in the United States. A marked increase in lung-cancer death rates in men was observed with a time lag reflecting the latency period for lung cancer, which appeared to follow the increase in sales of cigarettes. Had the increase in lung-cancer deaths followed a decrease in cigarette sales, it might have given researchers pause. It would not have precluded a causal inference, but the inconsistency of the trends in cigarette sales and lung-cancer mortality would have had to be explained.

Background Rate of Disease

The background rate of disease is neither a Hill/Gordis factor²⁵⁶ nor a consideration involved in determining whether an association should be judged as causal. Still, some courts have stated that, independent of epidemiologic studies, the background rate of the disease at issue must be identified and known by an

255. See, e.g., Dario Consonni et al., *Mortality and Cancer Incidence in a Population Exposed to TCDD After the Seveso, Italy, Accident (1976-2013)*, 81 *Occup. Env't Med.* 349 (2024) (describing association of exposure with various cancers and other illnesses after an accidental release of dioxin, depending on geographic location relative to the accident, gender, and time after the accident); Marcella Warner et al., *Dioxin Exposure and Cancer Risk in the Seveso Women's Health Study*, 119 *Env't Health Persps.* 1700, 1703 (2011) (reporting "a statistically significant, dose-related increased risk in overall cancer incidence associated with" levels of dioxin in blood).

256. This refers to the considerations for assessing the causal significance of an association first described by Sir Austin Bradford Hill as modified by Leon Gordis. See *supra* note 218.

expert testifying to general causation.²⁵⁷ This is incorrect and fails to appreciate epidemiologic methodology. Epidemiologists examine the difference in rates of disease between the exposed and unexposed groups in a study.²⁵⁸ In a well-designed epidemiologic study, the “background” rate—the likelihood of disease even absent exposure—will be reflected in the rate of disease in the unexposed group.²⁵⁹ The magnitude of the background rate is unimportant for determining if that rate is different from the rate in the exposed group. To put the point slightly differently, whether the background rate is very low, moderate, or relatively high does not affect the researcher’s assessment of the data’s probative value for determining general causation.²⁶⁰

Methods for Synthesizing or Combining the Results of Multiple Studies

The scientific record often includes a number of epidemiologic studies examining a similar exposure and outcome. Often those studies will have different

257. See *In re Deepwater Horizon Belo Cases*, No. 3:19CV963-MCR-HTC, 2022 WL 17721595, at *5 (N.D. Fla. Dec. 15, 2022) (“Thus, a failure to identify or describe the background risk of a disease is a ‘serious methodological deficiency’ and ‘substantial weakness’ in an expert’s general causation opinion.”) (quoting *Chapman v. Procter & Gamble Distrib., LLC*, 766 F.3d 1296, 1307 (11th Cir. 2014)); *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1308 (N.D. Fla. 2018); *Jones v. Novartis Pharms. Corp.*, 235 F. Supp. 3d 1244, 1280 (N.D. Ala. 2017) (“A failure to assess or identify the background risk of a disease is a ‘serious methodological deficiency’ because, ‘[w]ithout a baseline, any incidence may be coincidence.’”) (quoting *Chapman v. Procter & Gamble Distrib., LLC*, 766 F.3d 1296, 1307–08 (11th Cir. 2014)), *aff’d in part*, 720 F. App’x 1006 (11th Cir. 2018).

258. See section titled “Relative Risk” above. Alternatively, in a case-control design, epidemiologists examine the difference in the odds of exposure among groups with and without the disease. See section titled “Odds Ratio” above.

259. This is not to say that the background rate of disease is entirely unimportant to epidemiologists. If a disease is very rare, it may be difficult to conduct a study with enough subjects to generate statistically meaningful results, even if an exposure actually causes the disease. The background rate of disease also may play an important role in public health decision-making, as it can address the relative benefit of an intervention that reduces that rate of disease.

260. Some courts have implied that the presence of a relatively high background rate of a disease itself undermines an inference of general causation. To see why this is incorrect, imagine a disease that afflicts as many as 20% of the general population, but that—as revealed by a well-designed epidemiologic study—afflicts 100% of people exposed to a particular agent. In this example, the relative risk would be 5.0. We likely would have no trouble making the inference that the agent causes at least some cases of disease among those exposed, assuming that the relevant considerations epidemiologists take into account, see *supra* text accompanying notes 218–54, support that inference. The same would be equally true with an extremely low background rate of disease that was five times greater in the exposed group.

results; even with well-conducted studies, we should expect to find variation in the results.²⁶¹ Some may find an association while others may not, or studies may report associations, but of different magnitude.²⁶² Different studies may also be conducted in populations with different characteristics, apply different statistical techniques, measure exposure or the outcome differently, or control for different confounders, among other things, which may explain the different results. There are two main types of data-synthesis methodologies available when multiple studies address an issue of scientific interest: 1) systematic review²⁶³ and 2) meta-analysis.²⁶⁴ The two are similar in that they do not directly investigate the question of interest by gathering and analyzing primary data, but instead synthesize studies that have been previously performed. Systematic reviews²⁶⁵ are not quantitative; meta-analyses provide a quantitative summary of data gathered by multiple prior studies. Both are important because science is a cumulative process and all relevant prior work should be considered when addressing a scientific issue. Systematic reviews have been described as “a review of evidence relevant to a clearly formulated question that uses systematic and explicit methods to identify, select and critically appraise relevant research, and to collect and analyze data from the studies that are included within the review.”²⁶⁶

In view of the fact that studies may disagree and that studies may be based on a small number of individuals and lack the statistical power needed for firmer conclusions, the technique of meta-analysis was developed.²⁶⁷ Meta-analysis is a

261. See Valentin Amrhein et al., *Inferential Statistics as Descriptive Statistics: There Is No Replication Crisis if We Don't Expect Replication*, 73 *Am. Statistician* 262 (2019), <https://doi.org/10.1080/00031305.2018.1543137>.

262. See, e.g., *Zandi v. Wyeth a/k/a Wyeth, Inc.*, No. 27-CV-06-6744, 2007 WL 3224242 (Minn. Dist. Ct. Oct. 15, 2007) (plaintiff's expert cited 40 studies in support of a causal relationship between hormone therapy and breast cancer; many studies found different magnitudes of increased risk).

263. See generally *Cochrane Handbook for Systematic Reviews of Interventions* (Julian P.T. Higgins et al. eds., 2d ed. 2019). A set of guidelines, Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA), is used for systematic reviews to provide consistency and transparency and to improve the reliability of the reviews. See Matthew J. Page et al., *The PRISMA 2020 Statement: An Updated Guideline for Reporting Systematic Reviews*, 372 *Brit. Med. J.* n.71 (2021), <https://doi.org/10.1136/bmj.n71>.

267. See *In re Paoli R.R. Yard PCB Litig.*, 916 F.2d 829, 856 (3d Cir. 1990); *In re Viagra (Sildenafil Citrate) & Cialis (Tadalafil) Prods. Liab. Litig.*, 424 F. Supp. 3d 781, 787 (N.D. Cal. 2020) (“Meta-analysis has the advantage of pooling more data so that the results are less likely to be misleading solely due to chance.”). Thus, contrary to the suggestion by at least one court, multiple studies with small numbers of subjects may be pooled to reduce the possibility of sampling error. See *In re Joint E. & S. Dist. Asbestos Litig.*, 827 F. Supp. 1014, 1042 (S.D.N.Y. 1993) (“[N]o matter

method of pooling study results to arrive at a single measure of association to represent the totality of the studies reviewed.²⁶⁸ It is a way of systematizing the time-honored approach of reviewing the literature, which is characteristic of science, and placing it in a standardized framework with quantitative methods for estimating associations. In a meta-analysis, studies are given different weights in proportion to the sizes of their study populations and other characteristics.²⁶⁹

Meta-analysis is most useful when employed in pooling randomized experimental trials, because in that circumstance the studies included in the meta-analysis share an important methodologic characteristic, namely the randomized assignment of subjects to different exposure groups.²⁷⁰ Meta-analysis applied to observational studies is also useful but is more challenging.²⁷¹ Studies may vary in the methods employed (e.g., research design and statistical approaches) as well as in the extent to which they are affected by and may have adjusted or corrected for confounding, selection bias, and measurement error. Such differences raise questions about the appropriateness of combining studies' results. The production of a single estimate of association, sometimes with a narrow confidence interval, may thus provide a false sense of security. Meta-analyses should be evaluated as carefully as one would evaluate the overall literature to draw a conclusion about the likelihood that an exposure causes a disease.²⁷² For

how many studies yield a positive but statistically insignificant SMR for colorectal cancer, the results remain statistically insignificant. Just as adding a series of zeros together yields yet another zero as the product, adding a series of positive but statistically insignificant SMRs together does not produce a statistically significant pattern.”), *rev'd*, 52 F.3d 1124 (2d Cir. 1995).

268. For a nontechnical explanation of meta-analysis, along with case studies of a variety of scientific areas in which it has been employed, see Morton Hunt, *How Science Takes Stock: The Story of Meta-Analysis* (1997).

269. Petitti, *supra* note 121.

270. On rare occasions, meta-analyses of both clinical and observational studies are available. See, e.g., *In re Bextra & Celebrex Mktg. Sales Pracs. & Prod. Liab. Litig.*, 524 F. Supp. 2d 1166, 1175 (N.D. Cal. 2007) (referring to clinical and observational meta-analyses of a low dose of a drug; both analyses failed to find any effect).

271. See Jesse A. Berlin et al., *The Use of Meta-Analysis in Pharmacoepidemiology*, in *Pharmacoepidemiology*, at 897, 899–901 (Brian L. Strom et al. eds., 6th ed. 2020); Donna F. Stroup et al., *Meta-Analysis of Observational Studies in Epidemiology: A Proposal for Reporting*, 283 JAMA 2008, 2009 (2000), <https://doi.org/10.1001/jama.283.15.2008>; Zachary B. Gerbarg & Ralph I. Horwitz, *Resolving Conflicting Clinical Trials: Guidelines for Meta-Analysis*, 41 J. Clinical Epidemiology 503 (1988), [https://doi.org/10.1016/0895-4356\(88\)90053-4](https://doi.org/10.1016/0895-4356(88)90053-4). See also *Deutsch v. Novartis Pharm. Corp.*, 768 F. Supp. 2d 420, 451–52 (E.D.N.Y. 2011) (rejecting defendants' claim that meta-analysis is sufficiently reliable to support an expert opinion only if the meta-analysis is applied to clinical trials).

272. Courts have recognized that a properly performed meta-analysis can provide a basis for admissible expert testimony. In *Cooper v. Takeda Pharms. Am., Inc.*, 191 Cal. Rptr. 3d 67, 95 (Ct. App. 2015), the court reinstated a jury verdict for the plaintiffs, observing that in striking plaintiffs' experts' testimony after trial, “the trial court's piecemeal rejection of individual studies

instance, it is essential to ensure that the meta-analysis is well conducted. A well-conducted meta-analysis appropriately considers 1) the quality of the included studies, 2) whether publication bias (the greater probability of publication of significant findings) is likely to be present, 3) if unpublished studies should be sought and included, 4) whether criteria for including and excluding studies are appropriate, 5) whether appropriate subgroup analyses were conducted, and 6) whether results are exceedingly heterogeneous, and if so, whether the sources of heterogeneity (such as whether the effect of an exposure is truly different in populations with different characteristics) have been appropriately investigated.²⁷³

Specific Causation

Epidemiology is concerned with the incidence of disease in populations, and epidemiologic studies do not address the question of the cause of an individual's

was inappropriate and ignored the testimony by [plaintiffs' experts] that the results of the individual studies considered as a whole, including in the meta-analyses, was what really persuaded them that Actos causes bladder cancer." Similarly reflecting the value of meta-analysis, in *In re Bextra & Celebrex Mktg. Sales Pracs. & Prod. Liab. Litig.*, 524 F. Supp. 2d 1166 (N.D. Cal. 2007), the court relied on several meta-analyses of Celebrex at a 200-mg dose to conclude that the plaintiffs' experts who proposed to testify to toxicity at that dosage failed to meet the requirements of *Daubert*. The court criticized those experts for the wholesale rejection of meta-analyses of observational studies. And, in *In re Paoli Railroad Yard PCB Litig.*, 916 F.2d 829, 856–57 (3d Cir. 1990), the court overturned the district court's exclusion of a report that used meta-analysis, observing that meta-analysis is a regularly used scientific technique. But the Third Circuit recognized that the technique might be poorly performed and required the district court to reconsider the validity of the expert's work in performing the meta-analysis. See also *In re Zolof (Sertraline Hydrochloride) Prod. Liab. Litig.*, 858 F.3d 787, 796 (3d Cir. 2017) (affirming exclusion of expert testimony that involved meta-analyses because, even assuming that meta-analysis is a reliable technique, the expert did not "reliably apply the 'technique' to the body of evidence . . ."); *Carl v. Johnson & Johnson*, 237 A.3d 308 (N.J. Super. Ct. App. Div. 2020) (reversing exclusion of plaintiffs' experts' testimony and holding that the experts, who relied heavily on meta-analyses to support their opinions, "adhered to methodologies generally followed by experts in the field and relied upon studies and information generally considered an acceptable basis for inclusion in the formulation of expert opinions").

273. See Mathew J. Page et al., *The PRISMA 2020 Statement: an Updated Guideline for Reporting Systematic Reviews*, 134 J. Clinical Epidemiology 178, 186 (2021), <https://doi.org/10.1136/bmj.n71> (consensus statement describing update to a checklist of items to be included for "more transparent, complete, and accurate reporting of systematic reviews, thus facilitating evidence based decision making"); Stroup et al., *supra* note 271, at 2009 (consensus statement providing checklist of items to report in a meta-analysis based on a systematic review of published meta-analyses); Monika Mueller et al., *Methods to Systematically Review and Meta-Analyse Observational Studies: A Systematic Scoping Review of Recommendations*, 18 BMC Med. Rsch. Methodology 44 (2018), <https://doi.org/10.1186/s12874-018-0495-9> (summarizing recommendations for conducting meta-analyses of observational studies).

disease.²⁷⁴ This question, often referred to as specific causation, is beyond the domain of the science of epidemiology.²⁷⁵

Epidemiology has its limits at the point where an inference is made that the relationship between an agent and a disease is causal (general causation) and where the magnitude of excess risk attributed to the agent has been determined; that is, epidemiologists investigate whether an agent can cause a disease, not whether an agent did cause a specific plaintiff's disease.²⁷⁶

Nevertheless, the specific causation issue is a necessary legal element in a toxic tort case. The plaintiff must establish not only that the defendant's agent is capable of causing disease generally, but also that it caused the plaintiff's disease specifically.²⁷⁷ Thus, numerous cases have confronted the question of what is acceptable proof of specific causation and the role that epidemiologic evidence plays in answering that question.²⁷⁸ But this question is not addressed by

274. See *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 945 & n.6 (3d Cir. 1990) ("Epidemiological studies do not provide direct evidence that a particular plaintiff was injured by exposure to a substance."); *Rhyne v. U.S. Steel Corp.*, 474 F. Supp. 3d 733, 750 (W.D.N.C. 2020) ("epidemiology focuses on the issue of general causation, not specific causation"); *In re E. I. du Pont de Nemours & Co. C-8 Pers. Inj. Litig.*, No. 2:18-CV-00136, 2019 WL 6894069, at *6 (S.D. Ohio Dec. 18, 2019) (explaining that epidemiology focuses on general causation as opposed to specific causation (citing the third edition of this reference guide)); Michael Dore, *A Commentary on the Use of Epidemiological Evidence in Demonstrating Cause-in-Fact*, 7 Harv. Env't L. Rev. 429, 436 (1983); Khristine L. Hall & Ellen K. Silbergeld, *Reappraising Epidemiology: A Response to Mr. Dore*, 7 Harv. Env't L. Rev. 441, 445 (1983).

There are, however, some diseases that do not occur without exposure to a given toxic agent. This is the same as saying that the toxic agent is a necessary cause for the disease, and the disease is sometimes referred to as a signature disease (also, the agent is pathognomonic) because the existence of the disease necessarily implies the causal role of the agent. Two examples are asbestosis, which is a signature disease for asbestos, and vaginal adenocarcinoma (in young adult women), which is a signature disease for in utero DES exposure. See Kenneth S. Abraham & Richard A. Merrill, *Scientific Uncertainty in the Courts*, in *Issues Sci. & Tech.* 93, 101 (1986).

275. See *Jones v. Novartis Pharms. Corp.*, 235 F. Supp. 3d 1244, 1252 (N.D. Ala. 2017) ("No scientific methodology exists for assessing specific causation for an individual based on group studies."), *aff'd in part*, *Jones v. Novartis Pharms. Co.*, 720 F. App'x 1006 (11th Cir. 2018).

276. See *In re E. I. du Pont de Nemours & Co. C-8 Pers. Inj. Litig.*, No. 2:18-CV-00136, 2019 WL 6894069, at *6 (S.D. Ohio Dec. 18, 2019) (quoting the third edition of this reference guide).

277. See, e.g., *Adkisson v. Jacobs Eng'g Grp., Inc.*, 342 F. Supp. 3d 791, 798 (E.D. Tenn. 2018) (explaining the difference between general causation and specific causation and observing the distinction is "well-accepted in federal courts"). Specific-causation evidence only matters when general causation has been established. See *Williams v. Mosaic Fertilizer*, No. 8:14-CV-1748-T-35MAP, 2016 WL 7175657, at *11 (M.D. Fla. June 24, 2016) ("Without an adequate basis for establishing general causation, Dr. Mink's specific causation opinions are irrelevant."), *aff'd*, 889 F.3d 1239 (11th Cir. 2018).

278. In many instances, causation can be established without epidemiologic evidence. When the mechanism of causation is well understood, the causal relationship is well established, or the timing between cause and effect is close, scientific evidence of causation may not be required. This is frequently the situation when the plaintiff suffers traumatic injury rather than disease. This

epidemiology.²⁷⁹ It is instead a legal question—one with which numerous courts have grappled.²⁸⁰ The remainder of this section is predominantly an explanation of judicial opinions and the reasoning courts have used in applying risk estimates from epidemiology to address the issue of specific causation in individual cases.

Before proceeding, one last caveat is in order. This section assumes that epidemiologic evidence has been used as proof of causation for a given plaintiff. The discussion does not address whether a plaintiff must or should use epidemiologic evidence to prove causation.²⁸¹

section addresses only those situations in which causation is not evident, and scientific evidence is required.

279. Nevertheless, an epidemiologist may be helpful to the factfinder answering this question. Some courts have permitted epidemiologists, or those who use epidemiologic methods, to testify about specific causation. See *Ambrosini v. Labarraque*, 101 F.3d 129, 137–41 (D.C. Cir. 1996); *Zuchowicz v. United States*, 870 F. Supp. 15 (D. Conn. 1994); *Landrigan v. Celotex Corp.*, 605 A.2d 1079, 1088–89 (N.J. 1992); *Carl v. Johnson & Johnson*, 237 A.3d 308, 338 (N.J. Super. App. Div. 2020). But see *Rhyne v. U.S. Steel Corp.*, 474 F. Supp. 3d 733, 750 (W.D.N.C. 2020) (concluding epidemiologist was not qualified to testify to specific causation).

In general, courts seem more concerned with the basis of an expert's opinion than with whether the expert is an epidemiologist or clinical physician. See *Porter v. Whitehall*, 9 F.3d 607, 614 (7th Cir. 1992) (“curb side” opinion from clinician not admissible); *Burton v. R.J. Reynolds Tobacco Co.*, 181 F. Supp. 2d 1256, 1266–67 (D. Kan. 2002) (vascular surgeon permitted to testify to general causation over objection based on fact he was not an epidemiologist); *Wade-Greaux v. Whitehall Labs.*, 874 F. Supp. 1441, 1469–72 (D.V.I.) (clinician's multiple bases for opinion inadequate to support causation opinion), *aff'd*, 46 F.3d 1120 (3d Cir. 1994); *Landrigan*, 605 A.2d at 1083–89 (permitting both clinicians and epidemiologists to testify to specific causation provided the methodology used is sound); *Trach v. Fellin*, 817 A.2d 1102, 1118–19 (Pa. Super. Ct. 2003) (toxicologist and pathologist permitted to testify to specific causation).

280. See Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 cmt. c(3) (2010) (“Scientists who conduct group studies do not examine specific causation in their research. No scientific methodology exists for assessing specific causation for an individual based on group studies. Nevertheless, courts have reasoned from the preponderance-of-the-evidence standard to determine the sufficiency of scientific evidence on specific causation when group-based studies are involved. . .”).

281. See *id.* § 28 cmt. c(3) & rptrs. note (“most courts have appropriately declined to impose a threshold requirement that a plaintiff always must prove causation with epidemiologic evidence”); see also *Westberry v. Gislaved Gummi AB*, 178 F.2d 257 (4th Cir. 1999) (holding that expert's testimony on causation was properly admitted where there was an acute response, a differential diagnosis that ruled out other known causes of disease, and the absence of epidemiologic or toxicologic studies and there were dechallenge/rechallenge tests conducted by expert that were consistent with exposure to defendant's agent causing disease); *Zuchowicz v. United States*, 140 F.3d 381 (2d Cir. 1998); *In re Testosterone Replacement Therapy Prods. Liab. Litig.* Coordinated Pretrial Proc., No. 14 C 1748, 2017 WL 1833173, at *15 (N.D. Ill. May 8, 2017) (“Where the existing epidemiological research is limited or nonexistent, courts are more willing to allow expert testimony on causation that does not depend on epidemiological sources.”) (citing cases); *In re Tylenol (Acetaminophen) Mktg., Sales Prac. & Prods. Liab. Litig.*, No. 2:12-CV-07263, 2016 WL 3997046, at *7 (E.D. Pa. July 26, 2016) (rejecting defendant's contention that because there were no epidemiologic studies available, plaintiff's expert could not testify to causation of liver failure due to Tylenol use and explaining the reasons why such studies were unavailable for such a relationship).

Two legal issues arise with regard to the role of epidemiology in proving individual causation: admissibility and sufficiency of evidence to meet the burden of production. The first issue tends to receive less attention by the courts, because epidemiologic studies are rarely introduced independently into evidence,²⁸² but nevertheless deserves mention: An epidemiologic study that is sufficiently rigorous to justify a conclusion that it is scientifically valid should be admissible,²⁸³ as it tends to make an issue in dispute more or less likely.²⁸⁴

Far more courts have confronted the role that epidemiology plays with regard to the sufficiency of the evidence and the burden of production.²⁸⁵ The civil burden of proof is described most often as requiring the factfinder to “believe that what is sought to be proved . . . is more likely true than not true.”²⁸⁶ The relative risk from epidemiologic studies can be adapted to this 50%-plus standard to yield a probability or likelihood that an agent caused an individual’s disease.²⁸⁷ But while the discussion below speaks in terms of the magnitude of

282. Most often, epidemiologic and other scientific studies are used by expert witnesses as the basis of their causal opinions and are not independently admitted into evidence.

283. See *DeLuca v. Merrell Dow Pharms., Inc.*, 911 F.2d 941, 958 (3d Cir. 1990); cf. *Kehm v. Procter & Gamble Co.*, 580 F. Supp. 890, 902 (N.D. Iowa 1982) (“These [epidemiologic] studies were highly probative on the issue of causation—they all concluded that an association between tampon use and menstrually related TSS [toxic shock syndrome] cases exists.”), *aff’d*, 724 F.2d 613 (8th Cir. 1984). In *Ellis v. International Playtex, Inc.*, 745 F.2d 292, 303 (4th Cir. 1984), the court concluded that certain epidemiologic studies were admissible under an exception to the hearsay rule despite criticism of the methodology used in the studies. The court held that the claims of bias went to the studies’ weight rather than their admissibility.

284. Even if evidence is relevant, it may be excluded if its probative value is substantially outweighed by prejudice, confusion, or inefficiency. Fed. R. Evid. 403. In *Daubert*, 509 U.S. at 591, the Court invoked the concept of “fit,” which addresses the relationship of the basis for an expert’s scientific opinion to the facts of the case and the issues in dispute. In a toxic substance case in which cause in fact is disputed, an epidemiologic study of the same agent to which the plaintiff was exposed that examined the association with the same disease from which the plaintiff suffers would undoubtedly have sufficient “fit” to be a part of the basis of an expert’s opinion. The Court’s concept of “fit,” borrowed from *United States v. Downing*, 753 F.2d 1224, 1242 (3d Cir. 1985), appears equivalent to the more familiar evidentiary concept of probative value, albeit one requiring assessment of the scientific reasoning the expert used in drawing inferences from methodology or data to opinion.

285. We reiterate a point made at the outset of this section: This discussion of the use of a threshold relative risk for specific causation is not epidemiology or an inquiry an epidemiologist would undertake but an effort by courts and commentators to adapt the legal standard of proof to the available scientific evidence. See *supra* text accompanying notes 274–76.

286. Edward J. Devitt & Charles B. Blackmar, 2 Federal Jury Practice and Instruction § 71.13 (3d ed. 1977); see also *United States v. Fatico*, 458 F. Supp. 388, 403 (E.D.N.Y. 1978) (“Quantified, the preponderance standard would be 50%+ probable.”), *aff’d*, 603 F.2d 1053 (2d Cir. 1979).

287. An adherent of the frequentist school of statistics would resist this adaptation, which may explain why many epidemiologists and toxicologists also resist it. To use an epidemiologic study outcome to determine the probability of specific causation requires a shift from a frequentist approach, which involves sampling or frequency data from an empirical test, to a subjective probability about a discrete event. A frequentist might assert, after conducting a sampling test, that 60%

the relative risk or association found in a study, before an association or relative risk is used to make a statement about the probability of individual causation, the inferential judgment²⁸⁸ that the association is truly causal is required. “[A]n agent cannot be considered to cause the illness of a specific person unless it is recognized as a cause of that disease in general.”²⁸⁹ The following discussion should be read with this caveat in mind.²⁹⁰

Some courts have reasoned that when epidemiologic studies find that exposure to the agent causes an incidence in the exposed group more than twice the incidence in the unexposed group (i.e., a relative risk greater than 2.0), the probability that exposure to the agent caused a similarly situated individual’s disease is greater than 50%. These courts hold that when there is group-based evidence finding that exposure to an agent causes an incidence of disease in the exposed group that is more than twice the incidence in the unexposed group, the evidence is sufficient to satisfy the plaintiff’s burden of production and permit submission of specific causation to a jury. In such a case, the factfinder may find that it is more likely than not that the substance caused the particular plaintiff’s disease.²⁹¹ Courts, thus, have permitted expert witnesses to testify to specific causation based on the logic of the effect of a doubling of the risk.²⁹²

of the balls in an opaque container are blue. The same frequentist would resist the statement, “The probability that a single ball removed from the box and hidden behind a screen is blue is 60%.” The ball is either blue or not, and no frequentist data would permit the latter statement. “[T]here is no logically rigorous definition of what a statement of probability means with reference to an individual instance. . . .” Lee Loevinger, *On Logic and Sociology*, 32 *Jurimetrics J.* 527, 530 (1992), <https://doi.org/10.2307/1190721>; see also Steve Gold, *Causation in Toxic Torts: Burdens of Proof, Standards of Persuasion and Statistical Evidence*, 96 *Yale L. J.* 376, 382–92 (1986). Subjective probabilities about unique events are employed by those using Bayesian methodology. See Kaye, *supra* note 115, at 54–62; Kaye & Stern, *supra* note 16, “What is Bayes’ Rule?”

288. This is described in the section titled “Effect Modification” above.

289. Cole, *supra* note 94, at 10,284.

290. We emphasize this point both because it is not intuitive and because some courts have failed to appreciate the difference between an association and a causal relationship. See, e.g., *Forsyth v. Eli Lilly & Co.*, Civil No. 95–00185 ACK, 1998 U.S. Dist. LEXIS 541, at *26–*31 (D. Haw. Jan. 5, 1998). But see *Berry v. CSX Transp., Inc.*, 709 So. 2d 552, 568 (Fla. Dist. Ct. App. 1998) (“From epidemiologic studies demonstrating an association, an epidemiologist may or may not infer that a causal relationship exists.”).

291. A similar means to address probabilities in individual cases is use of the attributable risk (or attributable fraction parameter). The attributable risk is that portion of the excess risk that can be attributed to an agent, above and beyond the background risk that is due to other causes. See section titled “Attributable Risk” above. Thus, when the relative risk is greater than 2.0, the attributable fraction exceeds 50%.

292. For a comprehensive, if dated, list of cases that support proof of causation based on group studies, see *Restatement (Third) of Torts: Liability for Physical and Emotional Harm* § 28 cmt. c(4) rptrs. note (2010). The *Restatement* catalogs those courts that require a relative risk in excess of 2.0 as a threshold for sufficient proof of specific causation and those courts that recognize that even a lower relative risk than that can support specific causation, as explained below. Despite considerable disagreement on whether a relative risk of 2.0 is required or merely a taking-off point for determining

While this reasoning has a certain logic as far as it goes, there are a number of significant assumptions that require explication. These are addressed below.

A Valid Study and Risk Estimate. The propriety of this “doubling” reasoning depends on group studies identifying a genuine causal relationship and a reasonably reliable measure of the increased risk.²⁹³ This requires attention to the possibility of random error, bias, or confounding being the source of the association rather than a true causal relationship, as explained in the sections above titled “Sources of Error in Epidemiologic Studies” and “General Causation.”

Similarity of Study Participants and Plaintiff. Only if the study participants and the plaintiff are similar with respect to relevant risk factors will a risk estimate from a study or studies be valid when applied to an individual.²⁹⁴ Thus, if those exposed in a study of the risk of lung cancer from smoking have smoked half a pack of cigarettes a day for 20 years, the degree of increased incidence of lung cancer among them cannot be extrapolated to someone who smoked two packs of cigarettes for 30 years, without strong assumptions about the dose–response relationship.²⁹⁵ This principle is also applicable to risk factors for competing causes. If all of the participants in a study are participating because they were identified as

the sufficiency of the evidence on specific causation, two commentators who surveyed the cases observed that “[t]here were no clear differences in outcomes as between federal and state courts.” Russell S. Carruth & Bernard D. Goldstein, *Relative Risk Greater than Two in Proof of Causation in Toxic Tort Litigation*, 41 *Jurimetrics J.* 195, 199 (2001), <https://www.jstor.org/stable/29762698>.

293. Indeed, one commentator contends that because epidemiologic studies often are insufficiently precise to accurately measure small increases in risk, in general, studies that find a relative risk less than 2.0 should not be sufficient for causation. This concern is not with specific causation, but with general causation and the likelihood that an association less than 2.0 is noise rather than reflecting a true causal relationship. See Michael D. Green, *The Future of Proportional Liability*, in *Exploring Tort Law* (Stuart Madden ed., 2005); see also Robert F. Reynolds, *The Use of Randomized Controlled Trials for Pharmacoepidemiology*, in *Pharmacoepidemiology* 792, 794 (Brian L. Strom ed., 4th ed. 2005) (cautioning that small relative risks in observational studies can be the product of confounding); Gary Taubes, *Epidemiology Faces Its Limits*, 269 *Sci.* 164 (1995) (explaining views of several epidemiologists about a threshold relative risk of 3.0 to seriously consider a causal relationship); N.E. Breslow & N.E. Day, *Statistical Methods in Cancer Research*, in *The Analysis of Case-Control Studies* 36 (IARC Pub. No. 32, 1980) (“[r]elative risks of less than 2.0 may readily reflect some unperceived bias or confounding factor”); David A. Freedman & Philip B. Stark, *The Swine Flu Vaccine and Guillain-Barré Syndrome: A Case Study in Relative Risk and Specific Causation*, 64 *Law & Contemp. Probs.* 49, 61 (2001), <https://doi.org/10.1177/0193841X9902300603> (“If the relative risk is near 2.0, problems of bias and confounding in the underlying epidemiologic studies may be serious, perhaps intractable.”).

294. Council on Sci. Affs., Am. Med. Ass’n, *Radioepidemiological Tables*, 257 *JAMA* 806, 807 (1987) (“The basic premise of probability of causation is that individual risk can be determined from epidemiologic data for a representative population; however, the premise only holds if the individual is truly representative of the reference population.”).

295. Conversely, a risk estimate from a study that involved a greater exposure is not applicable to an individual exposed to a lower dose. See, e.g., *In re Bextra & Celebrex Mktg. Sales Prac. & Prod. Liab. Litig.*, 524 F. Supp. 2d 1166, 1175–76 (N.D. Cal. 2007) (relative risk found in studies of those who took twice the dose of others could not support an expert’s opinion of causation for the latter group); *In re Bextra & Celebrex*, No. 762000/2006, 2008 N.Y. Misc. LEXIS 720, at *29 (Sup.

having a family history of heart disease, the magnitude of risk found in a study of the effect of smoking on the risk of heart disease cannot validly be applied to an individual without such a family history.²⁹⁶

Similarly, if an individual has been differentially exposed to other risk factors from those in a study, the results of the study will not provide an accurate basis for the probability of causation for the individual.²⁹⁷ Consider a study of the effect of smoking on lung cancer among subjects who have no asbestos exposure. The relative risk of smoking in that study would not be applicable to an asbestos insulation worker.

More generally, the relative risk found in a study represents an average risk for the group. If some other factor(s) in addition to the exposure under study affect(s) the risk of the outcome of interest, and the study subjects are heterogeneous with regard to the other risk factor(s), then even among the study participants, the individual risks would be higher or lower than the study's reported relative risk.²⁹⁸ So too for a plaintiff who did not participate in the study: depending on the plaintiff's other risk factor(s), the plaintiff's individual risk from exposure could be higher or lower than the overall relative risk observed among the study participants.²⁹⁹

Ct. Jan. 7, 2008). Extrapolation is generally not possible because the shape of the dose–response curve is not known.

296. Family history in this context implies some shared genetic basis for an increased risk of heart disease. Genetics as a competing cause of disease is discussed *infra* in notes 310–17 and accompanying text.

297. See Kaye & Stern, *supra* note 16, at 536, n.180 and accompanying text (explaining that studies that use an average do not account for individual variation); David A. Freedman & Philip Stark, *The Swine Flu Vaccine and Guillain-Barré Syndrome: A Case Study in Relative Risk and Specific Causation*, 23 Evaluation Rev. 619 (1999), <https://doi.org/10.1177/0193841X9902300603> (analyzing the role that individual variation plays in determining the probability of specific causation based on the relative risk found in a study and providing a mathematical model for calculating the effect of individual variation); Mark Parascandola, *What Is Wrong with the Probability of Causation?*, 39 Jurimetrics J. 29 (1998).

298. For example, although the evidence is conflicting, some studies have found that certain variants of the NAT2 gene increase the relative risk of breast cancer for women exposed to tobacco smoke, even though studies of NAT2 variants alone or of tobacco smoke exposure alone have not found an association with breast cancer risk. See Petra Kasajova et al., *Active Cigarette Smoking and the Risk of Breast Cancer at the Level of N-acetyltransferase 2 (NAT2) Gene Polymorphisms*, 37 Tumor Biol. 7929, 7929 (2016), <https://doi.org/10.1007/s13277-015-4685-3>. If this is correct, then an epidemiologic study of tobacco smoke exposure and breast cancer that did not account for genetic variation in NAT2 would report a relative risk that did not apply either to the study participants with the high-risk variants (for whom the relative risk of exposure would be higher) or to the study participants without the high-risk variants (for whom the relative risk of exposure would be lower). If such a study hypothetically reported a relative risk of 3.5 for those exposed to tobacco smoke, quite possibly no study participant would have a 3.5-fold increased risk; those with low-risk genetic variants would have no increased risk while those with high-risk genetic variants would have more than a 3.5-fold increased risk.

299. The comment of two prominent epidemiologists on this subject is illuminating:

We cannot measure the individual risk, and assigning the average value to everyone in the category reflects nothing more than our ignorance about the determinants of lung cancer that interact with

Causation, Not Acceleration of Disease. Another assumption embedded in using the risk findings of a group study to determine the probability of causation in an individual is the assumption that the disease never would have been contracted absent exposure. Put another way, the assumption is that the agent did not merely accelerate occurrence of the disease without affecting the lifetime risk of contracting the disease. Birth defects are an example of an outcome that is not accelerated. However, for most of the chronic diseases of adulthood, it is possible, and may even be likely, that the primary avenue of effect is acceleration of disease. Yet it is not possible for epidemiologic studies to distinguish between acceleration of disease and causation of new disease. If, in fact, acceleration is involved, the relative risk from a study will understate the probability that exposure accelerated the occurrence of the disease.³⁰⁰ Of course, acceleration, if it occurs, could affect the determination of the amount of damages.³⁰¹

Agent Operates Independently. Employing a risk estimate to determine the probability of causation is not valid if the agent interacts with another cause in a way that increases disease beyond merely the sum of the increased incidence due

cigarette smoke. It is apparent from epidemiological data that some people can engage in chain smoking for many decades without developing lung cancer. Others are or will become primed by unknown circumstances and need only to add cigarette smoke to the nearly sufficient constellation of causes to initiate lung cancer. In our ignorance of these hidden causal components, the best we can do in assessing risk is to classify people according to measured causal risk indicators and then assign the average observed within a class to persons within the class.

Lash et al., *supra* note 50, at 9. See also Ofer Shpilberg et al., *The Next Stage: Molecular Epidemiology*, 50 J. Clinical Epidemiology 633, 637 (1997). [https://doi.org/10.1016/s0895-4356\(97\)00052-8](https://doi.org/10.1016/s0895-4356(97)00052-8) (“A 1.5-fold relative risk may be composed of a 5-fold risk in 10% of the population, and a 1.1-fold risk in the remaining 90%, or a 2-fold risk in 25% and a 1.1-fold for 75%, or a 1.5-fold risk for the entire population.”).

300. The short explanation is this: Suppose during the period in which instances of disease are ascertained, the agent under study accelerates occurrence of disease that would have occurred later in the period. Such cases will then not appear as excess cases of the disease in the exposed group, because they would have also occurred in the unexposed group, albeit at a later time in the period. For further discussion, see Sander Greenland & James M. Robins, *Conceptual Problems in the Definition and Interpretation of Attributable Fractions*, 128 Am. J. Epidemiology 1185 (1986), <https://doi.org/10.1093/oxfordjournals.aje.a115073>; Sander Greenland & James M. Robins, *Epidemiology, Justice, and the Probability of Causation*, 40 Jurimetrics J. 321 (2000); Sander Greenland, *Relation of Probability of Causation to Relative Risk and Doubling Dose: A Methodologic Error That Has Become a Social Problem*, 89 Am. J. Pub. Health 1166 (1999), <https://doi.org/10.2105/ajph.89.8.1166>. If acceleration occurs, then the appropriate characterization of the harm for purposes of determining damages would have to be addressed.

301. A defendant who only accelerates the occurrence of the harm of, say, chronic back pain, that would have occurred independently to the plaintiff at a later time is not liable for the same amount of damages as a defendant who causes a lifetime of chronic back pain. See David A. Fischer, *Successive Causes and the Enigma of Duplicated Harm*, 66 Tenn. L. Rev. 1127, 1127 (1999); Michael D. Green, *The Intersection of Factual Causation and Damages*, 55 DePaul L. Rev. 671 (2006).

to each agent separately. For example, the relative risk of lung cancer due to smoking is around 10, while the relative risk from asbestos exposure is approximately 5. The relative risk for someone exposed to both is not the arithmetic sum of the two relative risks (15) but closer to the product (50– to 60-fold), reflecting an interaction between the two.³⁰² Neither of the individual agents' relative risks can be employed to estimate the probability of causation in someone exposed to both asbestos and cigarette smoke.³⁰³

Other Assumptions. Additional assumptions essential to courts' risk-doubling logic have been identified. These include: (1) the agent of interest is not responsible for fatal diseases other than the disease of interest³⁰⁴ and (2) the agent does not provide a protective effect against the outcome of interest in a subpopulation of those being studied.³⁰⁵

Courts should be cognizant of the above assumptions when assessing the sufficiency of the evidence about specific causation. When one or more of these assumptions are questionable, the probability of specific causation for a given individual may be greater or less than the attributable risk derived from epidemiologic studies of an exposure and a disease.

Evidence in a given case may challenge one or more of these assumptions. Bias in a study may suggest that the study findings are inaccurate and should be estimated to be higher or lower, or even that the findings are specious—that is, they do not reflect a true causal relationship. A plaintiff may have been exposed to a dose of the agent in question that is greater or less than that to which those in the study were exposed.³⁰⁶ A plaintiff may be more or less susceptible to the

302. We use *interaction* to mean that the combined effect is other than the additive sum of each effect, which is what we would expect if the two agents operate independently. Statisticians often employ the term *interaction* in a different manner to mean that the outcome deviates from what was expected in the model specified in advance. See Jay S. Kaufman, *Interaction Reaction*, 20 *Epidemiology* 159 (2009); Sander Greenland & Kenneth J. Rothman, *Concepts of Interaction*, in Lash et al., *supra* note 49, at 329. The potential for interaction also exists with genetic risk factors. See *supra* notes 181 and 191 and accompanying text and notes 292–99.

303. See Restatement (Third) of Torts: Liability for Physical and Emotional Harm § 28 cmt. c(5) (2010); Jan Beyea & Sander Greenland, *The Importance of Specifying the Underlying Biologic Model in Estimating the Probability of Causation*, 76 *Health Physics* 269 (1999), <https://doi.org/10.1097/00004032-199903000-00008>.

304. This is because in the epidemiologic studies relied on, those deaths caused by the alternative disease process will mask the true magnitude of increased incidence of the studied disease when the study subjects die before developing the disease of interest.

305. See Sander Greenland & James M. Robins, *Epidemiology, Justice, and the Probability of Causation*, 40 *Jurimetrics J.* 321, 332–33 (2000).

306. See section titled “Dose–Response Relationship” above; see also *McManaway v. KBR, Inc.*, 852 F.3d 444, 453 (5th Cir. 2017) (“Proof that one is similarly situated to subjects in epidemiological studies must ‘include proof that the injured person was exposed to the same substance, that the exposure or dose levels were comparable to or greater than those in the studies, that the exposure occurred before the onset of injury. . . .’” (quoting *Merrell Dow Pharms., Inc. v. Havner*,

agent's toxic effects than the average of the participants in the study. Or a plaintiff may have individual factors, such as genetic risk factors, that make it less likely that exposure to the agent caused the plaintiff's disease. Similarly, an individual plaintiff may be able to rule out other known (background) causes of the disease, such as genetics or other exposures, and thereby increase the likelihood that the agent was responsible for that plaintiff's disease. Evidence of a pathological mechanism that is relevant to the cause of the plaintiff's disease may be available.³⁰⁷ A valid biomarker of the exposure, or of the exposure's effect, may be present or absent.³⁰⁸ These (and other) possibilities should be considered, as warranted by the evidence, before any attributable risk from an epidemiologic study is used to estimate the probability that the agent in question caused an individual plaintiff's disease.³⁰⁹

Recently, genetics has received increasing attention as an individual factor that could distinguish a plaintiff's own risk from the relative risk reported in epidemiologic studies. As discussed above, genetic variations may result in variable susceptibility to the toxic effect of exposure.³¹⁰ But as suggested by the preceding paragraph, genetics may also be an independent risk factor for disease. At the extreme, a plaintiff's disease may be a purely genetic disorder—the genetic

953 S.W.2d 706, 720 (Tex. 1997)); *Baker v. Chevron U.S.A. Inc.*, 533 F. App'x 509, 520 (6th Cir. 2013) ("[T]he subjects of the [expert's] cited studies generally had much higher exposures to benzene than the plaintiffs, and thus, 'there [was] simply too great an analytical gap between the data and the opinion proffered.'" (quoting *Gen. Elec. Co. v. Joiner*, 522 U.S. 136, 146 (1997)); *Ferebee v. Chevron Chem. Co.*, 736 F.2d 1529, 1536 (D.C. Cir. 1984) ("The dose–response relationship at low levels of exposure for admittedly toxic chemicals like paraquat is one of the most sharply contested questions currently being debated in the medical community.").

307. See *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1372–73 (N.D. Fla. 2018) (finding that plaintiff's experts appropriately relied on peer-reviewed, published scientific literature analyzing the biological mechanism by which the prescription drug Abilify can cause impulse control problems to establish general causation).

308. See section titled "Genetic and Molecular Epidemiologic Studies" above and *Eaton et al.*, *supra* note 60, "Use of Biomarkers in Toxicology Exposure Assessment." For a biomarker to be valid in this context, at the time of measurement (usually during litigation, possibly during medical treatment) the biomarker must accurately reflect an earlier exposure (possibly much earlier for diseases with long latency periods).

309. See *Merrell Dow Pharms., Inc. v. Havner*, 953 S.W.2d 706, 720 (Tex. 1997); *Smith v. Wyeth-Ayerst Labs. Co.*, 278 F. Supp. 2d 684, 708–09 (W.D.N.C. 2003) (describing expert's effort to refine relative risk applicable to plaintiff based on specific risk characteristics applicable to her, albeit in an ill-explained manner); *McDarby v. Merck & Co.*, 949 A.2d 223 (N.J. Super. Ct. App. Div. 2008); *Mary Carter Andruet, Proof of Cancer Causation in Toxic Waste Litigation*, 61 S. Cal. L. Rev. 2075, 2100–04 (1988). An example of a judge sitting as factfinder and considering individual factors for a number of plaintiffs in deciding cause in fact is contained in *Allen v. United States*, 588 F. Supp. 247, 429–43 (D. Utah 1984), *rev'd on other grounds*, 816 F.2d 1417 (10th Cir. 1987). See also *Manko v. United States*, 636 F. Supp. 1419, 1437 (W.D. Mo. 1986), *aff'd*, 830 F.2d 831 (8th Cir. 1987).

310. See *supra* notes 190–200 and accompanying text.

equivalent of a signature disease.³¹¹ A number of vaccine claims have been resolved against the claimant for this reason.³¹²

Much more typically, however, especially for the complex diseases that are often the subject of litigation, variations in genes are associated with increases in risk, sometimes relatively small ones, of diseases for which other risk factors are known. With the increasing availability of genetic information, and new methods and technologies such as genome-wide association studies (GWAS) and next-generation sequencing,³¹³ more and more of these associations are being identified³¹⁴—and are being suggested in litigation as competing causes of plaintiffs’ illnesses.³¹⁵ These associations, like any epidemiologic associations, may or

311. Well-known conditions that result from genetic variations include the sickle-cell trait (see Khoury & Dorfman, *supra* note 56, at 370), phenylketonuria (see Genetic & Rare Diseases Information Center, Phenylketonuria, <https://perma.cc/NQ8D-3XRT>), and cystic fibrosis (see Steven M. Rowe et al., *A Breath of Fresh Air*, Sci. Am., Aug. 2011, at 69, 71, <https://doi.org/10.1038/scientificamerican082011-5Uq2nwWGGgRCsPlzmDVY1>). Cystic fibrosis is an example of how some genes may occur in the population in many different variant forms that cause disease of varying severity. See Christopher Wills, Exons, Introns, and Talking Genes 212–13 (1991) (“mutations are found all over the [cystic fibrosis] gene”).

312. For example, the Federal Circuit has affirmed multiple special-master rulings that a mutation in the SCN1A gene, rather than a vaccination, more likely than not caused a child’s severe myoclonic epilepsy of infancy (SMEI, also known as Dravet’s syndrome), despite claimants’ contentions that a vaccine triggered onset of the genetically caused disease. Snyder v. Sec’y of HHS, 553 Fed. App’x 994, 999–1004 (Fed. Cir. 2014) (reversing Court of Federal Claims and reinstating special master’s denial of compensation); Deribeaux v. Sec’y of HHS, 717 F.3d 1363, 1368 (Fed. Cir. 2013) (affirming denial of compensation); Stone v. Sec’y of HHS, 676 F.3d 1373, 1384 (Fed. Cir. 2012) (same). It is not uncommon for a condition’s genetic basis or a claimant’s genotype—or both—to be discovered during the pendency of litigation. See, e.g., Sanchez v. Sec’y of HHS, 809 Fed. App’x 843, 854 (Fed. Cir. 2020) (remanding case with suggestion to reopen the record “[i]n light of the speed with which medical understanding of the course of genetic disorders such as Leigh’s syndrome has been expanding”); Bowen v. E.I. Du Pont de Nemours & Co., Inc., No. CIV.A. 97C-06-194 CH, 2005 WL 1952859 (Del. Super. Ct. June 23, 2005) (during litigation, child whose parents alleged she was sickened by exposure to a fungicide was found to have a genetic mutation thought to be the cause of child’s condition), *aff’d*, 906 A.2d 787 (Del. 2006).

313. See *infra* Glossary of Terms.

314. Witte & Thomas, *supra* note 50, at 969 (“The number of GWAS undertaken has expanded rapidly since 2005.”).

315. See, e.g., Stone v. Sec’y of Health & Hum. Servs., 676 F.3d 1373, 1381–83 (Fed. Cir. 2012) (affirming, as not arbitrary and capricious, special masters’ findings that children’s seizure disorders were caused by mutations in SCN1A gene and not by vaccine in conjunction with genetic susceptibility); *In re Prempro Litig.*, 586 F.3d 547, 566 (8th Cir. 2009) (affirming admission of plaintiff’s expert testimony on specific causation and jury verdict for plaintiff where defense expert testified that genetics were the cause but “every available genetic test . . . came back negative for the most common breast cancer genes”); Rhyne v. U.S. Steel Corp., 474 F. Supp. 3d 733, 753–55 (W.D.N.C. 2020) (denying motion to exclude testimony of plaintiff’s expert witness on specific causation despite acknowledged existence of some genetically caused cases of disease and lack of genetic testing of plaintiff); Bowen v. E.I. Du Pont de Nemours & Co., No. CIV.A. 97C-06-194 CH, 2005 WL 1952859 (Del. Super. Ct. June 23, 2005), *aff’d*, 906 A.2d 787 (Del. 2006) (excluding plaintiff’s expert testimony when, while litigation was pending, a newly discovered test for a newly

may not be causal and may be affected by systematic and nonsystematic error. Moreover, modeling them as competing causes to a toxic agent requires an assumption of independence, which may or may not be justified.³¹⁶ Studies of the association of genes with disease risk greatly outnumber studies that consider the possibility that genes may increase disease risk through interactions with environmental exposures.³¹⁷

Having additional evidence (genetic or otherwise) that bears on individual causation has led a few courts to conclude that a plaintiff may satisfy his or her burden of production even if a relative risk less than 2.0 emerges from the epidemiologic evidence.³¹⁸ For example, genetics might be known to be independently responsible for 50% of the incidence of a disease independent of exposure to the agent.³¹⁹ If the risk-conferring genotype can be ruled out in an individual's case, then a relative risk greater than 1.5 might be sufficient to support an inference that the agent was more likely to be responsible for the plaintiff's disease.³²⁰

discovered genetic variant established "the cause of" plaintiff's condition); *see also* Marchant, *supra* note 154, at 24 (describing cases).

316. *See supra* text accompanying notes 294–303.

317. *See* Witte & Thomas, *supra* note 50, at 969, 971–72.

318. *In re* Hanford Nuclear Reservation Litig., 292 F.3d 1124, 1137 (9th Cir. 2002) (applying Washington law) (recognizing the role of individual factors that may modify the probability of causation based on the relative risk); *Magistrini v. One-Hour Martinizing Dry Cleaning*, 180 F. Supp. 2d 584, 606 (D.N.J. 2002) ("[A] relative risk of 2.0 is not so much a password to a finding of causation as one piece of evidence, among others for the court to consider in determining whether an expert has employed a sound methodology in reaching his or her conclusion."); *Miller v. Pfizer, Inc.*, 196 F. Supp. 2d 1062, 1079 (D. Kan. 2002) (rejecting a threshold of 2.0 for the relative risk and recognizing that even a relative risk greater than 2.0 may be insufficient); *Pafford v. Sec'y, Dep't of Health & Hum. Servs.*, 64 Fed. Cl. 19 (2005) (acknowledging that epidemiologic studies finding a relative risk of less than 2.0 can provide supporting evidence of causation), *aff'd*, 451 F.3d 1352 (Fed. Cir. 2006).

319. *See generally* Gold, *supra* note 154, at 384–89, 412–16 (discussing genetic causes of disease and the role of genetic risk factors in causation disputes); Gary E. Marchant, *Genetic Susceptibility and Biomarkers in Toxic Injury Litigation*, 41 *Jurimetrics J.* 67, 67–68, 71–72, 90 (2000), <http://dx.doi.org/10.2139/ssrn.248461> (discussing role that knowledge about genetic contribution to disease might play in refining probability of causation based on epidemiologic studies of heterogeneous populations).

320. The use of probabilities in excess of 0.50 to support a verdict results in an all-or-nothing approach to damages that some commentators have criticized. The criticism is over the fact that defendants responsible for toxic agents with a relative risk just above 2.0 may be required to pay damages not only for the disease that their agents caused, but also for all instances of the disease. Similarly, those defendants whose agents increase the risk of disease by less than a doubling may not be required to pay damages for any of the disease that their agents caused. *See, e.g.*, Am. Law Inst., 2 Reporter's Study on Enterprise Responsibility for Personal Injury: Approaches to Legal and Institutional Change 369–75 (1991). Judge Posner has been in the vanguard of those advocating that damages be awarded on a proportional basis that reflects the probability of causation or liability. *See, e.g.*, *Doll v. Brown*, 75 F.3d 1200, 1206–07 (7th Cir. 1996). But to date, courts have not adopted a rule that would apportion damages based on the probability of cause in fact in toxic substances cases. *See* Green, *supra* note 293.

This idea of eliminating a known and competing cause is central to the methodology often referred to as differential diagnosis,³²¹ but it is more accurately referred to as differential etiology. The term differential diagnosis in a clinical context refers to identifying the patient's medical condition, whereas differential etiology refers to identifying the causal factors involved in an individual's condition. This is an important distinction, because for many health conditions, the cause of the condition has no relevance to its treatment, and physicians therefore do not pursue that question.³²²

The logic of differential etiology is sound: Eliminating other known and competing causes increases the probability that a given individual's disease was caused by exposure to the agent. In a differential etiology, an expert first determines other known causes of the disease in question and then attempts to ascertain whether those competing causes can be ruled out as a cause of plaintiff's disease,³²³ as in the genetics example above. Similarly, an expert attempting to determine whether an individual's emphysema was caused by occupational chemical exposure would inquire whether the individual was a smoker. By ruling out (or ruling in) the possibility of other causes, the probability that a given agent was the cause of an individual's disease can be refined. Differential etiologies are most critical when the agent at issue is relatively weak and is not responsible for a large proportion of the disease in question.

321. Physicians regularly employ differential diagnoses in treating their patients to identify the disease from which the patient is suffering. See Jennifer R. Jamison, *Differential Diagnosis for Primary Practice* (1999).

322. See *Zandi v. Wyeth a/k/a Wyeth, Inc.*, No. 27-CV-06-6744, 2007 WL 3224242 (Minn. Dist. Ct. Oct. 15, 2007) (commenting that physicians do not attempt to determine the cause of breast cancer); see also John B. Wong et al., *Reference Guide on Medical Testimony*, "Medical Versus Legal Terminology," in this manual; Edward J. Imwinkelried, *The Admissibility and Legal Sufficiency of Testimony About Differential Diagnosis (Etiology): of Under- and Over-Estimations*, 56 *Baylor L. Rev.* 391, 402–03 (2004); *Turner v. Iowa Fire Equip. Co.*, 229 F.3d 1202, 1208 (8th Cir. 2000) (distinguishing between differential diagnosis conducted for the purpose of identifying the disease from which the patient suffers and one attempting to determine the cause of the disease); *Creanga v. Jarda*, 886 A.2d 633, 639 (N.J. 2005) ("Whereas most physicians use the term to describe the process of determining which of several *diseases* is causing a patient's *symptoms*, courts have used the term in a more general sense to describe the process by which *causes* of the patient's *condition* are identified." (quoting *Clausen v. M/V New Carissa*, 339 F.3d 1049, 1057 n.4 (9th Cir. 2003))).

323. Courts regularly affirm the legitimacy of employing differential diagnostic methodology. See, e.g., *In re Ephedra Prods. Liab. Litig.*, 393 F. Supp. 2d 181, 187 (S.D.N.Y. 2005); *Easum v. Miller*, 92 P.3d 794, 802 (Wyo. 2004) ("Most circuits have held that a reliable differential diagnosis satisfies *Daubert* and provides a valid foundation for admitting an expert opinion. The circuits reason that a differential diagnosis is a tested methodology, has been subjected to peer review/publication, does not frequently lead to incorrect results, and is generally accepted in the medical community." (quoting *Turner v. Iowa Fire Equip. Co.*, 229 F.3d 1202, 1208 (8th Cir. 2000))); *Alder v. Bayer Corp., AGFA Div.*, 61 P.3d 1068, 1084–85 (Utah 2002).

Although differential etiology is a sound methodology in principle, this approach is only valid if general causation exists³²⁴ and a substantial proportion of competing causes are known.³²⁵ But for diseases for which the causes are largely unknown, such as most birth defects, a differential etiology is of little benefit.³²⁶ And like any scientific methodology, it can be performed in an unreliable manner.³²⁷

324. “Courts almost universally agree that one must ‘rule in’ the putative cause of an injury before ruling out alternative causes.” Joseph Sanders et al., *Differential Etiology: Inferring Specific Causation in the Law from Group Data in Science*, 63 Ariz. L. Rev. 851, 874 (2021). An excellent explanation for why differential etiologies generally are inadequate without further proof of general causation was provided in *Cavallo v. Star Enterprises*, 892 F. Supp. 756 (E.D. Va. 1995), *aff’d in relevant part*, 100 F.3d 1150 (4th Cir. 1996):

The process of differential diagnosis is undoubtedly important to the question of “specific causation”. If other possible causes of an injury cannot be ruled out, or at least the probability of their contribution to causation minimized, then the “more likely than not” threshold for proving causation may not be met. But, it is also important to recognize that a fundamental assumption underlying this method is that the final, suspected “cause” remaining after this process of elimination must actually be capable of causing the injury. That is, the expert must “rule in” the suspected cause as well as “rule out” other possible causes. And, of course, expert opinion on this issue of “general causation” must be derived from a scientifically valid methodology.

Cavallo, 892 F. Supp. at 771 (footnote omitted); *see also* C.W. *ex rel.* Wood v. Textron, Inc., 807 F.3d 827, 837–38, 839 (7th Cir. 2015); *Tamraz v. Lincoln Elec. Co.*, 620 F.3d 665, 674–76 (6th Cir. 2010); *Hoefling v. U.S. Smokeless Tobacco Co., LLC*, 576 F. Supp. 3d 262, 280–85 (E.D. Pa. 2021); *see generally* Joseph Sanders & Julie Machal-Fulks, *The Admissibility of Differential Diagnosis Testimony to Prove Causation in Toxic Tort Cases: The Interplay of Adjective and Substantive Law*, 64 Law & Contemp. Probs. 107, 122–25 (2001) (discussing cases rejecting differential diagnoses in the absence of other proof of general causation and contrary cases).

325. Courts have long recognized that to prove causation, the plaintiff need not eliminate all potential competing causes, only a sufficient number to conclude that the defendant’s agent was more likely than not a cause of the plaintiff’s disease. *See Stubbs v. City of Rochester*, 134 N.E. 137, 140 (N.Y. 1919). Of course, before a competing cause should be considered relevant to a differential diagnosis, there must be adequate evidence that *it* is a cause of the disease. *See Cooper v. Smith & Nephew, Inc.*, 259 F.3d 194, 202 (4th Cir. 2001); *Ranes v. Adams Labs., Inc.*, 778 N.W.2d 677, 690 (Iowa 2010).

326. *See* *Henricksen v. Conoco Phillips Co.*, 605 F. Supp. 2d 1142, 1162 (E.D. Wash. 2009) (excluding expert’s differential diagnosis testimony because “[s]tanding alone, the presence of a known risk factor is not a sufficient basis for ruling out idiopathic origin in a particular case”); *Perry v. Novartis Pharms. Corp.*, 564 F. Supp. 2d 452, 469 (E.D. Pa. 2008) (finding experts’ testimony inadmissible because of failure to account for idiopathic causes in conducting differential diagnosis); *Soldo v. Sandoz Pharms. Corp.*, 244 F. Supp. 2d 434, 480, 519 (W.D. Pa. 2003) (criticizing expert for failing to account for idiopathic causes); *Magistrini v. One-Hour Martinizing Dry Cleaning*, 180 F. Supp. 2d 584, 609 (D.N.J. 2002) (observing that 90–95% of leukemias are of unknown causes, but proceeding incorrectly to assert that plaintiff was obliged to prove that her exposure to defendant’s benzene was the cause of her leukemia rather than simply a cause of the disease that combined with other exposures to benzene).

327. Numerous courts have concluded that, based on the manner in which a differential diagnosis was conducted, it was unreliable and the expert’s testimony based on it is inadmissible. *See, e.g., Glastetter v. Novartis Pharms. Corp.*, 252 F.3d 986, 989 (8th Cir. 2001); *see generally* Joseph

Qualifications of Experts in Epidemiology

An epidemiology expert witness must be able to identify the relevant research literature and critically review its research methods, statistical analyses, and application to the causal issue presented in the case. No single academic degree, research specialty, or career path qualifies an individual as an expert in epidemiology. Many such experts hold a doctoral degree (Ph.D., Dr.P.H., or Sc.D.) in epidemiology or a related field such as public health or biostatistics; a master's degree (M.P.H., typically) or equivalent training, education, or work experience is usually required of an expert.³²⁸ Many epidemiologists have received a medical degree plus additional training in epidemiology, often a master's degree. Epidemiologists often specialize in subfields such as the epidemiology of infectious diseases, perinatal or reproductive outcomes, chronic diseases such as cancer or cardiovascular diseases, psychosocial factors, environmental or occupational health, research methods, or molecular epidemiology. Most courts have recognized that an expert epidemiologist need not be a clinician and is qualified to provide expert opinions even if the witness has not conducted research about the agent or disease involved in the case.³²⁹

Sanders et al., *Differential Etiology: Inferring Specific Causation in the Law from Group Data in Science*, 63 Ariz. L. Rev. 851 (2021).

328. For illustrations of the types of credentials courts routinely endorse as qualifying a witness to provide expert opinions about epidemiology, including testimony about the meaning and interpretation of epidemiologic studies, see, e.g., the following: *In re Proton-Pump Inhibitor Prods. Liab. Litig.*, No. 2:17-MD-2789 (CCC) (LDW) (MDL 2789), 2022 WL 18999830, at *12–*13 (D.N.J. July 5, 2022) (Ph.D. in biostatistics although not an epidemiologist); *Holcombe v. United States*, 516 F. Supp. 3d 660, 674 (W.D. Tex. 2021) (M.P.H. with doctorate in health policy and management); *In re Johnson & Johnson Talcum Powder Prods. Mktg. Sales Prac. & Prods. Litig.*, 509 F. Supp. 3d 116, 158 (D.N.J. 2020) (Ph.D. in epidemiology with M.D. degree); *id.* at 188 (professor of environmental health sciences and epidemiology who held M.D. degree and M.H.S. in epidemiology and clinical epidemiology); *Wagoner v. Exxon Mobil Corp.*, 813 F. Supp. 2d 771, 800 (E.D. La. 2011) (hematopathologist with M.P.H. who was board-eligible in occupational and environmental medicine and had years of experience consulting on occupation-related malignancies); *In re Welding Fume Prods. Liab. Litig.*, No. 1:03-CV-17000, 2010 WL 7699456, at *29 (N.D. Ohio June 4, 2010) (Ph.D. statistician who was not an epidemiologist but taught in a clinical epidemiology department); *id.* at *40–*41 (holder of M.P.H. and medical degrees who was board-certified in internal medicine and occupational medicine and “served as a medical epidemiologist with the Centers for Disease Control”); *id.* at *45–*46 (M.D. board-certified in preventive and occupational medicine who completed fellowship in occupational neurology and held an M.P.H.); *Tyler ex rel. Tyler v. Sterling Drug, Inc.*, 19 F. Supp. 2d 1239, 1243 (N.D. Okla. 1998) (M.D. who had been director of the Office of Epidemiology within the United States Food & Drug Administration).

329. E.g., *Johnson & Johnson Talcum Powder*, *supra* note 328, 509 F. Supp. 3d at 188 (holding that expert was “qualified to testify on epidemiology” in case involving ovarian cancer, even though witness’s primary research focus was pulmonary disease); *In re Fosamax Prods. Liab. Litig.*, 645 F. Supp. 164, 206 (S.D.N.Y. 2009) (holding that epidemiologist was qualified to testify about

Individuals with medical or other health professional degrees sometimes offer expert opinions on matters related to epidemiology.³³⁰ In some cases, courts applying the standard for expert witness qualification³³¹ have found that individuals without formal degrees in epidemiology have obtained sufficient expertise through their research or other experience.³³² Yet medical expertise and epidemiologic

general causation despite lack of clinical experience treating patients); *In re Silicone Gel Breast Implants Prods. Liab. Litig.*, 318 F. Supp. 2d 879, 895 (C.D. Cal. 2004) (holding that epidemiologist was qualified to provide expert opinion about epidemiologic studies although expert had not conducted studies of the exposure at issue, did not specialize in epidemiology of the disease at issue, and was not a medical doctor); *Erickson v. Baxter Healthcare, Inc.*, 151 F. Supp. 2d 952 (N.D. Ill. 2001) (holding, in case alleging that defendant manufactured and did not warn of virus-infected blood product, that epidemiologists specializing in blood-borne diseases were qualified to testify about state of the art despite lack of experience treating patients, running a blood bank, or manufacturing blood products). *But see* *Blackwell v. Wyeth*, 971 A.2d 235 (Md. 2009) (affirming ruling that board-certified psychiatrist who held M.P.H. degree was not qualified to testify that thimerosal-containing vaccines can cause autism).

330. One reason this occurs is the overlap of scientific evidence relevant to general causation (as to which epidemiology often plays a leading role) and to specific causation (about which epidemiologic evidence may have probative value although, as we noted in the section above titled “Specific Causation,” epidemiology does not directly address specific causation). *See supra* footnotes 281–85 and accompanying text. Courts have sometimes distinguished between the qualifications needed to opine about general causation and the qualifications needed to opine on specific causation. *Compare, e.g.,* *Smith v. Pfizer Inc. (Roerig Div.)*, 2001 WL 968369 (D. Kan. Aug. 14, 2001) (holding, in case alleging that a prescription drug caused a violent outburst, that a psychiatrist was qualified to opine as to specific causation but was not qualified to opine as to general causation), *with* *Rhyne v. U.S. Steel Corp.*, 474 F. Supp. 3d 733, 750–51 (W.D.N.C. 2020) (holding that because “epidemiology focuses on the issue of general causation, not specific causation,” an epidemiologist who was “not a hematologist, oncologist, toxicologist, or medical doctor” was not qualified to give opinion about specific causation) *and* *Poosh v. Phillip Morris USA, Inc.*, 287 F.R.D. 543, 550–51 (N.D. Cal. 2012) (holding that an epidemiologist, although “plainly qualified to testify regarding statistics and . . . studies linking smoking and lung cancer,” was “not a practicing medical doctor, and at most could testify that in his opinion it is likely (based on statistics) that smoking contributed to the development of plaintiff’s lung cancer”). Holdings like those in *Rhyne* and *Poosh* do not address an epidemiologist’s expertise in the field but rather reflect a view of the role epidemiologic data play in proving specific causation.

331. Federal Rule of Evidence 702 refers to a “witness who is qualified as an expert by knowledge, skill, experience, training, or education.” *See In re Proton-Pump Inhibitor Prods. Liab. Litig.*, 2022 WL 18999830, at *4 (D.N.J. July 5, 2022) (Rule 702 “does not require that an expert possess the best formal or substantive qualifications”).

332. *See generally In re Paoli R.R. Yard PCB Litig.*, 916 F.2d 829, 855–56 (3d Cir. 1990) (“various kinds of ‘knowledge, skill, experience, training, or education’ qualify an expert as such. . . . [W]e hold that the district court abused its discretion” by rejecting experts “simply because the experts did not have the degree or training which the district court apparently thought would be most appropriate.”). For examples of courts holding that experience qualified witnesses as experts in epidemiology, *see, e.g., In re Proton-Pump Inhibitor*, No. 2:17-MD-2789 (CCC) (LDW) (MDL 2789), 2022 WL 18999830, at *20–*21 (D.N.J. July 5, 2022) (holding that medical doctor with Ph.D. in biochemistry and master’s degree in biometrics, who had worked at the United States Food & Drug Administration, was qualified to testify about analysis of preclinical- and clinical-trial data); *In re Mirena IUD Prods. Liab. Litig.*, 169 F. Supp. 3d 396, 426 (S.D.N.Y. 2016) (holding

expertise are not identical.³³³ For medical professionals, training in epidemiology through postdoctoral training or a formal degree program is a strong indicator of

that OB/GYNs who were not epidemiologists but had “experience evaluating (and in some cases conducting) epidemiological studies” were qualified “to opine on epidemiological studies”); *id.* at 477 (holding that witness who was not an epidemiologist but who “helped design and issue an epidemiological study,” who “received training from an epidemiologist,” and whose work “involved analyzing research” by drug companies was qualified to testify about epidemiologic studies); *Arias v. Dyncorp*, 928 F. Supp. 2d 10, 20 (D.D.C. 2013) (holding that physician board-certified in occupational medicine who had “vast experience in environmental medicine, conducting risk assessments, and assessing the genesis of diseases caused by toxins” qualified as an expert despite lack of “formal education in epidemiology or toxicology”); *In re Yasmin & Yaz (Drospirenone) Mktg. Sales Pracs. & Prods. Liab. Litig.*, No. 3:09-CV-10012-DRH, 2011 WL 6740363 (S.D. Ill. Dec. 22, 2011) (denying motion to exclude testimony of six medical doctors who were not epidemiologists but had experience with clinical trials or epidemiologic studies); *In re Welding Fume Prods. Liab. Litig.*, *supra* note 328, No. 1:03-CV-17000, 2010 WL 7699456, at *29 (holding that industrial hygienists who were not epidemiologists were qualified to opine about whether literature supported conclusion that manganese is a neurotoxin); *Ashburn v. Gen. Nutrition Ctr.*, 533 F. Supp. 2d 770, 773 (N.D. Ohio 2008) (holding that holder of Ph.D. in exercise physiology who had designed studies of a nutritional supplement was qualified to opine as to general causation in a case involving that supplement).

333. Thus, in *Blackwell v. Wyeth*, 971 A.2d 235 (Md. 2009), plaintiffs alleged that a thimerosal-containing vaccine had caused a child’s autism. The court held that because “the complex field of epidemiology [was] central” to the case, it was not an abuse of discretion to reject as unqualified a board-certified genetic counselor, a professor of pharmacology, and a pediatrician who lacked degrees, certification, or experience in epidemiology. *Id.* at 268. Other courts have held medical professionals unqualified as experts on epidemiology. *See, e.g., Soldo v. Sandoz Pharm. Corp.*, 244 F. Supp. 2d 434, 571 (W.D. Pa. 2003) (physician who was not an epidemiologist or statistician was not qualified to opine that drug caused stroke); *In re Welding Fume Prods. Liab. Litig.*, *supra* note 328, at *42 (N.D. Ohio 2010) (pulmonologist was not qualified to opine about causal connection between welding fume exposure and manganese-induced parkinsonism); *Loverdi v. Medifast, Inc.*, 385 F. Supp. 3d 399, 407 (E.D. Pa. 2019) (nutritionist, who held a doctorate in interdisciplinary arts and sciences with a concentration in nutritional sciences, was not qualified to opine on causation because expert was “not qualified to make medical diagnoses [and had] no expertise in epidemiology”); *Morin v. United States*, 534 F. Supp. 2d 1179, 1185 (D. Nev. 2005) (plaintiff’s treating physician, who had “no expertise in toxicology, epidemiology, risk-assessment, or environmental medicine,” was not qualified to provide expert opinion of causal link between plaintiff’s exposure to jet fuel and plaintiff’s cancer); *Sutera v. Perrier Grp. of Am. Inc.*, 986 F. Supp. 655, 667 (D. Mass. 1997) (oncologist/hematologist who reviewed but had “quite limited” familiarity with relevant epidemiologic and toxicological literature was not qualified “to render an opinion as to whether . . . exposures to low levels of benzene” caused plaintiff’s illness).

By contrast, in *In re Yasmin and Yaz*, *supra* note 324, at *5, plaintiffs asked the court to rule that six employees of the defendant were “not qualified to comment on the design, methodology, or reliability of the epidemiological studies at issue.” All six witnesses had medical degrees. All admitted (in varying language) that they were not epidemiologists and did not have degrees or certifications in epidemiology, public health, or biostatistics. But all had experience with some combination of reviewing, evaluating, presenting data from, conducting, or designing clinical trials or other epidemiologic studies. The court denied plaintiff’s motion in limine with leave to renew after voir dire of each witness. *Id.* at *6–*10. Other courts have held medical professionals who were not epidemiologists qualified to give expert opinions on epidemiologic matters. *See, e.g., Miller v. Bayer Healthcare Pharm. Inc.*, 2016 WL 9047163, at *2 (W.D. Mo. Dec. 20, 2016) (“although the

expertise in the field. Organizations such as the American Board of Medical Specialties offer residencies in preventive medicine to physicians where they may receive training in epidemiology.³³⁴ Belonging to epidemiologic professional societies, such as the International Society of Environmental Epidemiology (ISEE) or the Society for Epidemiologic Research (SER), may demonstrate a commitment to the field and provide additional opportunities for continuing education. Courts do not necessarily require medical professionals with epidemiologic experience to possess such credentials to qualify as experts, however.³³⁵

Often an epidemiology expert has made significant contributions to research, including, but not limited to, experience conducting research studies, publishing papers in peer-reviewed journals, leading research teams, and mentoring others in the field. Such an expert may be recognized by peers with professional distinctions in the form of awards or invitations to speak at conferences. These accomplishments and recognitions indicate that an epidemiologist is acknowledged as an expert by other epidemiologists, well beyond the threshold to testify as an expert witness.

experts are not epidemiologists . . . the court finds that [four medical doctors] have sufficient knowledge and experience to qualify them” as expert witnesses); *Wagoner v. Exxon Mobil Corp.*, 813 F. Supp. 2d 771, 800 (E.D. La. 2011) (holding that treating physician who “had maintained a substantial interest in epidemiology . . . directly tied to his work as a treating physician . . . that has led him to become familiar with epidemiological studies” was qualified to opine as to general causation); *In re Vioxx Prods. Liab. Litig.*, 401 F. Supp. 2d 565, 590–92 (E.D. La. 2005) (holding, over objection that epidemiology expertise was required, that M.D. pathologists could rely on scientific literature to testify that drug caused decedent’s death); *Burton v. R.J. Reynolds Tobacco Co.*, 183 F. Supp. 2d 1308, 1311–12 (D. Kan. 2002) (holding that physician board-certified in internal medicine and pulmonary medicine, who had written numerous articles about health effects of smoking, was qualified to opine that smoking causes peripheral vascular disease (PVD), even though witness was not an epidemiologist and had never conducted a study of PVD); *id.* at 1314 (holding that plaintiff’s treating physician, a specialist in rehabilitation therapy, was qualified to testify that smoking caused plaintiff’s PVD); *Burton v. R.J. Reynolds Tobacco Co.*, 181 F. Supp. 2d 1256, 1267 (D. Kan. 2002) (concluding that because general causation was “within the reasonable confines of” vascular surgeon’s subject area, surgeon was qualified to opine that cigarette smoking caused plaintiff’s PVD “so long as it is established at trial that [the expert’s] opinions and assessments flow from his education and experience as a vascular surgeon”); *In re Joint E. & S. Dist. Asbestos Litig.*, 52 F.3d 1124, 1136 n.21 (2d Cir. 1995) (noting that trial court should have allowed plaintiff’s treating physician, a specialist in internal medicine, to give differential diagnosis testimony, although witness was not expert in asbestos-related illness or familiar with epidemiologic literature).

334. See *Knight v. Kirby Inland Marine, Inc.*, 363 F. Supp. 2d 859, 863 (N.D. Miss. 2005) (holding that an M.D. with certification from American Board of Preventive Medicine/Occupational Medicine, who had written articles on environmental and occupational health, was “a highly qualified epidemiologist and physician”).

335. See *Wagoner v. Exxon Mobil Corp.*, 813 F. Supp. 2d 771, 800 (E.D. La. 2011) (holding that a treating physician who “had maintained a substantial interest in epidemiology” qualified as an expert witness in the field); *Wolfe v. McNeil-PPC, Inc.*, 881 F. Supp. 2d 650, 659 (E.D. Pa. 2012) (holding that a witness’s “extensive medical training and experience” were sufficient to qualify the witness to interpret epidemiologic studies although the witness was not an epidemiologist).

Acknowledgments

The authors are grateful for the able research assistance provided by Murphy Horne (Wake Forest Law School Class of 2012) and Cory Randolph (Wake Forest Law School Class of 2010) in the preparation of the third edition of this reference guide. The authors are grateful for the able research assistance provided by Lyndsey Arneson Field (Wake Forest Law School Class of 2024) and Tia Mitchell, Willa Sweeney, Elizabeth van Winkle, and Laura Ensminger (Rutgers Law School Class of 2024) in the preparation of this fourth edition of the guide. The authors also acknowledge the kind assistance of Eli M. Snir, Senior Lecturer in Data Analytics, Olin Business School, Washington University in St. Louis, in constructing the diagram of a normal distribution and the dose–response curves contained in this reference guide.

Glossary of Terms

The following terms and definitions were adapted from a variety of sources, including *A Dictionary of Epidemiology* (Miquel M. Porta et al. eds., 6th ed. 2014); Joseph L. Gastwirth, *Statistical Reasoning in Law and Public Policy*, Vol. 1 (1988); James K. Brewer, *Everything You Always Wanted to Know About Statistics, But Didn't Know How to Ask* (1978); R.A. Fisher, *Statistical Methods for Research Workers* (1973); National Human Genome Research Institute, Talking Glossary of Genomic and Genetic Terms, <https://perma.cc/43TP-QECX>; National Cancer Institute, NCI Dictionary of Cancer Terms, <https://www.cancer.gov/publications/dictionaries/cancer-terms> (last visited Mar. 16, 2025); National Cancer Institute, NCI Dictionary of Genetics Terms, <https://www.cancer.gov/publications/dictionaries/genetics-dictionary> (last visited Mar. 16, 2025).

adjustment. Methods of accounting for factors that may distort the estimated association between an exposure being studied and a disease outcome. See also direct standardization, indirect standardization.

agent. Also called risk factor. A factor, such as a drug, microorganism, chemical substance, or form of radiation, whose presence or absence can result in the occurrence of a disease. A disease may be caused by a single agent or a number of independent alternative agents, or the combined presence of a complex of two or more factors may be necessary for the development of the disease.

allele. One of two or more forms (variants) of a gene. Individuals ordinarily inherit two copies of each gene, one from each parent. The alleles inherited from each parent may be the same or different.

alpha. The level of statistical significance chosen by a researcher to determine if any association found in a study is sufficiently unlikely to have occurred by chance (as a result of random sampling error) if the null hypothesis (no association) is true. Researchers commonly adopt an alpha of 0.05, but the choice is arbitrary, and other values can be justified.

alpha error. Also called Type I error and false-positive error, alpha error occurs when a researcher rejects a null hypothesis when it is actually true (i.e., when there is no association). This can occur when an apparent difference is observed between the control group and the exposed group, but the difference is not real (i.e., it occurred by chance). A common error made by lawyers, judges, and academics is to equate the level of alpha with the legal burden of proof.

association. The degree of statistical relationship between two or more events or variables. Events are said to be associated when they occur more or less frequently together than one would expect by chance. Association does not necessarily imply a causal relationship. Events are said not to have an

association when the agent (or independent variable) does not appear to be related to the incidence of a disease (the dependent variable). This corresponds to a relative risk of 1.0 or to a beta coefficient of 0. A negative association means that the events occur less frequently together than one would expect by chance, thereby implying a preventive or protective role for the agent (e.g., a vaccine).

attributable risk among the exposed. Also called attributable fraction and attributable proportion among the exposed. The proportion of disease in exposed individuals that can be attributed to exposure to an agent, as distinguished from the proportion of disease attributed to all other causes. Compare population attributable risk.

background rate of disease. Also called background risk of disease. Rate of disease in a population that has no known exposures to an alleged risk factor for the disease. For example, the background risk for all birth defects is 3–5% of live births.

Bayesian analysis. A method of statistical inference that involves using Bayes' theorem. It allows for combining prior information about a hypothesis with new evidence to get a revised estimate of the likelihood of the hypothesis. As opposed to standard (also called frequentist) analysis, which generates confidence intervals, Bayesian methods can be used to estimate so-called credible intervals which represent intervals that have a particular probability of containing the true value of an association given the observed data. Hence, if a study was repeated multiple times under identical conditions, a 95% credible interval would be expected to contain the true value 95% of the time.

beta coefficient. A measure of the strength of the association between an exposure and an outcome. The beta coefficient is calculated as the mean change in the outcome per unit change in the exposure. For example, if a study found that the beta coefficient for the association between prenatal exposure to lead (e.g., determined based on maternal serum concentrations expressed in micrograms per deciliter [$\mu\text{g}/\text{dL}$]) and child IQ was -0.3 , this would mean that, on average, child IQ would be 0.3 IQ point lower for every $\mu\text{g}/\text{dL}$ increase in maternal serum lead concentration.

beta error. Also called Type II error and false-negative error. Occurs when a researcher fails to reject a null hypothesis when it is incorrect (i.e., when there is an association). This can occur when no statistically significant difference is detected between the control group and the exposed group, but a difference does exist.

bias. Any effect at any stage of investigation or inference tending to produce results that depart systematically from the true values. In epidemiology, the term bias does not necessarily carry an imputation of prejudice or other

subjective factor, such as the experimenter's desire for a particular outcome. This differs from conventional usage, in which bias refers to a partisan point of view.

biological marker. See biomarker.

biological plausibility. Consideration of existing knowledge about human biology and disease pathology to provide a judgment about the plausibility that an agent causes a disease.

biomarker. Also called biological marker. A physiological change in tissue or body fluids that occurs as a result of an exposure to an agent and that can be detected in the laboratory. Biological markers are only available for a small number of chemicals.

case-comparison study. See case-control study.

case-control study. Also case-comparison study, case history study, case referent study, retrospective study. A study that starts with the identification of persons with a disease (or other outcome variable) and a suitable control (comparison, reference) group of persons without the disease. Such a study is sometimes referred to as retrospective because it starts after the onset of disease and looks back to the hypothesized causal factors. However, cohort studies can also use a retrospective study design. Thus, case-control study is not synonymous with retrospective study.

case group. A group of individuals who have been exposed to the disease, intervention, procedure, or other variable being studied for its influence on subjects.

causation. As used here, an event, condition, characteristic, or agent being a necessary element of a set of other events that can produce an outcome, such as a disease. Other sets of events may also cause the disease. For example, smoking is a necessary element of a set of events that result in lung cancer, yet there are other sets of events (without smoking) that cause lung cancer. A cause may be thought of as a necessary link in at least one causal chain that results in an outcome of interest. Epidemiologists generally speak of causation in a group context; hence, they will inquire whether an increased incidence of a disease in a cohort was "caused" by exposure to an agent.

clinical trial. Also called randomized trial. An experimental study performed to assess the efficacy and safety of a drug or other treatment. Unlike observational studies, clinical trials can be conducted as experiments and use randomization, because the agent being studied is thought to be beneficial.

cohort. Any designated group of persons followed or traced over a period of time to examine health or mortality experience.

cohort study. The method of epidemiologic study in which groups of individuals can be identified who are, have been, or in the future may be

differentially exposed to an agent or agents hypothesized to influence the occurrence of a disease or other outcome. The groups are observed to determine if the exposed group is more likely to develop disease. Alternative terms for a cohort study (concurrent study, follow-up study, incidence study, longitudinal study, prospective study) describe a frequent feature of this study design, which is observation of the population for a sufficient number of person-years to generate reliable incidence or mortality rates in the population subsets. This generally implies study of a large population, study for a prolonged period (years), or both. Some cohort studies can be retrospective, determining exposure by obtaining historical information about subjects' exposure, as was the case with the path-breaking work on asbestos exposure by Irving Selikoff and collaborators in the 1960s.

confidence interval. A range of values that reflects random error. Thus, if a confidence level of 0.95 is selected for a study, 95% of similar studies would result in the true relative risk falling within the confidence interval. The width of the confidence interval provides an indication of the precision of the point estimate or relative risk found in the study. Where the confidence interval contains a relative risk of 1.0, the results of the study are not statistically significant.

confounding factor. Also called confounder. A factor that is both a risk factor for the disease and a factor associated with the exposure of interest. Confounding refers to a situation in which an association between an exposure and outcome is distorted by a factor that affects the outcome but is unaffected by the exposure.

control group. A comparison group comprising individuals who have not been exposed to the disease, intervention, procedure, or other variable whose influence is being studied.

Cox proportional-hazards model. A statistical method used to investigate the time to an event, such as death or disease, after exposure to one or more independent variables. This method might be used, for example, to determine the difference in survival time for two groups, one of which was exposed to nuclear radiation fallout.

cross-sectional study. A study that examines the relationship between disease and variables of interest as they exist in a population at a given time. A cross-sectional study measures the presence or absence of disease and other variables in each member of the study population. The data are analyzed to determine if there is a relationship between the existence of the variables and disease. Because cross-sectional studies examine only a particular moment in time, they reflect the prevalence (existence) rather than the incidence (rate) of disease and can offer only a limited view of the causal association between the variables and disease.

data dredging. Jargon that refers to results identified by researchers who, after completing a study, pore through their data seeking to find any associations that may exist. In general, good research practice is to identify the hypotheses to be investigated in advance of the study; hence, data dredging is generally frowned on. In some cases, however, researchers use this approach to conduct exploratory studies designed to generate hypotheses for further study.

demographic study. See ecological study.

deoxyribonucleic acid (DNA). A long-chain molecule that carries genetic information via the sequential arrangement of four nucleotide bases in the DNA molecule.

dependent variable. The outcome that is being assessed in a study based on the effect of another characteristic—the independent variable. Epidemiologic studies attempt to determine whether there is an association between the independent variable (exposure) and the dependent variable (incidence or prevalence of disease).

differential misclassification. A form of bias that is due to the misclassification of individuals or a variable of interest when the misclassification varies among study groups, generally with respect to the exposure or outcome under study. This type of bias occurs when, for example, the probability of incorrectly determining that individuals in a study are exposed is larger among participants with the outcome (e.g., disease) relative to those who are healthy. See nondifferential misclassification.

direct standardization. A technique used to eliminate any difference between two study populations based on age, sex, or some other parameter that might result in confounding. Direct adjustment entails comparison of the study group with a large reference population to determine the expected rates based on the characteristic, such as age, for which adjustment is being performed. See adjustment.

directed acyclic graphs (DAGs). These graphs represent researchers' assumptions about the causal structure underlying a research question as informed by scientific knowledge. As such, DAGs may vary between investigators and over time as knowledge evolves. In DAGs, variables are represented by so-called nodes, and causal connections are shown by arrows pointing from causes to effects. DAGs are acyclic because no directed path (i.e., following a series of arrows) can form a closed loop (because a variable cannot cause itself). These graphs allow researchers to identify which variable to adjust for (and which not to adjust for) in order to remove bias.

dose. Generally refers to the intensity or magnitude of exposure to an agent, taking into account the amount or concentration of the agent and the duration or frequency of exposure. In human epidemiologic studies or experimental animal models, dose typically means the amount of chemical or

physical agent that is absorbed into the body and reaches the affected tissue, not just the amount or concentration to which a person or animal is externally exposed. Some toxicologists may also refer to the external exposure as an external dose.

dose–response relationship. A relationship in which a change in amount, intensity, or duration of exposure to an agent is associated with a change—either an increase or a decrease—in risk of disease.

double-blinding. A method used in experimental studies, in which neither the individuals being studied nor the researchers know during the study whether any individual has been assigned to the exposed or control group. Double-blinding is designed to prevent knowledge of the group to which the individual was assigned from biasing the outcome of the study.

ecological fallacy. Also called aggregation bias and ecological bias. An error that occurs from inferring that a relationship that exists for groups is also true for individuals. For example, if a country with a higher proportion of fishermen also has a higher rate of suicides, then inferring that fishermen must be more likely to commit suicide is an ecological fallacy.

ecological study. Also called demographic study. A study of the occurrence of disease based on data from populations, rather than from individuals. An ecological study searches for associations between the incidence or prevalence of disease and suspected disease-causing agents in the studied populations. Researchers often conduct ecological studies by examining easily available health statistics, making these studies relatively inexpensive in comparison with studies that measure disease and exposure to agents on an individual basis.

epidemiology. The study of the distribution and determinants of disease or other health-related states and events in populations. Epidemiology may be applied to control health problems and to improve public health.

epigenetics or epigenomics. The study of biochemical constituents that regulate the degree to which genes are expressed. Epigenetic factors alter the function of the genome without altering the sequence of bases in the DNA. Certain epigenetic changes may be inherited.

epigenome. The set of chemical compounds or “marks” that provide instructions regulating gene expression in a cell.

error. See random error.

etiologic factor. An agent that plays a role in causing a disease.

etiology. The cause of disease or other outcome of interest. Also the study of the cause of disease or other outcome of interest.

experimental study. A study in which the researcher directly controls the conditions. Experimental epidemiology studies (also clinical studies) entail

random assignment of participants to the exposed and control groups (or some other method of assignment designed to minimize differences between the groups).

exposed, exposure. In epidemiology, the exposed group (or the exposed) is used to describe a group whose members have been exposed to an agent that may be a cause of a disease or health effect of interest, or possess a characteristic that is a determinant of a health outcome.

false-negative error. See beta error.

false-positive error. See alpha error.

follow-up study. See cohort study.

gene. A segment of DNA that codes for the amino acid sequence of a protein or part of a protein.

gene expression. The transcription of a DNA base sequence into RNA and translation of the RNA base sequence into an amino acid chain that forms all or part of a protein. Which genes are expressed, and how much, varies from cell to cell depending on regulatory factors that turn genes on and off.

general causation. Issue of whether an agent increases the incidence of disease in a group and not whether the agent caused any given individual's disease. Because of individual variation, a toxic agent generally will not cause disease in every exposed individual.

generalizable. When the results of a study are applicable to populations other than the study population, such as the general population.

genetic epidemiology. Epidemiology that applies genetic data to the study of health at a population level. Genetic epidemiology includes study of the genetic basis of variable phenotypes in populations, the genetic components of diseases or other health outcomes, and the ways in which genetic variations and environmental exposures or other risk factors modify each other's effects.

genetic variant. See variant.

genome. The entire set of DNA instructions found in a cell.

genome-wide association study (GWAS). A research method that involves studying the genomes of many people to attempt to identify genetic variants that are associated with increased risk of a disease or increased occurrence of some other trait (phenotype). Genes identified in a GWAS may or may not be causally associated with the trait of interest.

genomics. The study of the entire genome.

genotype. An individual's genetic code with respect to a trait of interest. For most genes, an individual's genotype ordinarily is determined by the DNA sequence found in two copies of the gene, one inherited from each biological parent.

germline or **germ line**. Of or related to the reproductive (egg or sperm) cells. A germline mutation will be inherited and present in all cells of the offspring produced by the reproductive cell carrying that mutation.

hazard ratio. The ratio of hazard rates. Hazard rates are defined as the risk of an outcome at a specific point in time. The hazard ratio is used as an estimate of the relative risk. For example, the hazard ratio might be used to describe the ratio in death rates of an exposed and an unexposed group one year after a study began.

in vitro. Within an artificial environment, such as a test tube (e.g., the cultivation of tissue in vitro). Often refers to an experiment. Compare in vivo.

in vivo. Within a living organism (e.g., the examination of an experimental animal's organ in vivo). Often refers to an experiment. Compare in vitro.

incidence rate. The number of people in a specified population falling ill from a particular disease during a given time period. More generally, the number of new events (e.g., new cases of a disease in a defined population) within a specified period of time. In an epidemiologic study, calculations of incidence rate take into account the length of time that data are collected about the study subjects.

incidence study. See cohort study.

independent variable. A characteristic that is measured in a study and that is suspected to have an effect on the outcome of interest (the dependent variable). Thus, exposure to an agent is measured in a cohort study to determine whether that independent variable has an effect on the incidence of disease, which is the dependent variable.

indirect adjustment. A technique employed to minimize error that might result when comparing two populations because of differences in age, sex, or another parameter that may independently affect the rate of disease in the populations. The incidence of disease in a large reference population, such as all residents of a country, is calculated for each subpopulation (based on the relevant parameter, such as age). Those incidence rates are then applied to the study population with its distribution of persons to determine the overall incidence rate for the study population, which provides a standardized mortality or morbidity ratio (often referred to as SMR).

inference. The intellectual process of making generalizations from observations. In statistics, the development of generalizations from sample data, usually with calculated degrees of uncertainty.

information bias. Also called observational bias. Systematic error in measuring data that results in an incorrect estimate of the relation between an exposure and an outcome.

instrumental variable. A variable or characteristic that is robustly associated with an exposure of interest and can therefore be used as a proxy to explore the unconfounded causal effect of the exposure on an outcome of interest, provided certain assumptions are satisfied. Genetic variations are used as instrumental variables in Mendelian randomization studies.

interaction. A situation in which the magnitude and/or direction (positive or negative) of the effect of one exposure differs depending on the presence or level of the other. In interaction, the effect of two exposures together is different (greater or less) than the sum of their individual effects.

inverse probability weighting (IPW). A statistical method that creates a pseudo-population by assigning weights to individuals or observations to correct for bias. It is used to correct for selection bias by generating a pseudo-population in which variables assumed to determine selection in a study sample are randomized with respect to selection. It involves weighting each individual or observation by the inverse of its selection probability to correct for being over- or underrepresented in the dataset. IPW can also be used to remove confounding by randomizing confounders with respect to exposure.

linear regression. A statistical method employed to estimate the association between one or multiple exposures and a continuous outcome (e.g., IQ). When multiple variables are included (such as more than one exposure or exposure(s) and confounder(s)), this technique is known as multiple linear regression.

logistic regression. A statistical method employed to estimate the association between one or multiple exposures and a dichotomous outcome (e.g., the existence of cancer). When multiple variables are included (such as more than one exposure or exposure(s) and confounder(s)), this technique is known as multiple logistic regression.

Mendelian randomization. An analytical tool that uses genetic variants as instrumental variables—proxies of an exposure—to assess whether an observed association between the exposure and an outcome of interest may be causal.

meta-analysis. A technique used to combine the results of several studies to enhance the precision of the estimate of the effect size and reduce the plausibility that the association found is due to random sampling error. Meta-analysis is best suited to pooling results from randomly controlled experimental studies, but if carefully performed, it also may be useful for observational studies.

misclassification bias. Bias in the estimate of an association between an exposure and an outcome due to the erroneous classification of an individual as exposed to the agent when the individual was not (or vice-versa), or

incorrectly classifying a study individual with regard to disease. Misclassification bias may be equal in all study groups (see nondifferential misclassification, sometimes referred to as random misclassification) or may vary among groups (see differential misclassification).

molecular epidemiology. Epidemiology that applies the understanding of disease at a molecular level to the study of health at a population level. Molecular epidemiology is characterized by the use of biomarker information.

morbidity rate. State of illness or disease. Morbidity rate may refer to either the incidence rate or prevalence rate of disease.

mortality rate. Proportion of a population that dies of a disease or of all causes per unit of time. The numerator is the number of individuals dying; the denominator is the total population in which the deaths occurred. The unit of time is usually a calendar year.

multivariable analysis. A set of techniques used when the variation in several variables has to be studied simultaneously. In statistics, any analytical method that allows the simultaneous study of two or more exposures or variables.

mutation. A change in the DNA sequence. Germline mutations are inherited by offspring. Somatic mutations are not inherited by offspring.

nondifferential misclassification. Error due to misclassification of individuals or of a variable of interest into the wrong category when the misclassification varies among study groups. The error may result from limitations in data collection, may result in bias, and will often produce an underestimate of the true association. See differential misclassification.

null hypothesis. A hypothesis that states that there is no true association between a variable and an outcome. At the outset of any observational or experimental study, the researcher must state a proposition that will be tested in the study. In epidemiology, this proposition typically addresses the existence of an association between an agent and a disease. Most often, the null hypothesis is a statement that exposure to Agent A does not increase the occurrence of Disease D. The results of the study may justify a conclusion that the null hypothesis (no association) has been disproved (e.g., a study that finds a strong association between smoking and lung cancer). A study may fail to disprove the null hypothesis, but that alone does not justify a conclusion that the null hypothesis has been proved.

observational study. An epidemiologic study in situations in which nature is allowed to take its course, without intervention from the investigator.

odds. For a discrete event, the ratio of the probability that the event exists to the probability that the event does not exist. Thus, if a baseball team wins half of its games, the odds of it winning are 1 to 1 or 1.0.

odds ratio (OR). Also called cross-product ratio and relative odds. The ratio of the odds that a case (one with the disease) was exposed to an agent to the odds that a control (one without the disease) was exposed to the same agent. For rare outcomes, the odds ratio from a case-control study is similar to that of the risk ratio.

p (probability) or p -value. The p -value is the probability of getting a value of the test outcome equal to or more extreme than the result observed, given that the null hypothesis is true. The letter p , followed by the abbreviation “n.s.” (not significant) means that $p > 0.05$ and that the association was not statistically significant at the 0.05 level of significance. The statement “ $p < 0.05$ ” means that p is less than 5%, and, by convention, the result is deemed statistically significant. Other significance levels can be adopted, such as 0.01 or 0.1. The lower the p -value, the less likely that random error would have produced the observed relative risk if the true relative risk is 1. See significance level; statistical significance.

parametric g-formula. A method of standardization that can be used to address confounding in causal inference with observational data. This approach estimates the impact on health outcomes of hypothetical exposure interventions.

pathognomonic. When an agent must be present for a disease to occur. Thus, asbestos is a pathognomonic agent for asbestosis. See signature disease.

phenotype. An observable trait of an individual. A phenotype of interest may result from an individual’s genotype or from a combination of genotype and environmental factors.

placebo-controlled. In an experimental study, providing an inert substance to the control group, so as to keep the control and exposed groups ignorant of their status.

polymorphic gene. A gene that exists in more than one form in the population. See polymorphism.

polymorphism. Any of multiple forms of a gene that exist in a population. Polymorphisms originally arise via mutations. The simplest polymorphism, a “single nucleotide polymorphism” or SNP, is the substitution of one particular DNA nucleotide base with another. Many millions of these have been identified. Other types of polymorphisms exist. Polymorphisms may be harmful, beneficial, or may have no discernible effect. The term polymorphism may also refer to the condition of a gene existing in multiple forms. See also variant.

population attributable risk (PAR). Also called population attributable fraction. The fraction of risk that is attributable to exposure to a substance in a population (e.g., X percent of lung cancer is attributable to cigarettes). See attributable risk among the exposed.

power. The probability that a difference of a specified amount will be detected by the statistical hypothesis test, given that a difference exists. In less formal terms, power is like the strength of a magnifying lens in its capability to identify an association that truly exists. Power is equivalent to one minus Type II error. This is sometimes stated as $Power = 1 - \beta$.

prevalence. The percentage of persons with a disease in a population at a specific point in time.

prospective study. A study in which two groups of individuals are identified: (1) individuals who have been exposed to a risk factor and (2) individuals who have not been exposed. Both groups are followed for a specified length of time, and the proportion that develops disease in the first group is compared with the proportion that develops disease in the second group. See cohort study.

proteome. The complete set of proteins made by an organism.

proteomics. The study of the proteome.

random. The term implies that an event is governed by chance. See randomization.

random error. Also called sampling error and random sampling error. Random error is the error that is due to chance when the result obtained for a sample differs from the result that would be obtained if the entire population (or universe) were studied.

randomization. Assignment of individuals to groups (e.g., for experimental and control regimens) by chance. Within the limits of chance variation, randomization should make the control group and experimental group similar at the start of an investigation and ensure that personal judgment and prejudices of the investigator do not influence assignment. Randomization should not be confused with haphazard assignment. Random assignment follows a predetermined plan that usually is devised with the aid of a table of random numbers. Randomization cannot ethically be used where the exposure is known to cause harm (e.g., cigarette smoking).

randomized trial. See clinical trial.

recall bias. Systematic error resulting from differences between two groups in a study in accuracy of memory. For example, subjects who have a disease may recall exposure to an agent more frequently than subjects who do not have the disease.

relative risk (RR). The ratio of the risk of disease or death among people exposed to an agent to the risk among the unexposed. For instance, if 10% of all people exposed to a chemical develop a disease, compared with 5% of people who are not exposed, the disease occurs twice as frequently among the exposed people. The relative risk is $10\% \div 5\% = 2$. A relative risk of 1 indicates no association between exposure and disease.

research design. The procedures and methods, predetermined by an investigator, to be adhered to in conducting a research project.

retrospective study. A research design in which subjects' exposure to a suspected toxicant or toxicants is obtained from historical information, such as medical records. Most case-control studies are retrospective studies. Some cohort studies may use a retrospective design.

ribonucleic acid (RNA). RNA exists in different forms that have different functions in cells. In the process of gene expression, messenger RNA transcribes a gene's sequence of DNA bases into an RNA sequence. The transcribed sequence is then translated into an amino acid chain with the assistance of transfer RNA.

risk. A probability that an event will occur (e.g., that an individual will become ill or die within a stated period of time or by a certain age).

risk difference (RD). The difference between the risk of disease in the exposed population and the risk of disease in the unexposed population. The value of a risk difference will lie in the range between -1 and 1. Thus, if risk in the exposed population is .25 and risk in the unexposed population is .10, the risk difference is .15.

sample. A subset of a population, which may be selected randomly or nonrandomly. Sample may also refer to an environmental or biological specimen collected to test for the presence of an agent, a disease, or a biomarker.

sample size. The number of subjects who participate in a study. Sample size may also refer to the number of environmental or biological specimens included in a study.

sampling error. See random error.

secular-trend study. Also called timeline study. A study that examines changes over a period of time, generally years or decades. Examples include the decline of tuberculosis mortality and the rise, followed by a decline, in coronary heart disease mortality in the United States in the past 50 years.

selection bias. Systematic error that results from differences between the individuals included in a study (the study sample) and the "target" population to which researchers want to infer results. Selection bias can be due to the initial selection of participants in a study, when an analysis is restricted to certain participants, when participants are lost to follow up in a cohort study, or when controls are not appropriately selected in a case-control study.

sensitivity. Measure of the accuracy of a diagnostic or screening test or device in identifying disease (or some other outcome) when it truly exists. For example, assume that we know that 20 women in a group of 1,000 women have cervical cancer. If the entire group of 1,000 women is tested for cervical cancer and the screening test only identifies 15 (of the known 20) cases

of cervical cancer, the screening test has a sensitivity of 15/20, or 75%. See also specificity.

signature disease. A disease that is associated uniquely with exposure to an agent (e.g., asbestosis and exposure to asbestos). See also pathognomonic.

significance level. A somewhat arbitrary level selected to minimize the risk that an erroneous positive study outcome that is due to random error will be accepted as a true association. The lower the significance level selected, the less likely that false-positive error will occur. See *p*-value; statistical significance.

somatic. Of or relating to a body cell other than a reproductive (sperm or egg) cell. A somatic mutation will be inherited by all cells descended from the cell in which the mutation arose but will not be found in the remainder of an organism's cells. Somatic mutations are not inherited by offspring. Cancer cells typically have many somatic mutations. Compare germline.

specific causation. Whether exposure to an agent was responsible for a given individual's disease.

specificity. Measure of the accuracy of a diagnostic or screening test in identifying those who are disease-free. Once again, assume that 980 out of a group of 1,000 women do not have cervical cancer. If the entire group of 1,000 women is screened for cervical cancer and the screening test only identifies 900 women without cervical cancer, the screening test has a specificity of 900/980, or 92%.

standardized morbidity ratio (SMR). The ratio of the frequency of disease observed in the study population to the frequency of disease that would be expected if the study population had the same strata-specific (e.g., age-specific, sex-specific) frequency of disease as some selected reference population.

standardized mortality ratio (SMR). The ratio of the frequency of death observed in the study population to the frequency of death that would be expected if the study population had the same strata-specific (e.g., age-specific, sex-specific) frequency of death as some selected reference population.

statistical significance. A term used to describe a study result or difference that exceeds the Type I error rate (or *p*-value) that was selected by the researcher at the outset of the study. In formal significance testing, a statistically significant result is unlikely to be the result of random sampling error and justifies rejection of the null hypothesis. Some epidemiologists believe that formal significance testing is inferior to using a confidence interval to express the results of a study. Statistical significance, which addresses the role of random sampling error in producing the results found in the study, should not be confused with the importance (for public health or public policy) of a research finding. See *p*-value; significance level.

stratification. Separating a group into subgroups based on specified criteria, such as age, gender, or socioeconomic status. Stratification is used both to control for the possibility of confounding (by separating the studied populations based on the suspected confounding factor) and when there are other known factors that affect the disease under study. For example, the incidence of death increases with age, and a study of mortality might use stratification of the cohort and control groups based on age.

study design. See research design.

systematic error. See bias.

teratogen. An agent that produces abnormalities in the embryo or fetus by disturbing maternal or paternal health or by acting directly on the fetus in utero.

teratogenicity. The capacity for an agent to produce abnormalities in the embryo or fetus.

threshold phenomenon. A certain level of exposure to an agent below which disease does not occur and above which disease does occur.

timeline study. See secular-trend study.

toxic substance. A substance that is poisonous.

toxicology. The science of the nature and effects of poisons. Toxicologists study adverse health effects of agents on biological organisms, such as live animals and cells. Studies of humans are performed by epidemiologists.

true association. Also called real association. The association that really exists between exposure to an agent and a disease and that might be found by a perfect (but nonetheless nonexistent) study.

Type I error. Rejecting the null hypothesis when it is true. See alpha error.

Type II error. Failing to reject the null hypothesis when it is false. See beta error.

validity. The degree to which a measurement measures what it purports to measure.

variable. Any attribute, condition, or other characteristic of subjects in a study that can have different numerical characteristics. In a study of the causes of heart disease, variables that might be measured are blood pressure and dietary fat intake.

variant. Any of multiple forms of a particular gene or region of DNA that is found in a population. Variants originally arise via mutations that change the DNA nucleotide base sequence. Variants may be harmful, beneficial, or may have no discernible effect. The functional significance of many variants is currently unknown. It is estimated that each person's genome contains three to four million variants.

1. Sample of Selected Toxicological Endpoints and Examples of Agents of Concern in Humans, 1064

Introduction

The discipline of toxicology is concerned primarily with identifying and understanding the adverse effects of external chemical and physical agents on biological systems, including the prevention and amelioration of such adverse effects.¹ The field of risk assessment, when applied to chemicals, uses the basic principles of toxicology to help make informed decisions about how likely it is that a given proportion (e.g., 1 in 100,000) of individuals in an exposed population are likely to develop the toxic endpoint of concern. Such judgments are an essential component of regulatory toxicology in establishing health protective guidance and regulation for exposures to chemicals in the workplace, and chemical contaminants in air, drinking water, food, cosmetics, and pharmaceuticals.² In the context of toxic tort litigation, toxicology expert opinion is focused on the likelihood that an alleged exposure to an individual, or in some instances a group of individuals, was *more likely than not* a significant cause or contributor to the specific disease in question. Although it is an age-old science, toxicology has become a discipline distinct from pharmacology, biochemistry, cell biology, and related fields only in the past sixty years.

Fundamental Principles of Toxicology

There are three central tenets of toxicology. First, “the dose makes the poison”: This implies that all chemical agents are intrinsically hazardous; whether they cause harm is only a question of dose.³ Even water, if consumed in large quantities, can be toxic. Second, each chemical or physical agent tends to produce a specific pattern of biological effects that can be used to establish disease causation.⁴ Third, the toxic responses in laboratory animals are useful predictors of toxic responses in humans, with appropriate qualifications based on an understanding of how the chemical is metabolized in humans and experimental animals, and how the chemical causes its toxicity (so-called mechanism or mode of action). Each of these tenets, and their exceptions, is discussed in greater detail in this reference guide.

1. Casarett & Doull’s *Toxicology: The Basic Science of Poisons* (Curtis D. Klaassen ed., 9th ed. 2019) [hereinafter Casarett & Doull’s].

2. Elaine M. Faustman, *Risk Assessment*, in Casarett & Doull’s, *supra* note 1, at ch. 4.

3. For a discussion of more modern formulations of this principle, which was articulated by Paracelsus in the sixteenth century, see David L. Eaton, *Scientific Judgment and Toxic Torts—A Primer in Toxicology for Judges and Lawyers*, 12 J.L. & Pol’y 5, 15 (2003); Lauren M. Aleksunes & David L. Eaton, *Principles of Toxicology*, in Casarett & Doull’s, *supra* note 1, at ch. 2. A short review of the field of toxicology can be found in Curtis D. Klaassen, *Principles of Toxicology and Treatment of Poisoning*, in Goodman and Gilman’s *The Pharmacological Basis of Therapeutics* 1739 (11th ed. 2008).

4. Some substances, such as central nervous system toxicants, can produce complex and non-specific symptoms, such as headaches, nausea, and fatigue.

Reference Guide on Toxicology

The science of toxicology attempts to determine at what doses foreign agents produce their effects. The foreign agents classically of interest to toxicologists are all chemicals (including foods and pharmaceuticals) and physical agents in the form of radiation, but not living organisms that cause infectious diseases.⁵ However, the poisons that are produced by living organisms (properly called toxins), such as snake venom or botulinum toxin, are generally considered under the framework of toxicology. The discipline of toxicology provides scientific information relevant to the following questions:

1. What hazards does a chemical or physical agent present to human populations or the environment (ecotoxicology)?
2. What degree of risk is associated with chemical exposure at any given dose?⁶

This reference guide focuses on toxicology concepts used in regulatory, administrative, and toxic tort cases, with an emphasis on human health effects, rather than ecological effects. A set of model questions for evaluating the admissibility and strength of an expert's opinion is also included. Following each question is an explanation of the type of toxicological data or information that may be offered in response to the question, as well as a discussion of its significance. The relationship between toxicology, epidemiology, and exposure assessment is also addressed, with cross references to information included in the *Reference Guide on Epidemiology* and the *Reference Guide on Exposure Science and Exposure Assessment*.

Safety and Risk Assessment

Toxicological expert opinion also relies on formal safety and risk assessments. Safety assessment is the area of toxicology relating to the testing of chemicals and drugs for toxicity. It is a relatively formal approach in which the potential for toxicity of a chemical is tested in vivo or in vitro using standardized techniques. The protocols for such studies usually are developed through scientific consensus and are subject to oversight by governmental regulators or other watchdog groups.

After a number of bad experiences, including outright fraud, government agencies have imposed codes on laboratories involved in safety assessment,

5. Forensic toxicology, a subset of toxicology generally concerned with criminal matters, is not addressed in this reference guide, because it is a highly specialized field with its own literature and methodologies that do not relate directly to toxic tort or regulatory issues.

6. In standard risk assessment terminology, hazard—the ability of a chemical to cause (a) specific type(s) of toxic effect(s)—is an intrinsic property of a chemical or physical agent, while risk—the likelihood/probability that the effect will occur in an individual or population under a given set of circumstances—is dependent both upon hazard and on the extent of exposure (both the concentration or amount and the duration/frequency of exposure).

including industrial, contract, and in-house laboratories.⁷ Known as good laboratory practices (GLPs), these codes govern many aspects of laboratory standards, including such details as the number of animals per cage, dose and chemical verification, and the handling of tissue specimens. GLPs are remarkably similar across agencies, but the tests called for differ depending on the mission. For example, there are major differences between the Food and Drug Administration's (FDA) and the Environmental Protection Agency's (EPA) required procedures for testing drugs and environmental chemicals.⁸ The FDA requires and specifies both efficacy and safety testing of drugs in humans and animals. Carefully controlled clinical trials using doses within the expected therapeutic range are required for premarket testing of drugs, because exposures to prescription drugs are carefully controlled and should not exceed specified ranges or uses.

Although new chemicals manufactured for use as food additives, pharmaceuticals, pesticides, and cosmetics have required substantial toxicity testing prior to regulatory approval since at least the 1950s, the vast majority of industrial chemicals had little, if any, premarket toxicity testing until the mid-1970s. In 1976, Congress established new legislation, called the Toxic Substances Control Act (TSCA), to require chemical manufacturers of new chemical entities (chemicals not on an established list of the then approximately 60,000 chemicals in commerce) to submit premarket notifications that would require EPA evaluation and approval prior to the manufacture of significant quantities of the chemical. Although well intended, the legislation "lacked teeth" and over the years was widely viewed as ineffectual. In 2016, the TSCA was extensively revised under the Frank R. Lautenberg Chemical Safety for the 21st Century Act.⁹ This revised TSCA legislation (the Lautenberg Act) increases substantially the expectations for toxicity evaluation for existing chemicals, with a focus on those that the EPA believes pose the highest risk to human health and the environment, as well as giving the EPA more oversight prior to approval for the manufacturing of new chemicals. The EPA now provides extensive guidance to industry on the types of information and data

7. A dramatic case of fraud involving a pharmaceutical company reporting toxicology research to support the safety of a consumer product is described in *Schueneman v. Arena Pharmaceuticals, Inc.*, 840 F.3d 698 (9th Cir. 2016). The defendants made positive public statements to investors about the safety of its weight loss drug, specifically indicating that the drug was not carcinogenic and referred to supporting "animal studies." *Id.* at 700. However, it was discovered that the defendants were conducting a study in which the drug was given to lab rats, and the drug was in fact causing cancer in the rats. *Id.* at 701. The Ninth Circuit found that the plaintiff, one of the defendant's investors, successfully showed that the defendants intentionally and deliberately did not disclose the negative findings of the rat study to investors. *Id.* at 707–08.

8. *Comparison of FDA, EPA, OECD GLP* (Apr. 7, 2015), <https://www.fda.gov/inspections-compliance-enforcement-and-criminal-investigations/fda-bioresearch-monitoring-information/articles>.

9. See Frank R. Lautenberg Chemical Safety for the 21st Century Act, Pub. L. 114–182, 130 Stat. 448 (2016), <https://perma.cc/B4T2-9PV7>.

required under the TSCA Premanufacture Notification guidelines.¹⁰ While the law and regulatory guidance often do not explicitly specify which of the numerous available toxicity testing procedures must be performed, they usually do provide a framework. Such frameworks, which may vary between different regulations, enable both industry and the EPA to assess the potential harm a new chemical may pose to people or the environment.¹¹ Much of the evaluation relies upon chemical structure and comparison with other similar chemicals for which substantial toxicological and environmental data may be available.

In a similar manner, the European Union Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) requires extensive testing of both new chemicals and chemicals already in commerce.¹² Moreover, because exposures are less predictable, doses usually are given in a wider range in animal tests for nonpharmaceutical agents.¹³

10. See EPA, Points to Consider When Preparing TSCA New Chemical Notifications (June 2018), <https://perma.cc/H9G5-7SAT>.

11. The 2016 revisions of the TSCA set forth five possible EPA determinations on new chemical notices:

- The chemical or significant new use presents an unreasonable risk of injury to health or the environment;
- Available information is insufficient to allow the EPA to make a reasoned evaluation of the health and environmental effects associated with the chemical or significant new use;
- In the absence of sufficient information, the chemical or significant new use may present an unreasonable risk of injury to health or the environment;
- The chemical is or will be produced in substantial quantities and either enters or may enter the environment in substantial quantities or there is or may be significant or substantial exposure to the chemical; or
- The chemical or significant new use is not likely to present an unreasonable risk of injury to health or the environment.¹⁴

The lack of toxicity data for new chemicals (or new uses of existing chemicals) introduced into commerce has led the EPA to propose methods of evaluation using (1) in vitro toxicity pathway testing, (2) computational toxicology approaches using structural analogs for which toxicity information is available, (3) followed by whole-animal testing where warranted. See *EPA's Review Process for New Chemicals*, <https://perma.cc/U65D-WANT>.

12. REACH is a regulation of the European Union, adopted in 2007 to “improve the protection of human health and the environment from the risks that can be posed by chemicals, while enhancing the competitiveness of the EU chemicals industry. It also promotes alternative methods for the hazard assessment of substances in order to reduce the number of tests on animals.” See European Chemicals Agency, *Understanding REACH*, <https://perma.cc/AC3M-UTYF>.

The legislation was updated in 2022. See European Chemicals Agency, *Upcoming Changes to REACH Information Requirements*, <https://perma.cc/A6WV-L4GZ>.

13. The development of a new drug inherently requires searching for an agent that at useful doses has a biological effect (e.g., decreasing blood pressure), whereas those developing a new chemical for consumer use (e.g., a house paint) hope that at usual doses no biological effects will occur. There are other compounds, such as pesticides and antibacterial agents, for which a biological effect is desired, but it is intended that at usual doses humans will not be affected. These different expectations

A major impetus for both REACH and the Lautenberg Act was the recognition that less than 1% of the 60,000 to 75,000 chemicals in commerce had been subjected to a full safety assessment, and there were significant toxicological data on only 10% to 20% of them. Under the current U.S. and international approaches to testing chemicals with high production volume, the extent of toxicological information is expanding rapidly.¹⁵

Risk assessment is an approach increasingly used by regulatory agencies to estimate and compare the risks of hazardous chemicals and to assign priority for avoiding their adverse effects. The National Academy of Sciences defines four components of risk assessment: hazard identification, dose–response estimation, exposure assessment, and risk characterization.¹⁶

The Use of Toxicological Information in Risk Assessment

Risk assessment, as practiced by government agencies involved in regulating exposure to environmental chemicals, is highly dependent upon the science of toxicology and on the information derived from toxicological studies. The EPA, FDA, Occupational Safety and Health Administration (OSHA), Consumer Product Safety Commission, and other international (e.g., the World Trade Organization), national, and state agencies use risk assessment as a means to protect workers or the

are part of the rationale for the differences in testing information available for assessing toxicological effects. Under FDA rules, approval of a new drug usually will require extensive animal and human testing, including a randomized double-blind clinical trial for efficacy and toxicity. In contrast, under the TSCA, the only requirement before a new chemical can be marketed is that a premanufacturing notice be filed with the EPA, including any toxicity data in the company's possession.

15. For a comparison of European REACH legislation and the U.S. EPA's 2016 TSCA provisions, see Ágnes Botos, John D. Graham & Zoltán Illés, *Industrial Chemical Regulation in the European Union and the United States: a Comparison of REACH and the Amended TSCA*, 22 J. Risk Rsch. 1187, <https://doi.org/10.1080/13669877.2018.1454495>. For an overview of current trends in toxicity testing, see Ida Fischer, Catherine Milton & Heather Wallace, *Toxicity Testing Is Evolving!*, 9 Toxicology Rsch. 67 (2020), <https://doi.org/10.1093/toxres/tfaa011>; see also Daniel Krewski et al., *Toxicity Testing in the 21st Century: Progress in the Past Decade and Future Perspectives*, 94 Archives Toxicology 1 (2020), <https://doi.org/10.1007/s00204-019-02613-4>.

16. Nat'l Rsch. Council, Science and Decisions: Advancing Risk Assessment (2009). See also *In re Johnson & Johnson Talcum Powder Prods. Mktg., Sales Pracs. & Prods. Litig.*, 509 F. Supp. 3d 116 (D.N.J. 2020) (expert opinion that talcum powder may cause ovarian cancer based on risk assessment and analysis of Bradford Hill factors considerations is admissible). Recently, a National Academy of Sciences panel has discussed potential approaches using systematic review to improve the EPA's risk paradigm. See Nat'l Acads. of Scis., Eng'g & Med., *The Use of Systematic Review in EPA's Toxic Substances Control Act Risk Evaluations* (2021).

public from adverse effects.¹⁷ Acceptable risk levels—for example, 1 in 1,000 to 1 in 1,000,000—are usually well below what can be measured through epidemiological study. Inevitably, this means that risk assessment is usually based solely on toxicological data—or, if epidemiological findings of an adverse effect are observed, then toxicological reasoning must be used to extrapolate to the appropriate lower exposure or dose standard aimed at protecting the public.

The four-part paradigm of risk assessment is heavily based on toxicological precepts. First, hazard identification, which is roughly equivalent to the legal term general causation, reflects the toxicological rule of specificity of effects, and the second step, dose–response assessment, is based upon “the dose makes the poison” and is fundamental to specific causation. The hazard identification process often uses weight-of-evidence approaches in which the toxicological, mechanistic, and epidemiological data are rigorously assessed to form a judgment regarding the likelihood that the agent produces a specific effect. Second, establishing the appropriate dose–response curve, threshold, or “one-hit” model is an exercise in toxicological reasoning. Even for those chemicals known to be carcinogens, a threshold model is appropriate if the toxicological mechanism of action can be demonstrated to depend upon a threshold. The third step, exposure assessment, requires knowledge of specific toxicological dynamics; for example, the impact on the lung of an air pollutant varies by factors such as: inhalation rate per unit body mass, which is affected by exercise and by age; the size of a particle or the solubility of a gas, either of which will affect the depth of penetration into the more sensitive parts of the airways; the competence of the usual airway defense mechanisms, such as mucus flow and macrophage function; and the ability of the lung to metabolize the agent.¹⁸ The fourth and final step is the characterization of risk.¹⁹

Risk assessment is not an exact science. It should be viewed as a useful framework to organize and synthesize information and to provide estimates on which policy making can be based. In recent years, codification of the methodology used to assess risk has increased confidence that the process can be reasonably free of bias; however, significant controversy remains, particularly when actual data are limited and generally conservative default assumptions are used.

17. Pharmaceuticals intended for human use are an exception in that a tradeoff between desired and adverse effects may be acceptable, and human data are available prior to, and as a result of, the marketing of the agent.

18. Some toxic agents pass through the lung without producing any direct effects on this organ. For example, inhaled carbon monoxide produces its toxicity in essence by being treated by the body as if it is oxygen. Carbon monoxide readily combines with the oxygen–combining site of hemoglobin, the molecule in red blood cells that is responsible for transporting oxygen from the lung to the tissues. In this way, the effective transport and tissue utilization of oxygen is blocked.

19. See, e.g., *Nat. Res. Defense Council v. U.S. EPA*, 38 F.4th 34 (9th Cir. 2022) (according to the EPA’s Office of Research and Development, the EPA did not follow its 2005 Guidelines for Carcinogen Risk Assessment, which lay out four steps for conducting risk assessments of chemicals’ carcinogenic potential).

Although risk assessment information about a chemical, and the research data on which it is based, may be useful in setting reasonable boundaries regarding the likelihood of causation, the impetus for the development of risk assessment has been the regulatory process, which has different goals.²⁰ Because of their use of appropriately prudent assumptions in areas of uncertainty and their use of default assumptions when there are limited data, as well as legal requirements related to public health considerations, risk assessments often intentionally encompass the upper range of possible risks.²¹ An additional issue, particularly related to cancer risk, is that standards based on risk assessment often are set to avoid the risk caused by lifetime exposure at this upper-range estimate of risk. Exposure to levels exceeding this standard for a small fraction of a lifetime does not mean that the overall lifetime risk of regulatory concern has been exceeded.²² Given these issues, courts have taken different approaches to how information derived from risk assessments may be relied upon by experts.²³

20. See Nat'l Rsch. Council & Comm. on Improving Risk Analysis Approaches Used by the U.S. EPA, *Toward a Unified Approach to Dose–Response Assessment, in Science and Decisions: Advancing Risk Assessment* 127 (2009), <https://perma.cc/47RG-NKMG>. See also *Yates v. Ford Motor Co.*, No. 5:12-CV-752-FL, 2015 WL 2189774, at *17, *27 (E.D.N.C. May 11, 2015) (holding that an EPA pamphlet that includes regulatory risk assessment can be relied on by the plaintiff's experts only to “support the reliability of studies the experts themselves rely upon”).

21. It is also claimed that standard risk assessment will underestimate true risks, particularly for sensitive populations exposed to multiple stressors, an issue of particular pertinence to discussions of environmental justice. Comm. on Env't Just., Institute of Med., *Toward Environmental Justice: Research, Education, and Health Policy Needs* (1999), <https://doi.org/10.17226/6034>. In 2003, the EPA developed formal guidance for cumulative risk assessment, wherein it defined aggregate exposure as the “combined exposure of an individual (or defined population) to a specific agent or stressor via relevant routes, pathways, and sources.” EPA, *Framework for Cumulative Risk Assessment* (2003), <https://perma.cc/D7CT-Z2RT>. In 2022, the EPA released a draft update to this document, with an initial emphasis on identifying research needs. See EPA, *Cumulative Impacts: Recommendations for ORD Research* (2022), <https://perma.cc/B6SL-EHUT>.

22. A public health standard to protect against the lifetime risk of inhaling a known carcinogen will usually be based on lifetime exposure calculations of twenty-four hours a day, every day for seventy years. This is more than 25,000 days and 600,000 hours. Exceeding this standard for a few hours would presumably have little impact on cancer risk. In contrast, for a short-term standard set to avoid a threshold-based risk, exceeding the standard for this short time may make a major difference—for example, an asthma attack caused by being outdoors on a day that the ozone standard is exceeded. Regulatory statutes sometimes limit consideration of multiple pathways of exposure to the same chemical, potentially underestimating overall exposure and risk. See, e.g., Swati D. G. Rayasam et al., *Toxic Substances Control Act (TSCA) Implementation: How the Amended Law Has Failed to Protect Vulnerable Populations from Toxic Chemicals in the United States*, 56 *Env't Sci. & Tech.* 11969 (2022), <https://doi.org/10.1021/acs.est.2c02079>. However, the interpretation of how such evaluations under the revised TSCA law are done by the EPA has been criticized. See Anthony C. Tweedale, *Correspondence on “Toxic Substances Control Act (TSCA) Implementation: How the Amended Law has Failed to Protect Vulnerable Populations from Toxic Chemicals in the United States,”* 56 *Env't Sci. & Tech.* 16533 (2022), <https://doi.org/10.1021/acs.est.2c06032>.

23. See, e.g., *Hardeman v. Monsanto Co.*, 997 F.3d 941 (9th Cir. 2021) (discussion of appropriate use in an expert opinion of the IARC's classification of glyphosate as a “probable carcinogen”).

Toxicology and the Law

Toxicological studies, by themselves, rarely offer direct evidence that a disease in any one individual was caused by a chemical exposure.²⁴ However, toxicology can provide scientific information regarding the increased risk of contracting a disease at any given exposure or dose and help rule out other risk factors for the disease (see section titled “Toxicology and Epidemiology” below for discussion on disease causation). Toxicological evidence also contributes to the weight of evidence supporting causal inferences by explaining how a chemical causes a specific disease through describing metabolic, cellular, and other physiological effects of exposure. For certain chemicals that create sufficiently long-lasting changes to molecular structures suitable for testing, toxicology evidence may be offered to establish chemical-specific “fingerprints” that can strengthen the causal inference between a specific chemical exposure and the presence of a specific disease.

The interface of toxicological science with legal issues can be complex, in part reflecting the inherent challenges of bringing science into a courtroom, but also because of issues pertinent to toxicology.

Complexity in toxicology is derived primarily from three factors. The first is that chemicals often change within the body as they go through various routes to eventual elimination.²⁵ Thus absorption, distribution, metabolism, and excretion are central to understanding the toxicology of an agent.

The second is that human sensitivity to chemical and physical agents can vary greatly among individuals, often as a result of differences in absorption, distribution, metabolism, or excretion. Although toxic responses from a given chemical sometimes occur in multiple different organs in the body (e.g., liver, kidney, brain), toxic effects often occur selectively in specific tissues, which are then referred to as target organs. Both the disposition of the chemical (e.g., metabolism and excretion) and target organ sensitivity can be affected by a combination of genetic and environmental factors, including factors as mundane as drinking certain fruit juices.²⁶

24. There are exceptions—for example, when measurements of levels in the blood or other body constituents of the potentially offending agent are at a high enough level to be consistent with reasonably specific health impacts, such as in carbon monoxide poisoning and lead poisoning.

25. Direct-acting toxic agents are those whose toxicity is due to the parent chemical entering the body. A change in chemical structure through metabolism usually results in detoxification. Indirect-acting chemicals are those that must first be metabolized to a harmful intermediate for toxicity to occur. For an overview of metabolism in toxicology, see David L. Eaton & Julia Cui, *Biotransformation*, in *Patty's Toxicology* (James Klaunig ed., 7th ed. 2023), <https://doi.org/10.1002/0471125474.tox122>.

26. Grapefruit juices and certain other fruit juices at sufficient dose have the potential to inhibit the metabolism of a wide variety of drugs and chemicals. See Michael J. Hanley et al., *The Effect of Grapefruit Juice on Drug Disposition*, 7 *Expert Op. Drug Metabolism & Toxicology* 267 (2011), <https://doi.org/10.1517/17425255.2011.553189>; Meng Chen et al., *Food-Drug Interactions*

The third major source of complexity is the need for extrapolation—either across species, because many toxicological data are obtained from studies in laboratory animals, or across doses, because human toxicological and epidemiological data often are limited to specific exposure or dose ranges that may differ from the ranges of interest. All three of these factors are responsible for much of the complexity in utilizing toxicology for tort or regulatory judicial decisions and are described in more detail below.

The science of toxicology is useful in establishing general causation in toxic tort litigation through demonstrating that specific chemicals are capable of causing specific effects (e.g., specific types of cancers, birth defects, poisoning) and identifying when such effects may be manifested, either acutely or over time. Identifying such qualitative characteristics of a chemical is referred to as hazard evaluation and is often based on results of experimental animal studies. To determine the likelihood that a specific chemical caused a specific toxic effect in an individual person (specific causation in tort litigation) or a population (regulatory/population health guidance) requires careful consideration of the exposure characteristics (how much, when, and how often) that are central to determining the dose–response for the specific toxic endpoint in the individual or population. Such decisions are complex and may also rely on human epidemiological data where they exist.

Toxicology and Epidemiology

From the beginning of human history, “Why me?” is probably the most frequently asked question about disease. Epidemiology is the scientific discipline most closely involved in providing evidence to answer this question. Epidemiology is the study of the incidence and distribution of disease in human populations. Clearly, both epidemiology and toxicology have much to offer in elucidating the causal relationship between chemical exposure and disease.²⁷ These sciences often go hand in hand with assessments of the risks of chemical exposure, without

27. See Steve C. Gold et al., *Reference Guide on Epidemiology*, section titled “General Causation,” in this manual. See also Nat’l Acads. Sci., Eng’g & Med, *Assessing Causality from a Multidisciplinary Evidence Base for National Ambient Air Quality Standards* (2022), <https://perma.cc/6L9G-NBCN> (discussing the strengths and limitations of epidemiological studies in establishing “causation” between exposure to a hazardous chemical (in this case, various air pollutants) and the development of specific diseases). For example, in *In re Nexium Esomeprazole*, 662 F. App’x 528 (9th Cir. 2016), testimony on general causation was excluded as unreliable in which the expert did not adequately explain how he inferred a causal relationship from epidemiological studies that did not come to the same conclusions. However, epidemiological studies are not always necessary. *McMunn v. Babcock & Wilcox Power Generation Grp., Inc.*, No. 2:10CV143, 2014 WL 814878, at *15 (W.D. Pa. Feb. 27, 2014) (citing *Glastetter v. Novartis Pharms. Corp.*, 252 F.3d 986, 992 (8th Cir. 2001); *Rider v. Sandoz Pharms. Corp.*, 295 F.3d 1194, 1198 (11th Cir. 2002)).

artificial distinctions being drawn between them. However, although courts generally rule epidemiological expert opinion admissible, the admissibility of toxicological expert opinion has been more controversial because of uncertainties regarding extrapolation from animal and in vitro data to humans. This has been particularly true in cases in which relevant epidemiological research data exist. However, the methodological weaknesses of some epidemiological studies, including their inability to accurately measure exposure, the often small numbers of subjects, and issues such as recall bias when individuals with specific diseases are asked to recall their past exposure to chemicals in comparison with a control population, often render these studies difficult to interpret. As detailed in the *Reference Guide on Epidemiology*, an epidemiological study by itself can only show an association, which may or may not be causal.

The Role of Toxicology in Establishing Causation

The most well-known guidelines for considering causality of a specific effect by a specific cause are the Bradford Hill considerations.²⁸ Austin Bradford Hill was a British epidemiologist who contributed greatly to studies linking cigarette smoking to lung cancer. As discussed in detail in the *Reference Guide on Epidemiology*, Hill described nine points of consideration to facilitate the determination of a causal association seen in an epidemiology study. A modified list of the Bradford Hill considerations that inform epidemiologists in making judgments about causation includes:

1. Temporal relationship
2. Strength of the association
3. Dose–response relationship
4. Replication of the findings
5. Biological plausibility
6. Consideration of alternative explanations
7. Cessation of exposure
8. Specificity of the association
9. Consistency with other knowledge

28. Austin Bradford Hill, *The Environment and Disease: Association or Causation?*, 108 J. Royal Soc’y Med. 32 (2015) (reprint of 1965 article), <https://doi.org/10.1177/0141076814562718>. For a discussion of the Bradford Hill considerations, see Steve C. Gold et al., *Reference Guide on Epidemiology*, section titled “General Causation,” in this manual. Although the points raised by Bradford Hill in his 1965 article are often referred to as “criteria,” the author made it clear that none were absolutes. As discussed in the *Reference Guide on Epidemiology* in this manual, the term “consideration,” rather than “criteria” or even “guidelines,” is perhaps more appropriate to represent these ideas.

Toxicological evidence can provide insights into almost all of these considerations:

1. **Temporal relationship** is perhaps obvious and refers to a fundamental concept that, in order for a toxic substance to have caused an adverse effect in an individual (or population of individuals), the *exposure must have occurred before the onset of symptoms* of the disease. However, the temporality consideration would not exclude the potential for a chemical to enhance or aggravate a preexisting disease. Toxicology often considers the potential interaction of two chemicals, referred to as potentiation, where chemical A does not by itself cause a specific adverse response or disease, but when combined with exposure to chemical B, which has been established to cause the adverse response or disease in question, the magnitude of response to chemical B is much greater in the presence of chemical A. A classic example of potentiation would be someone who takes a statin drug to lower cholesterol, with no evident adverse effects, but, upon regular consumption of large amounts of grapefruit juice, develops muscle weakness and spasms (rhabdomyolysis), a symptom of statin toxicity. In this example, the causal agent is actually the statin drug, but effects occur only after consuming large amounts of grapefruit juice.
2. **Strength of association** refers to the overall magnitude of effect and is largely pertinent to epidemiology studies.
3. **Dose–response** is a fundamental tenet of toxicology and is highly relevant to both toxicological and epidemiological studies. This is discussed in greater detail in other parts of this reference guide.
4. **Replication of the findings** is also relevant to both epidemiology and toxicology. For toxicology, this is most important in demonstrating another Bradford Hill consideration, biological plausibility, whereby several independent studies under different conditions demonstrate that chemical A reproducibly causes effect B. This reproducibility could be in animal studies, in vitro studies with human tissues, or both.
5. **Biological plausibility** is, of all of the Bradford Hill considerations, perhaps the most relevant to toxicology. As discussed in detail later in this reference guide, understanding the cellular, biochemical, and molecular processes (mechanisms and mode of action) by which a toxic substance causes an adverse effect is a critical element that can support a causal association in epidemiology studies, largely by demonstrating that adverse effects seen in experimental animals are relevant to humans because they share common mechanisms/modes of action, supporting biological plausibility. Because of ethical considerations, with the exception of pharmaceutical agents, controlled in vivo studies are largely limited to experimental animals, which is the domain of toxicology.

6. **Consideration of alternative explanations** is largely confined to epidemiology, although the consideration of mechanisms/modes of action of a toxic substance determined in experimental animals (the domain of toxicology) may be informative of alternative explanations—for example, a workplace where exposure to multiple different substances is associated with an elevated incidence of disease. Determining which, if any, of the substances has been shown through toxicological studies to cause the disease in question may support an alternative explanation.
7. **Cessation of exposure** can also be supported by animal studies in which the toxic response or disease in question is reduced or eliminated following cessation of exposure. This would be similarly informative and provide biological plausibility for such observations seen in epidemiology studies.
8. **Specificity of the association** is also relevant to toxicology, where a specific adverse effect can be shown to cause an unusual or uncommon effect in animals. Toxicological studies on mechanism or mode of action may demonstrate a specific or even unique development of a particular disease or symptom in experimental animals and/or human tissues in vitro, lending biological plausibility to the specificities of association observed in epidemiology studies.
9. **Consistency with other knowledge** also fits equally well in toxicology studies, again focused on a scientific understanding of how the toxic substance in question causes a specific adverse outcome or disease.

Thus, toxicology may contribute to the Bradford Hill considerations, for consistency considerations, particularly biological plausibility. Making sense of whether an association is causal is affected by whether there is a likely biological pathway between the exposure and the effect, for which the evidence is often based on animal toxicology studies. However, Hill argues that biological plausibility cannot be demanded, because it depends upon the biological knowledge of the day. The importance of biological plausibility to setting environmental regulation is evident in that it is now being routinely included as a chapter or subchapter in EPA analyses on which air pollution and other standards are based.

In recent decades, medical science has been challenged by the need to derive actionable information from the medical literature—a breadth of literature that has increased both in size and in the diversity of medical specialties and subspecialties that are being applied to solve problems related to diagnosis and treatment of disease. This has led to the development of formal systematic approaches to gathering and evaluating the pertinent epidemiological literature. The National Institutes of Health (NIH) held consensus-developing conferences from 1977 to 2013 aimed at controversial topics in clinical decision-making, which included

toxicological data where relevant. These were discontinued as no longer necessary because many other organizations had developed similar approaches.²⁹

A more recent example of a common approach to developing a systematic review process for evaluating the medical science literature has been that of the Cochrane reviews.³⁰ These are systematic approaches that analyze the existing literature and focus almost exclusively on epidemiological findings, primarily related to diagnosis and treatment of disease. In part building on the Cochrane review model, systematic reviews have been suggested for toxicology³¹ and for public health.³²

In contrast to epidemiology, because animal and cell studies permit researchers to isolate the effects of exposure to a single chemical or to mixtures, toxicological findings offer unique information concerning dose–response relationships, mechanisms of action, specificity of response, and other information relevant to the assessment of causation—although these can present issues related to extrapolation to humans.³³

The gold standard in clinical epidemiology and in the testing of pharmaceutical agents is the randomized double-blind placebo control study in which the control and intervention groups are usually well matched. Although appropriate and very informative for the testing of pharmaceutical agents, it is generally unethical for chemicals used for other purposes. The randomized control design in essence is what is used in a classic toxicological study in laboratory animals,

29. For a review of consensus approaches in general and the importance of unbiased selection of members of review committees that reflect the broad disciplines involved, see Bernard D. Goldstein, *What the Trump Administration Taught Us About the Vulnerabilities of EPA's Science-Based Regulatory Processes: Changing the Consensus Processes of Science into the Confrontational Processes of Law*, 31 Health Matrix 299 (2021), <https://perma.cc/YJ3H-TPPR>. 32. See also Steve C. Gold et al., *Reference Guide on Epidemiology*, section titled “Methods for Synthesizing or Combining the Results of Multiple Studies,” in this manual.

33. Courts have found animal studies to be relevant evidence of causation where there is a sound basis for extrapolating conclusions from those studies to humans in real-world conditions. See *Hardeman v. Monsanto Co.*, 997 F.3d 941 (9th Cir. 2021); see also *Milana v. Eisai, Inc.*, No. 8:21-cv-831-CEH-AEP, 2022 WL 846933 (M.D. Fla. Mar. 22, 2022) (increase in tumors in mammary tissue of experimental animals compared to higher rates of cancer in patients taking weight loss drug); *In re Levaquin Prods. Liab. Litig.*, No. 08–1943 (JRT), 2010 WL 8400514, at *2–4, *8 (D. Minn. Nov. 8, 2010); *Brandeis Univ. v. Keebler Co.*, No. 1:12-cv–01508, 2013 WL 5911233 (N.D. Ill. Jan. 18, 2013); *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1310 (N.D. Fla. 2018).

although matching is more readily achieved because the animals are bred to be genetically similar and have identical environmental histories.

Dose issues are at the intersection between toxicology and epidemiology. Many epidemiological studies of the potential risk of chemicals do not have direct information about dose, although qualitative differences among subgroups or in comparison with other studies can be inferred. The epidemiology database includes many studies that are probing for the potential for an association between a cause and an effect. Thus, a study asking all those suffering from a specific disease a multiplicity of questions related to potential exposures is bound to find some statistical association between the disease and one or more exposure conditions due to chance alone. Such studies generate hypotheses that can then be evaluated by subsequent studies that more narrowly focus on the potential cause-and-effect relationship. One way to evaluate the strength of the association is to assess whether those epidemiological studies evaluating cohorts with relatively high exposure support the association.³⁴

The requirement in certain jurisdictions for epidemiological evidence of a relative risk greater than two ($RR > 2$) for general causation also has limited the utilization of toxicological evidence.³⁵ A firm legal requirement for such evidence means that if the epidemiological database only showed statistically significant evidence that cohorts exposed to ten parts per million of an agent for twenty years produced an 80% increase in risk, the court could not hear the case of a plaintiff alleging that exposure to fifty parts per million for twenty years of the same agent caused the adverse outcome. Yet to a toxicologist, there would be little question that exposure to the fivefold-higher dose of an agent producing an 80% increase in risk would lead to more than a 100% increase in risk, i.e., more than doubling of the risk.

34. As an example of considering dose and exposure issues across epidemiological studies, see Luoping Zhang et al., *Formaldehyde Exposure and Leukemia: A New Meta-Analysis and Potential Mechanisms*, 681 *Mutation Resch.* 150 (2008), <https://doi.org/10.1016/j.mrrev.2008.07.002>. The subject of the strength of an epidemiological association and its relation to causality is considered in Steve C. Gold et al., *Reference Guide on Epidemiology*, in this manual; see also note 79, *infra*.

35. The basis for the use of $RR > 2$ is the translation of the preponderance of evidence rule, or “more likely than not” legal standard, into the epidemiological concept of at least a doubling of risk. An example is the *Havner* rule in Texas, which for general causation requires that there be reliable epidemiological studies with a statistically significant $RR > 2$ associating a putative cause with an effect. See *Bostic v. Ga. Pac. Corp.*, 439 S.W.3d 332 (Tex. 2014). But see *Hardeman v Monsanto Co.*, 997 F.3d 941, 966 (9th Cir. 2021) (“[W]e have never suggested that a headline increase in a risk statistic, or even an adjusted odds ratio above 2.0, is necessary for finding a strong association. To the contrary, flexibility is warranted considering the contextual nature of the *Daubert* inquiry.”) (citations omitted). For a discussion of the use by courts in various jurisdictions of relative risk > 2 for general and specific causation, see Russel S. Carruth & Bernard D. Goldstein, *Relative Risk Greater Than Two in Proof of Causation in Toxic Tort Litigation*, 41 *Jurimetrics* 195 (2001); for the toxicological issues, see Bernard D. Goldstein, *Toxic Torts: The Devil Is in the Dose*, 16 *J.L. & Pol’y* 551–85 (2008).

Even though there is little toxicological data on many of the approximately 75,000 compounds in general commerce, there is usually far more information from toxicological studies than from epidemiological studies.³⁶ It is much easier, and usually more economical, to expose an animal to a chemical or to perform *in vitro* studies than it is to perform epidemiological studies. This difference in data availability is evident even for cancer causation, for which toxicological study is particularly expensive and time consuming. Of the approximately fifty specific chemicals that reputable international authorities agree are known human carcinogens based on positive epidemiological studies, almost all of them have also been shown to cause cancer in laboratory animal studies. Yet there are hundreds of known animal carcinogens for which there is either no valid epidemiological database or for which the epidemiological database has been equivocal.³⁷

To clarify any findings, regulators can require a repeat of an equivocal two-year animal toxicological study or the performance of additional laboratory

36. See, for example, Nat'l Toxicology Prog., 15th Rep. on Carcinogens (2021), <https://perma.cc/V4DP-3YNZ>, for a discussion of how epidemiology and animal toxicity studies are used to assess the potential cancer risk of different chemicals.

37. See, e.g., Int'l Agency for Rsch. on Cancer, IARC Monographs on the Identification of Carcinogenic Hazards to Humans, <https://perma.cc/R56M-EQMM>; Nat'l Toxicology Prog., *supra* note 36; *Waite v. All Acquisition Corp.*, 194 F. Supp. 3d 1298 (S.D. Fla. 2016) (court remains "unconvinced" that lack of statistically significant epidemiological studies properly overcomes all other types of scientific evidence including animal, cellular, and molecular studies). The absence of epidemiological data is due, in part, to the difficulties in conducting cancer epidemiology studies, including the lack of suitably large groups of individuals exposed for a sufficient period of time, long latency periods between exposure and manifestation of disease, the high variability in the background incidence of many cancers in the general population, and the inability to measure actual exposure levels. See also *Parker v. Mobil Oil Corp.*, 857 N.E.2d 1114 (N.Y. 2006), in which New York's highest court reviewed an appeal from a summary judgment of a lower court that had dismissed a plaintiff's case because of the lack of a specific exposure estimate by the plaintiff's experts. The plaintiff's experts claimed that unusual work practices during his seventeen years employed at a gasoline station led to higher exposure to benzene, a known cause of acute myelogenous leukemia (AML) from which the patient suffered, than would have occurred in the work practices of a usual gasoline station worker. The higher court found for the plaintiff on the lack of a need for a specific exposure assessment, citing other cases finding that an expert does not need to establish the amount of exposure the plaintiff experienced. *Id.* at 1121 (citing *McClain v. Metabolife Int'l, Inc.*, 401 F.3d 1233, 1241 n.6 (11th Cir. 2005)). However, the same court ruled for the defense based on the absence of epidemiological evidence that gasoline caused AML, despite the fact that benzene is a component of the gasoline mixture. Court preference for epidemiology is also evident in the *Havner* rule (see *supra* note 35). The requirement for epidemiological evidence of a doubling of risk precludes toxicological reasoning related to dose. For example, suppose there were two epidemiological studies showing a statistically significant 80% increase of an adverse endpoint in large workforces in well-regulated industries that were exposed to ten parts per million (ppm) of a chemical for thirty years. Suppose also that there was a plaintiff with the same endpoint whose experts presented evidence that the plaintiff was exposed to fifty ppm for thirty years to the same chemical. Based on dose considerations, a toxicologist could argue that the plaintiff's level of exposure would exceed 100%, i.e., more than double the plaintiff's risk. But under a strict interpretation of the *Havner* rule, the plaintiff's case would be dismissed.

studies in which animals deliberately are exposed to the chemical. Such deliberate exposure is not possible in humans. As a general rule, unequivocally positive epidemiological studies reflect prior workplace practices that led to relatively high levels of chemical exposure for a limited number of individuals and that, fortunately, in most cases no longer occur now. Thus, an additional prospective epidemiological study often is not possible, and even the ability to do retrospective studies is constrained by the passage of time.

In essence, epidemiological findings consistently demonstrating an adverse effect in humans of a manufactured chemical represent a failure of toxicology as a preventive science. A corollary of the tenet that, depending upon dose, all chemical and physical agents are harmful is that society depends upon toxicological science to discover and anticipate these harmful effects, and we also rely on regulators and other responsible parties to prevent human exposure to a harmful level or to ensure that the agent is not manufactured and distributed. In this regard epidemiology is a valuable backup approach that functions to detect failures of primary prevention. The two disciplines complement each other, particularly when the approaches are iterative.

Toxicologists may use epidemiological findings in their expert opinions concerning general causation and specific causation. This is particularly true for well-studied compounds that have been thoroughly evaluated by respected organizations, such as the International Agency for Research on Cancer (IARC, affiliated with the World Health Organization (WHO)) or the National Toxicology Program (NTP, affiliated with the U.S. Department of Health and Human Services), which include toxicologists and epidemiologists in their review of the evidence. For example, in mortality studies of large cohorts of workers exposed to high levels of a carcinogenic agent in which all types of cancer are reported, but only an increase in brain cancer is noted, the toxicologist may consider this information in determining if a pancreatic cancer was caused by exposure to a lesser dose of the agent. In terms of assessing specific causation for exposure to this known carcinogen, there may be the equivalent of a No Observed Adverse Effect Level (NOAEL; see section titled “Toxicological Study Design” below) in the reviewed and accepted epidemiological data in which an increase in brain cancer risk is seen only in the more highly exposed populations. Whether a toxicologist is qualified to offer an opinion based on both toxicology and epidemiology data depends on the particular background of the proffered expert and the legal standard applied in the jurisdiction.

Toxicology and Exposure Science

In recent decades, exposure assessment has developed into a scientific field (exposure science) with journals, learned societies, and research funding processes.

Exposure science methodologies include mathematical models used to predict exposure resulting from an emission source, which might be a long distance upwind; chemical or physical measurements of media such as air, food, and water; and biological monitoring within humans, including measurements of blood and urine specimens if available, for the chemical of concern and/or its metabolites. Extrapolation back to the level of external exposure depends upon toxicokinetic analyses (see section titled “Safety and Risk Assessment” above). In this continuum of exposure metrics, the closer to the human body, the greater the overlap with toxicology.³⁸ An exposure assessment should also look for competing exposures from other sources of the chemical of concern.

Exposure assessment is central to epidemiology as well and is often the limiting factor in using an epidemiological study to infer causation. Many of the causal associations between chemicals and human disease have been developed from epidemiological studies relating a workplace chemical to an increased risk of the specific disease in cohorts of workers, often with only a qualitative assessment of exposure. More sophisticated modern approaches to chemical exposures at complex workplaces include development of a job exposure matrix based on specific exposure levels throughout the working lifetime. An improved quantitative understanding of such exposures enhances the likelihood of observing causal relations.³⁹ It also can support the opinion of the expert toxicologist on the likelihood that a specific exposure was responsible for an adverse outcome.

38. Toxicologists also have indirect means of approaching exposure through symptoms— e.g., for many agents, there is a known threshold for smell and a reasonable range of levels that might cause symptoms. For example, the use of toxicological expertise is appropriate in a situation in which chronic exposure to a volatile hydrocarbon is alleged to have occurred at levels at which acute exposure would be expected to render the individual unconscious. Toxicologists may also contribute knowledge of the extent of individual exposure based upon appropriate assumptions concerning inhalation rate or water use; for example, children inhale more per body mass than do adults, and outdoor workers in hot climates will drink more fluids than those in cool climates. For a discussion of general issues regarding assessment of exposure of toxic substances, see M. Elizabeth Marder & Joseph V. Rodricks, *Reference Guide on Exposure Science and Exposure Assessment*, in this manual.

39. In terms of general causation, accurate exposure assessment is important because a true effect can be missed owing to confounding caused by cohorts that often include workers with little exposure to the putative offending agent, thereby diluting the actual effect. See Peter F. Infante, *Benzene Exposure and Multiple Myeloma: A Detailed Meta-analysis of Benzene Cohort Studies*, 1076 *Annals N.Y. Acad. Scis.* 90 (2006), <https://doi.org/10.1196/annals.1371.081>, for a discussion of this issue in relation to a meta-analysis of the potential causative role of benzene in multiple myeloma. On the other hand, an association between exposure and effect occurring solely by chance is more likely if the effect does not meet the expected standard of being more pronounced in those receiving the highest dose. See Goldstein, *supra* note 35. Setting regulatory standards based on the observed effect in a cohort often requires a risk assessment, which in turn is dependent on understanding the extent of the exposure. This has led to extensive retrospective reconstruction of exposure in key cohorts.

Use of Biomarkers in Toxicology Exposure Assessment

The term biomarker is used to identify the measurement of a chemical or biological molecule present in tissue when such tests are available for the substance at issue, and where the tests have been administered within the time frame when the substance may be present in the body to indicate past and/or current exposure.⁴⁰ There are three different types of biomarkers of relevance in toxicology: a) biomarkers of exposure, b) biomarkers of effect, and c) biomarkers of susceptibility. Biomarkers may be persistent in tissue or may rapidly disappear, depending on the chemicals at issue.

Biomarkers of Exposure

A widely used biomarker of exposure is blood alcohol levels estimated by the Breathalyzer test, frequently used by law enforcement to establish whether an automobile driver is inebriated. The science behind the breathalyzer test has been the subject of many court decisions. In a similar manner, measurements of the concentration of drug(s) in the blood may be used to establish cause of death. However, alcohol and most drugs have relatively short half-lives (the time it takes for 50% of the chemical to disappear from the blood), on the order of a few hours or less, and thus are useful only if the blood (or breath) sample is collected soon after the exposure occurred.

The concentration of lead in the blood and/or bones of an individual is another example of a biomarker of exposure that has been extensively studied. In the case of lead exposure, the half-life in blood is about one month, so repeated exposures in the workplace or environment can result in blood lead concentrations above what is measured in the environment. The half-life of lead in bone is on the order of twenty-five to thirty years, so assessment of lead in bone, performed noninvasively through an X-ray fluorescence technique, provides a window into past exposures to lead over a lifetime. Some other environmentally relevant toxic substances, referred to collectively as persistent organic pollutants or POPs (e.g., polychlorinated biphenyls (PCBs), dioxins, certain organochlorine pesticides like DDT and chlordane, and more recently a group of fluorinated chemicals collectively called per- and polyfluoroalkyl substances, or PFAS⁴¹),

40. See Nat'l Rsch. Council, *Human Biomonitoring for Environmental Chemicals* (2006), <https://perma.cc/9AQ2-QXUQ>; see also Lesa L. Aylward, *Integration of Biomonitoring Data into Risk Assessment*, 9 *Current Op. Toxicology* 14 (2018), <https://doi.org/10.1016/j.cotox.2018.05.001>.

41. Sometimes also referred to in the popular press as “forever chemicals.” For an EPA summary of research on PFAS, see <https://perma.cc/JLV4-54XX>.

have half-lives measured in years, and thus slow accumulation from environmental exposures can occur over many years. For these types of chemicals, blood concentrations are indicative of lifetime exposures—not just recent exposure—and can be useful to establish whether an unusual exposure to a specific agent has occurred in the past.

The Centers for Disease Control and Prevention's (CDC) National Health and Nutrition Examination Survey (NHANES) monitors a broad level of biological markers of health—e.g., blood cholesterol levels—on a U.S. population sample. This survey now includes measurements of a wide variety of environmental and dietary substances. For environmental agents, the CDC considers blood levels above the statistical ninety-fifth percentile level in the NHANES samples as an indication of an “unusual exposure,” although it does not state whether exposures above, or below, the ninety-fifth percentile are necessarily harmful or safe, respectively.⁴² However, other regulatory agencies might use such levels to indicate that an exposure at that level is associated with an unacceptable risk.

Biomarkers of Effect

Research on certain toxic chemicals has established the presence of biological changes indicative of the effects of that specific chemical and, thus, can also provide evidence of exposure, at least within the time period that the biological changes remain within the body. For example, when carbon monoxide enters the bloodstream, it binds to hemoglobin, the molecule responsible for delivering oxygen from the lungs to the rest of the body. Once bound, it prevents oxygen from binding, which results in oxygen deprivation that can be rapidly fatal. For sublethal doses of carbon monoxide, the time to full equilibrium with blood hemoglobin is eight to twelve hours, depending largely on breathing rate. The measurement of the amount of this carboxyhemoglobin in blood is therefore both a biomarker of exposure—reflecting carbon monoxide exposure during the past eight to twelve hours—as well as a biomarker of effect, as it is on the direct pathway to toxicity. Carbon monoxide can also be measured in expired air, in which case it primarily reflects exposure. Another example of a biomarker of exposure and effect is provided by a broad class of insecticides known as organophosphorus chemicals (OPs). As a chemical class, OPs bind to and inhibit an important

42. For more details on the NHANES program, see <https://perma.cc/UY4L-S8TY>. One objective of the NHANES program was to “establish reference ranges that physicians and scientists can use to determine whether a person or group has an unusually high exposure. . . . The 95th percentile is helpful when determining whether levels observed in separate public health investigations or other studies are unusual.” CDC, Fourth National Report on Human Exposure to Environmental Chemicals (Volume Three: Analysis of Pooled Serum Samples for Select Chemicals, NHANES 2005–2016), <https://perma.cc/E28W-X5HL>.

enzyme in nerve function called cholinesterase and can be rapidly lethal. Cholinesterase activity unrelated to its role in the nervous system is also present in red blood cells and in plasma. Measurements of cholinesterase in the blood can thus be an effects-related biomarker of exposure to many OP pesticides. This test is used frequently in the occupational environment and clinically to diagnose OP poisoning. Where available, and when testing is done within the required time frames, such effects-related biomarkers provide information that is directly on the pathway between external exposure and internal effects. Although currently there are only a relatively few chemicals for which specific biomarkers are available, it is predicted that the increasing understanding of molecular effects of toxic substances will lead to more effects-related biomarkers of exposure.

Biomarkers of Susceptibility

Just as biological measurement of environmental exposures is an area of research interest, another area of research interest is DNA analyses to identify individuals who may be more susceptible to exposures, such as genetically determined variability in enzymes responsible for detoxifying chemicals of concern. Given the complexities of environmental and genetic interactions, much discussion in this area remains theoretical.

Toxicological Study Design

Toxicological studies usually involve exposing laboratory animals (in vivo research) or cells or tissues (in vitro research) to chemical or physical agents, monitoring the outcomes (such as cellular abnormalities, tissue damage, organ toxicity, or tumor formation), and comparing the outcomes with those for unexposed control groups. As explained below,⁴³ the extent to which animal and cell experiments accurately predict human responses to chemical exposures is subject to debate. However, because it is generally unethical to experiment on humans by exposing them to known doses of chemical agents, animal toxicological evidence often provides the best scientific information about the risk of disease from a chemical exposure.⁴⁴

43. See section titled “Extrapolation from Animal (In Vivo) and Cell (In Vitro) Research to Humans” below.

44. Clinical drug trials for therapeutic drugs are an example of experimental human exposure, where as a policy matter potential benefit is considered greater than the risk of adverse events. Notably, information from animal research is used to determine risk profiles, prior to human trials. The human trials are highly regulated, and subject to ethical requirements, including informed

In contrast to their exposure to drugs, only rarely are humans exposed to environmental chemicals in a manner that permits a quantitative determination of adverse outcomes.⁴⁵ This area of toxicological study may consist of individual or multiple case reports, or even experimental studies in which individuals or groups of individuals have been exposed to a chemical under circumstances that permit analysis of dose–response relationships, mechanisms of action, or other aspects of toxicology. For example, individuals occupationally or environmentally exposed to PCBs have been studied to determine the routes of absorption, distribution, metabolism, and excretion for this group of industrial chemicals. Human exposure occurs most frequently in occupational settings where workers are often exposed each working day to industrial chemicals. In well-regulated workplaces, there is often information about the exposure levels of specific chemicals of concern to the average worker. However, even under these circumstances, determining the amount (concentration, frequency, and duration) of exposure of an individual worker is more problematic, particularly as it must be done retrospectively in most toxic tort cases. Moreover, human populations are exposed to many other chemicals and risk factors, including those associated with normal aging, making it more difficult to isolate the role of any one chemical in the increased risk of a disease.⁴⁶

Toxicologists use a wide range of experimental techniques, depending in part on their area of specialization. Toxicological research may focus on classes of chemical compounds, such as solvents, metals, and pesticides; body system effects, such as effects on the nervous system (neurotoxicology), the liver (hepatotoxicology), the reproductive system (reproductive toxicology), and the immune system (immunotoxicology); chemical effects on complex disease processes such as cancer (chemical carcinogenesis) and birth defects (developmental toxicology); and effects on physiological processes, including inhalation toxicology, cardiovascular toxicology, and dermal (skin) toxicology. Each of these subdisciplines utilizes both *in vivo* and *in vitro* research.⁴⁷ Of importance to all of these types of toxicological studies is the rapidly growing field of molecular toxicology, which examines how certain chemicals interact with biomolecules within the cell, such as proteins, lipids, and DNA. Molecular toxicology studies provide critical insights into cross-species extrapolation, dose–response, and mode of action that demonstrates the biological plausibility used for causal inference following human exposure.

consent. See, e.g., FDA, Clinical Trials Guidance Documents, <https://www.fda.gov/science-research/clinical-trials-and-human-subject-protection/clinical-trials-guidance-documents>.

45. However, it is from drug studies in which multiple animal species are compared directly with humans that many of the principles of toxicology have been developed.

46. See, e.g., OECD, Considerations for Assessing the Risks of Combined Exposure to Multiple Chemicals (2018), <https://perma.cc/L48K-W79J>.

47. See, e.g., Casarett & Doull's, *supra* note 1.

The insights provided by molecular toxicology are of particular interest to regulatory toxicologists who are exploring whether these insights can form the basis for new, more sensitive screening techniques to determine the risk of new or existing chemicals.⁴⁸

In Vivo Research: Use of Live Animals in Toxicity Testing and Safety Assessment

Animal research in toxicology generally falls under two headings: safety assessment and classic laboratory research, with a continuum between them. As explained in the section titled “Safety and Risk Assessment” above, safety assessment is a relatively formal approach in which a chemical’s potential for toxicity is tested in vivo or in vitro using standardized techniques often prescribed by regulatory agencies, such as the EPA and the FDA.⁴⁹

The roots of toxicology in the science of pharmacology are reflected in an emphasis on understanding the absorption, distribution, metabolism, and excretion of chemicals. Basic toxicological laboratory research also focuses on the mechanisms or modes of action of external chemical and physical agents.⁵⁰ Such research is based on the standard elements of scientific studies, including appropriate experimental design using control groups and statistical evaluation. In general, toxicological research attempts to hold all variables constant except for that of the chemical exposure. Any change in the experimental group not found in the control group is assumed to be caused by the chemical.

Determining Dose–Response Relationships

An important component of toxicological research is dose–response relationships. Thus, most toxicological studies generally test a range of doses of the chemical. Animal experiments are conducted to determine the dose–response relationships of a compound by measuring how response varies with dose,

48. Robert J. Kavlock et al., *Accelerating the Pace of Chemical Risk Assessment*, 31 Chem. Res. Toxicology 287 (2018), <https://doi.org/10.1021/acs.chemrestox.7b00339>.

49. See, e.g., Michael Dorato et al., *The Toxicologic Assessment of Pharmaceutical and Biotechnology Products*, in Hayes’ Principles and Methods of Toxicology 325 (A. Wallace Hayes & Claire L. Kruger eds., 6th ed. 2014), <https://doi.org/10.1201/b17359>.

50. The terms *mechanism of action* and *mode of action* are conceptually similar and are used to describe the specific molecular, biochemical, and cellular changes that are responsible for the observed toxic effects following the administration of a chemical. Although not identical, the two terms have similar meaning. Generally, mode of action is somewhat broader and refers to the generalized sequence of molecular events that lead to toxicity, whereas mechanism of action refers to a specific cellular, biochemical, or molecular target of the substance (e.g., a specific receptor).

including diligently searching for a dose that has no measurable adverse effect. This information is useful in understanding the mechanisms of toxicity and in extrapolating data from animals to humans.⁵¹

Acute Toxicity Testing and the Lethal Dose 50% (LD₅₀)

To determine the dose–response relationship for a compound, a short-term lethal dose 50% (LD₅₀) may be derived experimentally. The LD₅₀ is the dose at which a compound kills 50% of laboratory animals and usually is determined from a single exposure, although the observation may extend for a period of days to weeks. The use of this easily measured endpoint for acute toxicity largely has been replaced, in part because recent advances in toxicology have provided other pertinent endpoints, and in part because of animal welfare concerns that have focused on reduction, refinement, or replacement of the use of animals in laboratory research.⁵² Although determining the LD₅₀ was frequently the primary goal of acute toxicity testing, much additional useful information is obtained, such as the identification of the target organ(s) of effect, overall characterization of the symptoms, and progression of toxicity following single doses. Acute toxicity studies are also necessary to establish the dose range necessary for subsequent repeated-dose (subacute, usually fourteen days; and subchronic, usually ninety days) toxicity studies.

No Observed Adverse Effect Level (NOAEL)

A dose–response study also permits the determination of another important characteristic of the biological action of a chemical—the no observed adverse effect level (NOAEL; Figure 1).⁵³ The NOAEL sometimes is called a threshold, because it is the level above which observed adverse or toxic effects in test

51. See sections titled “Benchmark Dose (BMD),” “Linearized Non-Threshold (LNT) Model and Determination of Cancer Risk,” and “Maximum Tolerated Dose (MTD) and Chronic Toxicity Tests” below.

52. Dale M. Cooper et al., *The Humane Use and Care of Laboratory Animals in Toxicology Research*, in Hayes’ *Principles and Methods of Toxicology* 1023, *supra* note 49.

53. For example, undiluted acid on the skin can cause a horrible burn. As the acid is diluted to lower and lower concentrations, less and less of an effect occurs until there is a concentration sufficiently low (e.g., one drop in a bathtub of water, or a sample with less than the acidity of vinegar) that no effect occurs. This “no observed effect” concentration differs from person to person. For example, a baby’s skin is more sensitive than that of an adult, and skin that is irritated or broken responds to the effects of an acid at a lower concentration. However, the key point is that there is some concentration that is completely harmless to the skin.

animals are believed to occur and below which no toxicity is observed.⁵⁴ Of course, because the NOAEL is dependent on the ability to observe an effect, the level is sometimes lowered after more sophisticated methods for detecting effects are developed. Typically, NOAEL studies involve the administration of the test chemical at varying different doses, daily over a period of ninety days. At least three doses (plus the “zero dose” control) are used, with doses generally spanning a dose range of thirty- to one hundred-fold, with the highest dose causing clear evidence of toxicity, and the lowest dose showing no evidence of toxicity. Typically, rats are used, with at least ten males and ten females for each dose group. The ultimate goal is to establish a dose–response curve, with at least one dose that does not show any evidence of toxicity. In circumstances where the lowest dose tested resulted in an adverse effect, the terminology for that dose is the lowest observed adverse effect level (LOAEL), which may then be used in place of a NOAEL, with additional caveats (e.g., uncertainty factors) if used in risk assessment.

Benchmark Dose (BMD)

For regulatory toxicology, the NOAEL has been replaced by a more statistically robust approach known as the benchmark dose (BMD; Figure 1). The BMD is determined based on dose–response modeling and is defined as the exposure associated with a specified low incidence of risk, generally in the range of 1% to 10%, of a health effect, or the dose associated with a specified measure or change of a biological effect (thus, if the lower range on the BMD is set at a 10% response, it is referred to as a BMD₁₀). To model the BMD, sufficient data must exist, such as at least a statistically or biologically significant dose–related trend in the

54. The significance of the NOAEL was relied on in an action alleging various health issues caused by hazardous levels of wind-borne thallium dust that escaped a military base landfill and entered plaintiff’s living environment. *Myers v. United States*, No. 02cv1349–BEN, 2014 WL 6611398 (S.D. Cal. Nov. 20, 2014), *aff’d*, 673 F. App’x 749 (9th Cir. 2016). The court ruled in favor of defendants, in part from finding persuasive evidence that the low amount of thallium found in soil at the landfill was significantly below the NOAEL. 2014 WL 6611398, at *31. *See also* *Env’t L. Found. v. Beech-Nut Nutrition Corp.*, 235 Cal. App. 4th 307, 311, 317–18 (2015), *as modified on denial of reh’g* (Apr. 16, 2015) (affirming judgment in favor of defendants because it found the trial court did not err in relying on the defendant’s toxicology expert testimony that the average and single-exposure levels of lead in the manufacturer’s baby food does not exceed the NOAEL (i.e., the regulatory safe harbor exposure level)). *But see* *Chiaracane v. Port Auth. Trans-Hudson Corp.*, No. 18-CV-2995, 2020 WL 906268, at *4, *8 (S.D.N.Y. Feb. 25, 2020) (holding that plaintiffs’ expert testimony by a neurotoxicologist on the issue of causation of respiratory symptoms by a cleaning chemical cannot be admitted because, although the expert spoke to NOAEL, the expert did not quantify the plaintiffs’ dose or exposure to the chemical in his analysis).

Figure 1. Classical dose–response relationship showing various terms associated with points of departure for use in risk assessment.

Data reflect hypothetical experiment with twenty animals at each of five dose groups and a control group:

- NOAEL, No Observed Adverse Effect Level (dose; mg/kg-d)
- LOAEL, Lowest Observed Adverse Effect Level (dose; mg/kg-d)
- BMD₁₀, Benchmark Dose at 10% response level (mg/kg-d)
- BMDL₁₀, 95th percentile Lower Confidence Limit on the BMD10 (mg/kg-d)

selected endpoint.⁵⁵ Although the NOAEL and BMD are conceptually similar, the BMD is generally considered to be a more scientifically robust value because it uses all of the dose–response information from a multidose study, rather than just the single dose point that was associated with no observable response. In the regulatory arena, the upper and lower 95% confidence limits on the BMD are often statistically determined. The lower confidence limit, called the BMDL, is often used as the point of departure (POD) for extrapolating to lower doses or determining reference doses (RfD) or acceptable daily intakes (ADIs). If the BMD₁₀ is used, then the lower bounds response is called the BMDL₁₀ (Figure 1). RfDs and ADIs are then determined by dividing the point of departure by uncertainty or safety

55. Courts also recognize the benchmark dose. *See, e.g., Wyman v. U.S. Surgical Corp.*, No. 1:18-cv-00095-JAW, 2020 WL 1932338, at *21 (D. Me. Apr. 21, 2020) (explaining that the EPA bases its estimations of daily exposure levels of methylmercury a human can have without “appreciable risk of deleterious effects during a lifetime” on benchmark doses, which are amounts of methylmercury that are “associated with the threshold for a health effect on sensitive populations according to epidemiological studies”); *Kolakowski v. Sec’y of Health & Hum. Servs.*, No. 99-0625V, 2010 WL 5672753, at *11 (Fed. Cl. Nov. 23, 2010) (explaining that the National Academy of Sciences establishes its risk assessment benchmark dose for mercury “from a percentage of the population with a physical response to the dose”).

factors. Many chemicals have multiple different toxic effects, and the dose–response relationship for each adverse outcome (toxic effect) may be different. Typically, regulatory agencies use the most sensitive toxic effect (the effect associated with the lowest dose or threshold) to establish regulatory values, such as Maximum Contaminant Levels (MCLs) under the Clean Water Act, or National Ambient Air Quality Standards (NAAQS) under the Clean Air Act. Thus, in the absence of robust epidemiological data, the NOAEL or BMDL for the most sensitive toxic effect are frequently used to establish “safe” or “acceptable” levels of exposure, which are obtained by simply dividing the POD (identified as the BMDL₁₀ or NOAEL) by safety or uncertainty factors (SF or UF). In the early days of regulation of food additives and contaminants, NOAELs were established as discussed above, and typically divided by a factor of one hundred to account for: (1) potential species differences, with a default assumption that humans might be tenfold more sensitive than the rat or mouse used to derive the NOAEL, and (2) interindividual variability within the human population, with a default assumption of another factor of ten. Today, regulatory agencies such as the EPA and the FDA often still use these basic assumptions or uncertainty factors but may modify overall uncertainty by adding additional uncertainty factors based on the quality of the study and the target population of concern. For example, the Food Quality Protection Act of 1996⁵⁶ generally requires an additional uncertainty factor (again, usually a factor of ten) if potentially susceptible populations, such as children and pregnant women, are likely to be exposed.

In toxic tort litigation related to a specific effect (i.e., a particular type of birth defect, liver or kidney disease, neurological damage, etc.), experts may argue that the dose of the agent was below the threshold and thus insufficient to have caused or substantially contributed to the disease. An individual plaintiff’s levels of exposure to a toxic substance can sometimes be estimated using exposure science techniques (see *Reference Guide on Exposure Science and Exposure Assessment*) and are usually expressed in units of milligrams (mg) of chemical per kilogram (kg) of body weight, per day. These are the same units used in determining NOAEL and BMDL levels from experimental animal studies, and sometimes from human epidemiology studies where airborne, dietary, or drinking water concentrations have been measured. Comparison of the estimated NOAEL or BMDL to the estimated dose of an individual can provide a useful approximation of whether the estimated exposure is likely to have exceeded a level known to be toxic. The ratio of the human-exposed dose to that of an estimate of a potential “threshold” (e.g., BMDL or NOAEL with appropriate safety factor adjustments) is called the Margin of Exposure (MOE). The larger the MOE, the less likely it is that an individual’s actual exposure could have caused or contributed to the disease. Thus, an MOE greater than 1,000 is unlikely to be sufficient to have caused or

56. See EPA, Summary of the Food Quality Protection Act, <https://perma.cc/5G7J-KYLS>.

substantially contributed to a toxic effect, whereas an MOE that is less than 1.0 might reasonably be anticipated to have caused or contributed to the toxic effect in question. However, there are many assumptions that go into such estimates and comparisons, and each assumption should be justified with data. It is important to note that this approach to estimation of a potential adverse outcome (risk) is generally not used for estimating the probability of cancer risk from chemicals that are thought to cause cancer by damaging DNA—so-called genotoxic carcinogens. The reason for this is that regulatory policies for genotoxic carcinogens have generally assumed that risk is proportionately related to dose and thus there is some risk at any dose, as discussed below.

Linearized Non-Threshold (LNT) Model and Determination of Cancer Risk

Certain genetic mutations, such as those leading to cancer and some inherited disorders, have been widely hypothesized to occur without any threshold. In theory, the cancer-causing mutation to the genetic material of the cell can be produced by any one molecule of certain chemicals. The LNT model led to the development of the one-hit hypothesis of cancer risk, in which each molecule of a cancer-causing chemical has some finite possibility of producing the mutation that leads to cancer. (See Figure 2 for an idealized comparison of an LNT and threshold dose–response.) This risk is very small, because it is unlikely that any one molecule of a potentially cancer-causing agent will reach that one particular spot in a specific cell’s DNA and result in the specific change that then eludes the body’s defenses and leads to a clinical case of cancer. However, the LNT hypothesis holds that the risk is not zero. The same model also can be used to predict the risk of inheritable mutational events. There is also considerable scientific controversy over the origins of the LNT model and whether it is scientifically appropriate to use for risk assessment of chemical carcinogens.⁵⁷

57. For further discussion of the LNT model of carcinogenesis, see James E. Klaunig & Zemin Wang, *Chemical Carcinogenesis*, in Casarett & Doull’s, *supra* note 1, at 329. See also Edward J. Calabrese et al., *Dose Response and Risk Assessment: Evolutionary Foundations*, 309 *Env’t Pollution* 119787 (2022), <https://doi.org/10.1016/j.envpol.2022.119787>; Rebecca A. Clewell et al., *Dose-Dependence of Chemical Carcinogenicity: Biological Mechanisms for Thresholds and Implications for Risk Assessment*, 301 *Chemico-Biological Interactions* 112 (2019), <https://doi.org/10.1016/j.cbi.2019.01.025>. Although the one-hit model may explain the response to some carcinogens, there is accumulating evidence that for most cancers there is in fact a multistage process and that some cancer-causing agents, so-called epigenetic or nongenotoxic agents, act through non-mutational processes. For example, the multistage cancer process may explain the carcinogenicity of benzo[a]pyrene (produced by the combustion of hydrocarbons such as oil) and aflatoxin (a mold toxin that contaminates corn and peanuts). However, non-mutational responses to asbestos, dioxin, and estradiol cause their carcinogenic effects. The appropriate mathematical model to use to depict the dose–response relationship for such carcinogens is still a matter of debate. See John E. Doe et al., *The Codification of Hazard and Its Impact on the Hazard Versus Risk Controversy*, 95 *Archives Toxicology* 3611 (2021), <https://doi.org/10.1007/s00204-021-03145-6>.

Figure 2. Idealized comparison of a linearized non-threshold and threshold dose–response relationship.

Proposals have been made to merge cancer and noncancer risk assessment models. Nat'l Rsch. Council & Comm. on Improving Risk Analysis Approaches Used by the U.S. EPA, *supra* note 20. The controversy over the use of non-threshold carcinogenesis models in regulatory risk assessment is described by J.V. Rodricks, *When Risk Assessment Came to Washington: A Look Back*, 17 Dose Response 1 (2019), <https://doi.org/10.1177/1559325818824934>. Recent efforts to improve risk assessment for non-genotoxic carcinogens, which are generally not thought to follow low dose, linear response, are underway. See Christian Strupp et al., *Increased Cell Proliferation as a Key Event in Chemical Carcinogenesis: Application in an Integrated Approach for the Testing and Assessment of Non-Genotoxic Carcinogenesis*, 24 Int'l J. Molecular Scis. 13246 (2023), <https://doi.org/10.3390/ijms241713246>.

Courts continue to grapple with the non-threshold model. The District of Columbia Court of Appeals noted “‘mounting judicial skepticism’ of no-threshold models. . . .” *N. Am.’s Bldg. Trades Unions v. Occupational Safety & Health Admin.*, 878 F.3d 271, 284 (D.C. Cir. 2017). Nonetheless, the court upheld OSHA’s use of a non-threshold model to determine risk for silicosis and lung cancer from silica exposure as “supported by substantial evidence” and “in line with our precedent.” *Id.* at 283–84. In another case, the District of Massachusetts excluded an expert’s opinion based on a non-threshold model, noting that such an “opinion is inadmissibly unreliable” because “there is no scientific evidence that the linear no-safe threshold analysis is an acceptable scientific technique” to determine specific causation. *Milward v. Acuity Specialty Prods. Grp., Inc.*, 969 F. Supp. 2d 101, 110 (D. Mass. 2013), *aff’d sub nom.* *Milward v. Rust-Oleum Corp.*, 820 F.3d 469, 474–75 (1st Cir. 2016). *But see* *McManaway v. KBR, Inc.*, No. H-10-1044, 2012 WL 13059744, at *11–12 (S.D. Tex. Aug. 22, 2012) (permitting expert to use non-threshold model despite an argument that the “theory . . . is unsupported by relevant case law and in the relevant scientific community” because the Fifth Circuit has “no bright line” rule excluding the model).

Maximum Tolerated Dose (MTD) and Chronic Toxicity Tests

Another type of study uses different doses of a chemical agent to establish over a ninety-day period what is known as the maximum tolerated dose (MTD), the highest dose that does not cause significant overt toxicity. The MTD is important because it enables researchers to calculate the dose of a chemical to which an animal can be exposed without reducing its lifespan, thus permitting the evaluation of the chronic effects of exposure.⁵⁸ These studies are designed to last the lifetime of the species.

Chronic toxicity tests evaluate carcinogenicity or other types of toxic effects. Federal regulatory agencies frequently require carcinogenicity studies on both sexes of two species, usually rats and mice, administered daily over the lifetime (generally two years) of the animals. A pathological evaluation is done on the tissues of animals that died during the study and those that are sacrificed at the conclusion of the study.

The rationale for using the MTD in chronic toxicity tests, such as carcinogenicity bioassays, often is misunderstood. It is preferable to use realistic doses of carcinogens in all animal studies. However, this leads to a loss of statistical power, thereby limiting the ability of the test to detect carcinogens or other toxic compounds. Consider the situation in which a realistic dose of a chemical causes a tumor in one in one hundred laboratory animals. If the lifetime background incidence of tumors in animals without exposure to the chemical is six in one hundred, a toxicological test involving one hundred control animals and one hundred exposed animals who were fed the realistic dose would be expected to reveal six control animals and seven exposed animals with the cancer. This difference is too small to be recognized as statistically significant. However, if the study started with ten times the realistic dose, the researcher would expect to get ten additional cases, for a total of sixteen cases in the exposed group and six cases in the control group, a statistically significant difference that is unlikely to be overlooked.

Unfortunately, even this example does not demonstrate the difficulties of determining risk. Regulators are responding to public concern about cancer by regulating risks often as low as one in 1,000,000—not one in one hundred, as in the example given above. To test risks of one in 1,000,000, a researcher would have to either increase the lifetime dose from ten times to 100,000 times the realistic dose or expand the numbers of animals under study into the millions. However, increases of this magnitude are beyond the world's animal testing capabilities and are also prohibitively expensive. Inevitably, then, animal studies

58. Even the determination of the MTD can be fraught with controversy. See Environmental Science Deskbook § 4:5 (2022) (illustrating problems with making inferences about human toxicity based on MTD established by animal studies).

must trade statistical power for extrapolation from higher doses to lower doses. However, recent research indicates that the MTD used in studies of some chemicals—and perhaps even the lower doses—may overwhelm biologically important protective pathways, thereby causing cellular damage integral to the disease process that would not occur at lower, more realistic doses to which humans may be exposed. Because of these concerns, there has been increasing research interest among toxicologists to redefine the MTD to include assessment of repair response pathways, where data are available, such as DNA repair processes, to ensure that the highest dose used does not overwhelm protective pathways that are operable at lower doses.⁵⁹

Accordingly, proffered toxicological expert opinion on potentially disease-causing chemicals almost always is based on evaluation of the research studies that extrapolate from animal experiments involving doses significantly higher than that to which humans are exposed.⁶⁰ In both regulatory and toxic tort scenarios, such extrapolation is backed up by other types of data, where available, such as epidemiological studies.

In Vitro Research

In vitro research concerns the effects of a chemical on human or animal cells, bacteria, yeast, isolated tissues, or embryos. Thousands of in vitro toxicological tests have been described in the scientific literature. Many tests are for chemicals that cause changes in DNA (mutations) in bacterial or mammalian systems. There are short-term in vitro tests for just about every physiological response and every organ system, such as perfusion tests and DNA studies. Many of these short-term tests have been thoroughly validated, and standardized protocols for conducting such studies are widely available.⁶¹ However, in vitro studies often do not

Pa. 2014); *In re Mirena IUS Levonorgestrel-Related Prods. Liab. Litig. (No. II)*, 341 F. Supp. 3d 213, 294–95 (S.D.N.Y. 2018), *aff'd*, 982 F.3d 113 (2d Cir. 2020); *Davis v. McKesson Corp.*, No. CV-18-1157-PHX-DGC, 2019 WL 3532179, at *17 (D. Ariz. Aug. 2, 2019); *In re Incretin-Based Therapies Prods. Liab. Litig.*, 524 F. Supp. 3d 1007 (S.D. Cal. 2021), *aff'd*, No. 21-55342, 2022 WL 898595 (9th Cir. Mar. 28, 2022).

accurately reflect the complexity of in vivo biological responses to chemicals, and thus can be misleading. A particular challenge with interpreting in vitro studies is how to compare the concentration of the test chemical used in the test tube or petri dish with the actual concentration of the same chemical in target tissues of the individual exposed to the chemical (the in vivo situation). As such, in vitro studies are often “hypothesis generating,” rather than providing definitive scientific proof that a chemical can cause a particular type of toxic response in vivo.

The criteria of reliability for an in vitro test include the following: (1) whether the test has come through a published protocol in which many laboratories used the same in vitro method on a series of unknown compounds prepared by a reputable organization (such as the NIH or the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use [ICH]) to determine if the test consistently and accurately measures toxicity; (2) whether the test has been adopted by a U.S. or international regulatory body; and (3) whether the test is predictive of in vivo outcomes related to the same cell or target organ system.

Understanding the molecular pathways that are responsible for the ability of a chemical to cause a particular toxic effect, such as a specific type of cancer, is of value to a toxicologist charged with assessing the likelihood that a specific chemical caused a specific cancer in an individual. Identification of biological pathways is an important component of specific causation in most toxic tort cases. Thus, in vitro toxicology studies that investigate exactly how it is that a chemical causes its adverse biological effects are relevant to toxic tort litigation and can contribute significant support to a toxicologist’s expert opinions on specific causation.⁶²

New Approach Methodologies (NAMs)

Advances in analyzing the impact of external chemical agents are dependent primarily on advances in biology and in medicine leading to a greater understanding of normal body functions and of the changes observed in disease states. Integrating advances in biological and medical understanding of the cellular, subcellular, and molecular basis for normal function is reflected in the continued incorporation of new multidisciplinary science into toxicology.

62. See, e.g., *In re Johnson & Johnson Talcum Powder Prods. Mktg., Sales Pracs. & Prods. Liab. Litig.*, 509 F. Supp. 3d 116 (D.N.J. 2020) (expert may opine that his in vitro studies show that talc causes cellular inflammation and oxidative stress but may not offer an opinion on a causal link between talc and ovarian cancer); see also *In re Denture Cream Prods. Liab. Litig.*, No. 09-2051-MD, 2015 WL 392021 (S.D. Fla. Jan. 28, 2015) (expert’s failure to explain the relevancy of in vitro studies to humans or to account for factors needed to make a proper extrapolation renders expert’s opinion unreliable); *Hardeman v. Monsanto Co.*, 997 F.3d 941, 963 (9th Cir. 2021) (“[C]ell studies can support more substantial evidence of causation.”).

The driving forces for incorporating these newer advances into the field of toxicology have included the recognition that a large percentage of chemicals in commerce had been inadequately tested for toxicity. The resultant changes in laws in the European Union (REACH), the United States (the Lautenberg Act), and elsewhere have led to development and adoption of new approach methodologies (NAMs) that could replace standard animal toxicology.⁶³ Pressure toward the use of subcellular and computer-based *in silico* methodologies has also come from animal rights proponents. Pharmaceutical companies also have invested in developing *in silico* technology for rapid survey of the potential biological impact of large numbers of chemicals to support their search for therapeutic agents without unanticipated side effects. NAMs have also considered how to more effectively incorporate individual and population exposure data into chemical evaluation.

The NAMs collectively have a distance to go before they can be fully accepted as pertinent to regulatory decisions or to toxic torts. Important issues include understanding whether a gene or a biological pathway that is turned on by a chemical in a test tube or *in silico* will result in a similar response *in vivo*; uncertainties about the implications of the response to human or ecosystem function; the importance of reproducing the wide range of human sensitivity and environmental variability; and the potential difficulty of distinguishing between a pathway to an adverse effect in contrast to a desirable response that counteracts the potential for an adverse effect. Dose–response analysis is also problematic, as it is usually highly uncertain how a concentration of a chemical in a test tube or cell culture flask relates to a blood concentration following an *in vivo* exposure. Comparison of the relative efficacy of these newer methodologies will determine whether they will be incorporated into expert opinions in tort or regulatory law cases.

Extrapolation from Animal (In Vivo) and Cell (In Vitro) Research to Humans

Two types of extrapolation must be considered: from animal data to humans and from higher doses to lower doses.⁶⁴ In qualitative extrapolation, one can usually rely on the fact that a compound causing an effect in one mammalian species will cause it in another species. This is a basic principle of toxicology and pharmacology, when properly qualified by known differences in absorption, metabolism, excretion, and other known biological differences (e.g., differences in

63. Nat'l Rsch. Council, *Toxicity Testing in the 21st Century: A Vision and a Strategy* (2007), <https://doi.org/10.17226/11970>. 64. See EPA, *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation* (2014), <https://perma.cc/JJ2K-SD8C>.

receptor binding affinity) between humans and experimental animals. If a heavy metal, such as mercury, causes kidney toxicity in laboratory animals, it is highly likely to do so at some dose in humans. However, the dose at which mercury causes this effect in laboratory animals is modified by many internal factors, and the dose–response curve may be different from that for humans. Through the study of factors that modify the toxic effects of chemicals, including absorption, distribution, metabolism, and excretion, researchers can improve the ability to extrapolate from laboratory animals to humans and from higher to lower doses.⁶⁵ The mathematical depiction of the process by which an external exposure is absorbed into the bloodstream and then moves through various compartments in the body until it reaches the target organ is often called physiologically based pharmacokinetic or toxicokinetic (PBPK/PBPT) modeling.⁶⁶

Extrapolation from studies in nonmammalian species to humans is much more difficult but can be done if there is sufficient information on similarities in absorption, distribution, metabolism, and excretion. Advances in computational toxicology have increased the ability of toxicologists to make such extrapolations.⁶⁷ Quantitative determinations of human toxicity based on *in vitro* studies usually are not considered appropriate. *In vitro* or *in vivo* animal data for elucidating the mechanisms of toxicity are more persuasive when positive human epidemiological data or human tissue–based toxicological information also exists.

65. For example, benzene undergoes a complex metabolic sequence that results in toxicity to the bone marrow in all species, including humans. Martyn T. Smith, *Advances in Understanding Benzene Health Effects and Susceptibility*, 31 Annual Rev. Public Health 133 (2010), <https://doi.org/10.1146/annurev.publhealth.012809.103646>. The exact metabolites responsible for this bone marrow toxicity are the subject of much interest but remain unknown. Mice are more susceptible to benzene than are rats. If researchers could determine the differences between mice and rats in their metabolism of benzene, they would have a useful clue about which portion of the metabolic scheme is responsible for benzene toxicity to the bone marrow. See, e.g., Angela L. Slitt, *Absorption, Distribution, and Excretion of Toxicants*, in Casarett & Doull’s, *supra* note 1, at 159–92; Andrew Parkinson et al., *Biotransformation of Xenobiotics*, in Casarett & Doull’s, *supra* note 1, at 193–400.

Toxicological Processes and Target Organ Toxicity

The biological, chemical, and physical phenomena that are the basis of life are astounding in their complexity. As a result, human subcellular, cellular, and organ function are both delicately balanced and highly robust. Small changes caused by external chemical and physical agents can have major effects; yet, through the millennia, evolutionary pressures have led to the emergence of safety mechanisms that defend against adverse environmental stresses.

The specialization that is a hallmark of organ development in vertebrates inherently leads to diversity in the underlying processes that are the basis of organ function. Certain chemicals poison virtually all cells by affecting a basic biological process essential to life. For example, cyanide interferes with the conversion of oxygen to energy in a subcellular component known as mitochondria.⁶⁸ Other chemical agents interfere selectively with an organ-specific process. For example, organophosphorus pesticides and chemically related biological warfare agents (i.e., some nerve gases) specifically interfere with the way nerve cells transmit signals—a process that is pertinent primarily to the nervous system. Other chemicals, such as the widely used over-the-counter analgesic acetaminophen, can cause specific damage to the liver if the dose is sufficient to overwhelm the normal protective pathways in the liver.⁶⁹ Table 1 provides arbitrarily selected examples of toxicological endpoints and agents of concern, which are not meant to be inclusive or exhaustive.

Despite this specialization, there are pathological processes common to diseases affecting many different organs. For example, chronic inflammation of the skin leads to fiber formation that is recognized as scarring. Similarly, cirrhosis of the liver can result from fibrogenic processes caused by repetitive inflammation of the liver, such as from the overuse of ethanol, and fibrosis of the lung is a pathological process resulting from exposure to asbestos, silica, and

68. Note that the diffuse toxicity of cyanide also reflects its ability to spread widely in the body. Certain mitochondrial poisons primarily affect the brain and active muscles, including the heart, which are particularly oxygen dependent. Others, unable to penetrate the blood–brain barrier, will primarily affect peripheral muscles including the heart.

69. Acetaminophen (TylenolTM) is among the most widely used analgesic/non-steroidal anti-inflammatory drugs, and is used safely every day by millions of people at normal therapeutic doses (less than five grams per day). However, doses in excess of ten to fifteen grams in a single day deplete an intracellular antioxidant called glutathione (GSH), and the excess dose can cause serious damage to the liver. Acetaminophen overdose is among the leading causes of acute liver failure in the United States. To produce toxicity it must first be metabolized to a reactive form by a specific enzyme that is only present in significant amounts in the liver. This is why acetaminophen is only toxic to the liver.

Table 1. Sample of Selected Toxicological Endpoints and Examples of Agents of Concern in Humans

Organ System	Examples of Endpoints	Examples of Agents of Concern
Skin	allergic contact dermatitis	nickel, poison ivy, cutting oils
	chloracne	dioxins and dioxin-like compounds
	cancer	polycyclic aromatic hydrocarbons
Respiratory Tract	nonspecific irritation (reactive airway disease)	formaldehyde, acrolein, ozone
	asthma	toluene diisocyanate
	chronic obstructive pulmonary disease	cigarette smoke
	fibrosis, pneumoconiosis	silica, mineral dusts, cotton dust, beryllium
	cancer	cigarette smoke, arsenic, asbestos, nickel
Blood and the Immune System	anemia	arsine, lead, methyldopa
	secondary polycythemia	cobalt
	methemoglobinemia	nitrites, aniline dyes, diaminodiophenyl sulfone
	pancytopenia	benzene, radiation, chemotherapeutic agents
	secondary lupus erythematosus	hydralazine
	leukemia	benzene, radiation, chemotherapeutic agents
Liver and Gastro-intestinal Tract	hepatic damage (hepatitis)	acetaminophen, ethanol, carbon tetrachloride, vitamin A
	cancer	aflatoxin, vinyl chloride
Urinary Tract	kidney toxicity	ethylene and diethylene glycols, lead, melamine, aminoglycoside antibiotics
	bladder cancer	aromatic amines, arsenic
Nervous System	nervous system toxicity	cholinesterase inhibitors, mercury, lead, n-hexane, bacterial toxins (botulinum, tetanus), many organochlorine insecticides
	Parkinson's disease/ Parkinson's-like symptoms	manganese, MPTP

Table 1. Continued

Organ System	Examples of Endpoints	Examples of Agents of Concern
Reproductive and Developmental Toxicity	fetal malformations decreased male fertility	thalidomide, ethanol dibromochloropropane (DBCP)
Endocrine System	thyroid toxicity	radioactive iodine, perchlorate
Cardiovascular System	heart toxicity high blood pressure arrhythmias	anthracyclines, cobalt lead plant glycosides (e.g., digitalis)

Note: This table presents only examples of toxicological endpoints and examples of agents of concern in humans and is provided to help illustrate the variety of toxic agents and endpoints. It is not an exhaustive or inclusive list of organs, endpoints, or agents. Absence from this list does not indicate that any specific chemical is not a cause of the target organ toxicity.

other agents.⁷⁰ The potential for endocrine disruption by chemicals, particularly those that persist within the body, has become an increasing concern. Many of these persistent agents belong to families of chemically similar compounds, such as dioxins, PCBs, or per- and polyfluoroalkyl substances (PFAS) that may differ in their effect. Judges may encounter cases in which a wide variety of toxic effects are alleged to have been caused by endocrine-disrupting chemicals. Possible adverse outcomes from endocrine disruption include loss of fertility, birth defects, metabolic diseases that may result from thyroid disruption, and potentially some forms of cancer. While the concept of dose–response is still applicable, there is some evidence that some toxic effects of endocrine-disrupting chemicals may appear at lower doses but not be seen at higher doses, usually because the higher doses produce biological changes that mask the effects at lower doses (so-called “non-monotonic” dose–response relationship). This is an area of considerable controversy in toxicology. Vitamins also provide an example of differing adverse effects at levels above or below the normal range: e.g., too much vitamin A can cause liver disease and too little will cause blindness.

Particularly challenging to standard toxicological approaches are agents that react with different receptors present on the surface or internal components of the cell. These receptors often belong to complex families of related cellular components that are continually interacting with the broad range of hormones produced by our bodies.⁷¹ The intricate dynamic processes of normal endocrine

70. Lung fibrosis is a key pathological finding in a group of diseases known as pneumoconiosis that includes coal miners’ black lung disease, silicosis, asbestosis, and other conditions usually caused by occupational exposures to small airborne particles.

71. As a simplification, agent–receptor interactions often are described as a key in a lock, with the key needing to be able to both fit into the lock and turn the mechanism. An example from the

activity include daily cycles controlled by internal “biological clocks,” and feedback loops that allow cyclic variation, such as in the menstrual cycle or in the variations of hormone and receptor levels that are linked to normal functions such as sleeping and sexual activity. These complex normal up-and-down variations produce conceptual difficulties when attempting to extrapolate the results from model systems to the functioning human.⁷²

The understanding of the relationship between mutation and cancer discussed previously led to some of the first toxicological tests to determine whether an external agent could cause cancer. Such tests have grown in sophistication because of the advances in molecular biology and computational toxicology that have occurred concomitantly with an increased understanding of the variety of potential pathways that lead to mutagenesis.⁷³

Toxicological testing for chemical carcinogens ranges from relatively simple studies to determine whether the substance is capable of producing bacterial mutations to observation of cancer incidence as a result of long-term administration of the substance to laboratory animals. Between these two extremes are a multiplicity of tests that build upon the understanding of the mechanism of cancer causation. In vitro or in vivo tests may focus on the evidence of effects in DNA, such as the presence of adducts of the chemical or its metabolites bound to the DNA molecule or the cross-linking of the DNA molecule to protein. Researchers may look for changes in the nucleus of the cell suggestive of DNA damage that could result in mutagenesis and carcinogenesis, for example, the micronucleus test or the comet assay. Certain mutagens cause an increase in the normal exchange of nuclear material among DNA components during normal cell division, which gives rise to a test known as the sister chromatid exchange.⁷⁴ The direct observation of chromosomes

nervous system is the use in treating a heroin overdose of another opiate that has a much higher affinity for the receptor site but produces little effect once bound. When given to a normal person, this second opiate would have a mild depressant effect, but it can reverse a near fatal overdose of heroin by displacing the heroin from the receptor site. Thus, the directionality of opiate effect depends on the interaction of the components of the mixture. This interaction is even more complex when dealing with estrogenic agents that are naturally occurring as well as made within the body at different levels in response to different external and internal stimuli and at different time intervals.

72. See, e.g., *In re Denture Cream Prods. Liab. Litig.*, No. 09-2051-MD, 2015 WL 392021 (S.D. Fla. Jan. 28, 2015) (expert’s failure to correct for circadian rhythm fluctuations in zinc plasma levels rendered his opinion inadmissible). In another example, the complexity of the interaction of a mixture of dioxins with receptors governing the endocrine system can be contrasted with that of the reaction of carbon monoxide with the hemoglobin oxygen receptor discussed *supra*, note 18. The latter is unidirectional in that any additional carbon monoxide will interfere with oxygen delivery, of which there cannot be too much under normal physiological conditions.

73. See, e.g., James E. Klaunig, *Carcinogenesis*, in *An Introduction to Interdisciplinary Toxicology: From Molecules to Man* 87 (2020), <https://doi.org/10.1016/B978-0-12-813602-7.00008-9>.

74. All of these tests require validation regarding their relevance to predicting human carcinogenesis, as well as to their technical reproducibility. See Klapacz & Gollapudi, *supra* note 61, for a discussion of the wide variety of short-term mutagenesis assays for predicting mutagenic and potentially carcinogenic potential of chemicals.

to look for specific abnormalities, known as cytogenetic analysis, is providing more information about the pathways of carcinogenesis. For cancers such as acute myelogenous leukemia, it has long been recognized that those individuals who present with recognizable chromosomal abnormalities are more likely to have been exposed to a known human chemical leukemogen such as benzene.⁷⁵ These and other tests provide information that can be used in evaluating whether a chemical is a potential human carcinogen.

The recent almost explosive growth in the ability to measure minuscule changes in the complex genome, a process known as next-generation sequencing, is rapidly being applied to a broad range of human diseases. The emphasis thus far has been on the promise of developing new therapies appropriate to personalized medicine, but the same techniques may in the future provide a fingerprint of the interaction of a chemical with DNA. However, there are very few chromosomal abnormalities or specific mutations that are unequivocally linked to a specific chemical or physical carcinogen.⁷⁶

Assessing whether a chemical or physical agent produces human cancer requires careful evaluation. The World Health Organization's IARC and the U.S. National Toxicology Program (NTP) have formal processes to evaluate the weight of evidence that a chemical causes cancer.⁷⁷ Each classifies chemicals on the basis of epidemiological evidence, toxicological findings in laboratory animals, and mechanistic considerations, and then assigns a specific category of carcinogenic potential to the individual chemical or exposure situation (e.g., employment as a painter).⁷⁸ Only a small percentage of the total chemicals in commerce

75. Patrick J. Kerzic & Richard D. Irons, *Distribution of Chromosome Breakpoints in Benzene-Exposed and Unexposed AML Patients*, 55 *Env't Toxicology & Pharmacology* 212 (2017), <https://doi.org/10.1016/j.etap.2017.08.033>.

76. See Luoping Zhang et al., *The Nature of Chromosomal Aberrations Detected in Humans Exposed to Benzene*, 32 *Critical Revs. Toxicology* 1 (2002), <https://doi.org/10.1080/20024091064165>. However, studies on liver cancer patients exposed to the potent dietary carcinogen aflatoxin B1 (AFB) have demonstrated that a specific mutation in codon 249 in the important cancer gene called TP53 is uniquely associated with exposure to AFB. Only liver tumors from patients with a history of AFB exposure showed this specific mutation. S. P. Hussain et al., *TP53 Mutations and Hepatocellular Carcinoma: Insights into the Etiology and Pathogenesis of Liver Cancer*, 26 *Oncogene* 2166 (2007), <https://doi.org/10.1038/sj.onc.1210279>.

77. The U.S. National Toxicology Program issues a congressionally mandated report on carcinogens. *Nat'l Toxicology Prog., 15th Rep. on Carcinogens* (2021), <https://perma.cc/V4DP-3YNZ>. IARC produces its reports through a monograph series that provides detailed description of the agents or processes under consideration as well as the findings of the IARC expert working group. See the IARC website for a list of these monographs, <https://perma.cc/UEP2-5L9A>.

78. IARC uses the following classifications:

- Group 1, The agent (mixture) is carcinogenic to humans;
- Group 2A, The agent (mixture) is probably carcinogenic to humans;
- Group 2B, The agent (mixture) is possibly carcinogenic to humans;
- Group 3, The agent (mixture) is not classifiable as to its carcinogenicity to humans.

are considered to be known human carcinogens, although this must be considered in the context of how many of these chemicals have been rigorously tested (see discussion of REACH and the Lautenberg Act above). In the past, when chemicals were evaluated for carcinogenicity, assignment to the highest category was dependent almost totally on whether epidemiological research had been conducted, although animal data and mechanistic information were also considered. In recent years, with improved understanding of the mechanism of action of chemical carcinogens, there has been increased use of mechanistic data.⁷⁹ For example, higher credence is given to the likelihood that a chemical is a human carcinogen if the metabolite found to be responsible for carcinogenesis in a laboratory animal is also found in the blood or urine of humans exposed to this chemical, or if there is evidence of the same type of DNA damage in humans as there is in laboratory animals in which the agent does cause cancer.⁸⁰

Inherent in putting chemicals into distinct categories when there is a continuum for the strength of the evidence is that some chemicals will be very close to the dividing line between the discrete categories. Inevitably, small differences in the interpretation of the evidence for such chemicals will lead to disagreement regarding categorization.

79. See Daniele S. Wikoff et al., *A Framework for Systematic Evaluation and Quantitative Integration of Mechanistic Data in Assessments of Potential Human Carcinogens*, 167 *Toxicological Scis.* 322 (2019), <https://doi.org/10.1093/toxsci/kfy279>, for a discussion and for specific examples of the use of mechanistic data in evaluating carcinogens. The evolution in the approach to determining cancer causality is evident from reviewing the guidelines used to assemble the weight of evidence for causality by IARC and NTP, two of the organizations that have the lengthiest track record of responsibility for the hazard identification of carcinogens. Both have increased the weight given to mechanistic evidence in characterizing the overall strength of the total evidence used to classify the potential for a chemical or an exposure to be causal. IARC now permits classification in Group 1 when there is less than sufficient evidence in humans but sufficient evidence in animals and “strong evidence in exposed humans that the agent exhibits key characteristics of carcinogens and sufficient evidence of carcinogenicity in experimental animals.” IARC Preamble, *supra* note 60, at 23. The criterion used by NTP for listing a chemical as a known human carcinogen in its biannual Report on Carcinogens is: “There is sufficient evidence of carcinogenicity from studies in humans,* which indicates a causal relationship between exposure to the agent, substance, or mixture, and human cancer.” The asterisk is particularly notable in that it specifies that the evidence need not be solely epidemiological: “*This evidence can include traditional cancer epidemiology studies, data from clinical studies, and/or data derived from the study of tissues or cells from humans exposed to the substance in question, which can be useful for evaluating whether a relevant cancer mechanism is operating in humans.” See *Nat’l Toxicology Prog.*, *supra* note 77, at 6. For a recent discussion on using mechanism/mode of action data in assessment of genotoxic carcinogens, see also Andrea Hartwig et al., *Mode of Action-Based Risk Assessment of Genotoxic Carcinogens*, 94 *Archives Toxicology* 1787 (2020), <https://doi.org/10.1007/s00204-020-02733-2>. The EPA also considers mechanism of action in its regulatory approaches and distinguishes further between mechanism of action and mode of action. See Kathryn Z. Guyton et al., *Improving Prediction of Chemical Carcinogenicity by Considering Multiple Mechanisms and Applying Toxicogenomic Approaches*, 681 *Mutation Resch.* 230, 240 (2009), <https://doi.org/10.1016/j.mrrev.2008.10.001>.

80. An example is the IARC evaluation of formaldehyde that upgraded the categorization from 2A to 1 based on epidemiological data that were strongly supported by the finding of nasal cancer in laboratory animals and by the presence of DNA-protein cross-links in the nasal tissue of the

Demonstrating an Association Between Exposure and Risk of Disease

In toxic tort cases, once an expert in toxicology has been qualified, they are expected to offer an opinion on whether the plaintiff's disease was caused by exposure to a chemical. To do so, the expert relies on the principles of toxicology to provide a scientifically valid methodology for establishing causation and then applies the methodology to the facts of the case.

An opinion on causation should be premised on three preliminary assessments. First, the expert should analyze whether the disease can be related to chemical exposure by a biologically plausible hypothesis. Second, the expert should examine whether the plaintiff was exposed to the chemical in a manner that can lead to absorption into the body. Third, the expert should offer an opinion about whether the dose to which the plaintiff was exposed is sufficient to cause the disease. In complex cases, multiple experts may offer opinions as to specific aspects of disease causation.

The following questions help evaluate the strengths and weaknesses of toxicological evidence.

On What Species of Animals Was the Compound Tested? What Is Known About the Biological Similarities and Differences Between the Test Animals and Humans? How Do These Similarities and Differences Affect the Extrapolation from Animal Data in Assessing the Risk to Humans?

All living organisms share a common biology that leads to marked similarities in the responsiveness of subcellular structures to toxic agents. Among mammals, more than sufficient common organ structure and function readily permit the extrapolation from one species to another in most instances. Comparative information concerning factors that modify the toxic effects of chemicals, including

laboratory animals and of humans inhaling formaldehyde. However, epidemiological evidence associating formaldehyde with human acute myelogenous leukemia was questioned on the basis of the lack of mechanistic evidence, including questions about how such a highly reactive agent could reach the bone marrow following inhalation. See *Formaldehyde, 2-Butoxyethanol and 1-tert-Butoxypropan-2-ol*, in 88 IARC Monographs on the Evaluation of Carcinogenic Risks to Humans (2006).

absorption, distribution, metabolism, and excretion, enhances the expert's ability to extrapolate from laboratory animals to humans.⁸¹

The expert should review similarities and differences between the animal species in which the compound has been tested and humans. This analysis should form the basis of the expert's opinion regarding whether extrapolation from animals to humans is warranted.

In general, an overwhelming similarity is apparent in the biology of all living things, and there is a particularly strong similarity among mammals. Of course, laboratory animals differ from humans in many ways. For example, rats do not have gallbladders. Thus, rat data would not be pertinent to the possibility that a compound produces human gallbladder toxicity.⁸² The life stage at which exposure occurs can also be an important determinant of toxicity. It is generally recognized that the developing embryo and fetus are unusually susceptible to many toxic substances, and thus exposure of a pregnant animal requires special consideration for toxic effects that might occur to the developing offspring. In a similar manner, it is also generally recognized that early life exposure (from infancy through adolescence) is also a period of enhanced susceptibility, and effects not seen in adults may occur. This is especially true for chemicals that affect the nervous system, since the development of the nervous system is not complete until early adulthood. Thus, for example, the effects of lead poisoning in children are manifest mostly through impacts on the central nervous system that lead to impairment of learning and development, whereas adults exposed to the same level of lead have little or no detectable effects on the central nervous system, although at high doses lead can cause effects on the peripheral nervous system in adults (so-called "lead palsy").

Note that, in animal studies, many subjective symptoms are poorly modeled regardless of the age of exposure. Thus, complaints that a chemical has caused nonspecific symptoms, such as nausea, headache, and weakness, for which there may be no objective manifestations in humans, are difficult to test in laboratory animals.

81. See generally *supra* note 3 and references therein.

82. See, e.g., *Hardeman v. Monsanto Co.*, 997 F.3d 941, 963 (9th Cir. 2021) ("Animal studies are relevant evidence of causation where there is a sound basis for extrapolating conclusions from those studies to humans in real-world conditions."). See generally David Spurgeon et al., *Species Sensitivity to Toxic Substances: Evolution, Ecology and Applications*, 8 *Frontiers Env't Sci.* 1 (2020), <https://doi.org/10.3389/fenvs.2020.588380>. Species differences that produce a qualitative difference in response to xenobiotics are well known. Sometimes understanding the mechanism underlying the species difference can allow one to predict whether the effect will occur in humans. Thus, carbaryl, an insecticide commonly used for gypsy moth control, produces fetal abnormalities in dogs but not in hamsters, mice, rats, and monkeys. Dogs lack the specific enzyme involved in metabolizing carbaryl; the other species tested all have this enzyme, as do humans. Therefore, it has been assumed that humans are not at risk for fetal malformations produced by carbaryl.

Another important variable in extrapolating laboratory animal data to humans is that animals used in experimental research are maintained on nutritionally adequate diets and clean, healthy environments that are designed to maintain optimal health. The diets are free of other chemical contaminants, and the rest of their environment is equally pristine. This is in contrast to humans, who may have unhealthy diets and may be exposed to multiple different toxic substances from their diets, workplace, and general environment. This is one of the reasons that regulatory agencies typically use additional safety or uncertainty factors when extrapolating laboratory animal data to humans.

Does Research Show That the Compound Affects a Specific Target Organ? Will Humans Be Affected Similarly?

Some toxic agents affect only specific organs and not others. This organ specificity may be due to particular patterns of absorption, distribution, metabolism, and excretion; the presence of specific receptors; or organ function. For example, organ specificity may reflect the presence in the organ of relatively high levels of an enzyme capable of metabolizing or changing a compound to a toxic form of the compound,⁸³ or it may reflect the relatively low level of an enzyme capable of detoxifying a compound. An example of the former is liver toxicity caused by inhaled carbon tetrachloride, which affects the liver but not the lungs because of extensive metabolism to a toxic metabolite within the liver but relatively little such metabolism in the lung.⁸⁴

Some chemicals, however, may cause nonspecific effects or even multiple effects. Lead is an example of a toxic agent that affects many organ systems, including the blood, the central and peripheral nervous systems, the reproductive system, and the kidneys.

83. Certain chemicals act directly to produce toxicity, whereas others require the formation of a toxic metabolite. For example, the potent rat liver carcinogen, N-nitroso-dimethylamine (NDMA, present at trace levels in a typical diet and in some pharmaceutical preparations), requires metabolic activation in order to bind to DNA and cause mutations that lead to cancer in experimental animals. In humans, there appears to be only one enzyme capable of activating NDMA to its reactive intermediate, and this enzyme (called CYP2E1) is only expressed in the liver, suggesting that liver cancer would be the only kind of cancer expected in humans exposed to NDMA. However, other carcinogenic nitrosamines can be activated by enzymes present in other human tissues, as well as the liver. See Yupeng Li & Stephen S. Hecht, *Metabolic Activation and DNA Interactions of Carcinogenic N-Nitrosamines to Which Humans Are Commonly Exposed*, 23 *Int'l J. Molecular Scis.* 4559 (2022), <https://doi.org/10.3390/ijms23094559>.

84. Brian J. Day et al., *Potentiation of Carbon Tetrachloride-Induced Hepatotoxicity and Pneumotoxicity by Pyridine*, 8 *J. Biochem. Toxicology* 11 (1993), <https://doi.org/10.1002/jbt.2570080104>.

Specificity often reflects the function of individual organs. For example, the thyroid is particularly susceptible to radioactive iodine in atomic fallout because thyroid hormone is unique within the body in that it requires iodine. Through evolution, a very efficient and specific mechanism has developed that concentrates any absorbed iodine preferentially within the thyroid, rendering the thyroid particularly at risk from radioactive iodine. In a test tube, the radiation from radioactive iodine can affect the genetic material obtained from any cell in the body, but in the intact laboratory animal or human, only the thyroid is at risk.

The unfolding of the human genome already is beginning to provide information pertinent to understanding the wide variation in human risk from environmental chemicals. The impact of this understanding on toxic tort causation issues continues to be explored.⁸⁵ Several examples of the importance of genetic variability in response to toxic substances is provided later in the section titled “What is the likelihood that the disease would have occurred without the specific exposure?”

What Is Known About the Chemical Structure of the Compound and Its Relationship to Toxicity?

Understanding the structural aspects of chemical toxicology has led to the use of structure activity relationships (SAR) as a formal method of predicting the potential toxicity of new chemicals. This technique compares the chemical structure of compounds with known toxicity and the chemical structure of compounds with unknown toxicity. Toxicity then is estimated based on the molecular similarities between the two compounds. Although SAR is used

85. Nat'l Rsch. Council, *Applications of Toxicogenomic Technologies to Predictive Toxicology and Risk Assessment* (2007), <https://doi.org/10.17226/12037>. Genomics can also be misinterpreted. An example is the use of white blood cell gene expression to determine whether benzene was a cause of acute myelogenous leukemia (AML) in individual workers. Martyn T. Smith, *Misuse of Genomics in Assigning Causation in Relation to Benzene Exposure*, 14 Int'l J. Occupational & Env't Health 144 (2008), <https://doi.org/10.1179/oeh.2008.14.2.144>, describes why the failure to match a pattern of DNA expression in workers with AML who were previously exposed to benzene is not scientifically defensible as a means to establish the lack of causation, as said to have been done in workers' compensation cases in California. The wide range in the rate of metabolism of chemicals is at least partly under genetic control. A study of Chinese workers exposed to benzene found approximately a doubling of risk in people with high levels of either an enzyme that increased the rate of formation of a toxic metabolite or an enzyme that decreased the rate of detoxification of this metabolite. There was a sevenfold increase in risk for those who had both genetically determined variants. Nathan Rothman et al., *Benzene Poisoning, A Risk Factor for Hematological Malignancy, Is Associated with the NQO1 609C→T Mutation and Rapid Fractional Excretion of Chlorzoxazone*, 57 Cancer Rsch. 2839 (1997), <https://perma.cc/4BDM-JXNZ>. See also Lucio G. Costa & David L. Eaton, *Gene Environment Interactions: Fundamentals of Ecogenetics* (2006).

extensively by the EPA in evaluating many new chemicals required to be tested under the registration requirements of the TSCA, its reliability has a number of limitations.⁸⁶

Has the Compound Been the Subject of In Vitro Research, and If So, Can the Findings Be Related to What Occurs In Vivo?

Cellular and tissue culture research can be particularly helpful in identifying mechanisms of toxic action and potential target organ toxicity. The major barrier to the use of in vitro results is the frequent inability to relate doses that cause cellular toxicity to doses that cause whole-animal toxicity. In many critical areas, knowledge that permits such quantitative extrapolation is lacking.⁸⁷ Nevertheless, the ability to quickly test new products through in vitro tests, using

86. For example, benzene and the alkyl benzenes (which include toluene, xylene, and ethyl benzene) share a similar chemical structure. SAR works exceptionally well in predicting the acute central nervous system anesthetic-like effects of both benzene and the alkyl benzenes. Although there are slight differences in dose–response relationships, they are readily explained by the inter-related factors of chemical structure, vapor pressure, and lipid solubility (the brain is highly lipid). Nat’l Rsch. Council, *The Alkyl Benzenes* (1981). However, only benzene produces damage to the bone marrow and leukemia; the alkyl benzenes do not have this effect. This difference is the result of specific toxic metabolic products of benzene in comparison with the alkyl benzenes. Thus, SAR is predictive of neurotoxic effects but not bone marrow effects. See David A. Eastmond et al., *Lymphohematopoietic Cancers Induced by Chemicals and Other Agents and Their Implications for Risk Evaluation: An Overview*, 761 *Mutation Rsch.* 40 (2014), <https://doi.org/10.1016/j.mrrev.2014.04.001>. Advances in computational approaches also show promise in improving SAR. See Nat’l Rsch. Council, *supra* note 63. For an example of how gains in computational sciences and “artificial intelligence” (e.g., “Deep Learning”) are being applied to improve SAR analysis for predicting chemical toxicity, see Gabriel Idakwo et al., *Deep Learning-Based Structure-Activity Relationship Modeling for Multi-Category Toxicity Classification: A Case Study of 10K Tox21 Chemicals With High-Throughput Cell-Based Androgen Receptor Bioassay Data*, 10 *Frontiers Physiology* 2044 (2019), <https://doi.org/10.3389/fphys.2019.01044>. In *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579 (1993), the Court rejected a per se exclusion of SAR, animal data, and reanalysis of previously published epidemiological data where there were negative epidemiological data. Most cases involving SAR expert opinion involve patent litigation or analogous drugs under the Controlled Substance Analogue Enforcement Act. See, e.g., *Takeda Pharm. Co. v. Torrent Pharms. Ltd.*, No. 17-3186 (SRC)(CLW), 2020 WL 549594, at *26 (D.N.J. Feb. 4, 2020), *aff’d*, 844 F. App’x 339 (Fed. Cir. 2021); *United States v. Cooper*, No. 3:14-cr-014-J-20MCR, 2015 WL 13850123, at *6, *9 (M.D. Fla. Jan. 14, 2015).

87. See, e.g., *In re Denture Cream Prods. Liab. Litig.*, No. 09-2051-MD, 2015 WL 392021 (S.D. Fla. Jan. 28, 2015) (expert failed to explain relevancy of in vitro studies to humans or account for factors needed to make a proper extrapolation).

human cells, provides invaluable “early warning systems” for toxicity.⁸⁸ For example, screening of new chemicals with a simple bacterial mutagenicity assay such as the Ames test will identify if the new chemical is likely to be mutagenic, and thus carcinogenic. The pharmaceutical industry routinely evaluates new chemicals for mutagenic/carcinogenic potential, and generally will not spend large amounts of time and money in further development if the candidate drug is identified through such simple tests as likely to be mutagenic and thus carcinogenic.

Is the Association Between Exposure and Disease Biologically Plausible?

No matter how strong the temporal relationship between exposure and the development of disease, or the supporting epidemiological evidence, it is difficult to accept an association between a compound and a health effect when no plausible mechanism can be identified by which the chemical or physical exposure leads to the putative effect.⁸⁹

Specific Causal Association Between an Individual’s Exposure and Onset of Disease

An expert who opines that exposure to a compound caused a person’s disease engages in deductive clinical reasoning.⁹⁰ In most instances, cancers and other diseases do not wear labels documenting their causation. The opinion is based on an assessment of the individual’s exposure, including the amount, the temporal relationship between the exposure and disease, and other disease-causing factors. This information is then compared with scientific data on the relationship

88. Despite its limitations, in vitro research can strengthen inferences drawn from whole-animal bioassays and can support opinions regarding whether the association between exposure and disease is biologically plausible. See Klapacz & Gollapudi, *supra* note 61; Rogers, *supra* note 61.

89. See, e.g., *Sarkees v. E.I. DuPont de Nemours & Co.*, No. 17-CV-651, 2020 WL 906331 (W.D.N.Y. Feb. 25, 2020) (expert reviewed animal studies, in vitro studies, and human studies and the inferential steps utilized by researchers to propose a likely mechanism for toxic effects in humans).

90. For an example of deductive clinical reasoning based on known facts about the toxic effects of a chemical and the individual’s pattern of exposure, see Bernard D. Goldstein, *Is Exposure to Benzene a Cause of Human Multiple Myeloma?*, 609 *Annals N.Y. Acad. Scis.* 225 (1990), <https://doi.org/10.1111/j.1749-6632.1990.tb32070.x>.

between exposure and disease. The certainty of the expert's opinion depends on the strength of the research data demonstrating a relationship between exposure and the disease at the dose in question and the presence or absence of other disease-causing factors (also known as confounding factors).⁹¹

Particularly problematic are generalizations made in personal injury litigation from regulatory positions. Regulatory standards are set for purposes far different than determining the preponderance of evidence in a toxic tort case. Further, if regulatory standards are discussed in toxic tort cases to provide a reference point for assessing exposure levels, it must be recognized that there is a great deal of variability in the extent of evidence required to support different regulations.⁹² The extent of evidence required to support regulations depends on

1. the law (e.g., the Clean Air Act National Ambient Air Quality Standard provisions have language focusing regulatory activity for primary pollutants on adverse health consequences to sensitive populations with an adequate margin of safety and with no consideration of economic consequences, while regulatory activity under the TSCA and its revision, the Lautenberg Act, clearly asks for some balance between the societal benefits and risks of new chemicals⁹³);
2. the specific endpoint of concern (e.g., consider the concern caused by cancer and adverse reproductive outcomes versus almost anything else); and

91. Causation issues are discussed in Steve C. Gold et al., *Reference Guide on Epidemiology*, section titled "General Causation and Specific Causation," and John B. Wong et al., *Reference Guide on Medical Testimony*, section titled "Medical Decision-Making," both in this manual. For a detailed analysis of the challenges of assessing epidemiological and toxicological data to establish causal relationships between exposure and disease, see Nat'l Acads. Scis., Eng'g, & Med., *Advancing the Framework for Assessing Causality of Health and Welfare Effects to Inform National Ambient Air Quality Standard Reviews* (2022).

92. See, e.g., *Kirk v. Schaeffler Grp. USA, Inc.*, 887 F.3d 376, 392 (8th Cir. 2018) (noting that regulatory standards are "designed to protect public health," not to be a measure of causation, and that regulatory agencies may set standards "without having precise data on the question of how much harm, or what kind of harm, some specific amount of . . . substance might reasonably be expected to cause" (quoting *Wright v. Willamette Indus., Inc.*, 91 F.3d 1105, 1107 (8th Cir. 1996)); *Williams v. Mosaic Fertilizer, LLC*, 889 F.3d 1239, 1247 (11th Cir. 2018) (stating that regulatory standards are designed to be protective whereas "dose-response calculations aim to identify the exposure levels that actually cause harm").

93. *Cnty. Voice v. U.S. Env't Prot. Agency*, 997 F.3d 983, 990–91 (9th Cir. 2021) (citing *Whitman v. Am. Trucking Ass'ns*, 531 U.S. 457, 467–68 (2001)) (explaining TSCA's consideration of "non-health factors such as achievability and cost" and the opposite for the Clean Air Act, which the Supreme Court has held "does not" permit "the EPA to consider costs in setting clean air standards"). See also *Nat'l Res. Defense Council v. U.S. Env't Prot. Agency*, 38 F.4th 34 (9th Cir. 2022) (challenge to the EPA's conclusions on human health risks and cost-benefit analysis for glyphosate under FIFRA, based on the EPA's failure to follow its Cancer Guidelines, resulting in court vacating human health portion of the EPA's Interim Decision and remanding).

3. the societal impact (e.g., the public's support for control of an industry that causes air pollution versus the public's relative lack of desire to alter personal automobile use patterns).

These three concerns, as well as others, including costs, politics, and the virtual certainty of litigation challenging the regulation, have an impact on the level of scientific proof required by the regulatory decision-maker.⁹⁴

In addition, regulatory standards traditionally include protective factors to reasonably ensure that susceptible individuals are not put at significant risk. Furthermore, standards often are based on the risk that results from lifetime exposure. Accordingly, the mere fact that an individual has been exposed to a level above a standard does not necessarily mean that an adverse effect has occurred or will occur.

Was the Plaintiff Exposed to the Substance, and If So, Did the Exposure Occur in a Manner That Can Result in Absorption into the Body?

Evidence of exposure is essential in determining the effects of harmful substances.⁹⁵ Basically, potential human exposure is measured in one of three ways. First, when direct measurements cannot be made, exposure can be measured by

94. These concerns are discussed in Stephen Breyer, *Breaking the Vicious Circle: Toward Effective Risk Regulation* (1993).

95. “[S]cientific knowledge of the harmful level of exposure to a chemical” is a ‘minimal fact’ necessary for establishing causation.” *Cooper v. Meritor, Inc.*, No. 4:16-CV-52-DMB-JMV, 2019 WL 545271, at *5 (N.D. Miss. Feb. 11, 2019) (quoting *Allen v. Pa. Eng’g Corp.*, 102 F.3d 194, 199 (5th Cir. 1996)). In toxic tort cases, the plaintiff bears the burden of demonstrating the level of exposure. *Zellers v. NexTech Ne. LLC*, 895 F. Supp. 2d 734, 741 (E.D. Va. 2012) (citing *Westberry v. Gislaved Gummi AB*, 178 F.3d 257, 260 (4th Cir. 1999)). The court in *Zellers* discussed cases from the Fourth, Fifth, and Seventh Circuit U.S. Courts of Appeal where expert opinions were or were not found to be reliable, noting that where “substantial exposure” is established by the expert, “more detailed quantitative data about [the plaintiff’s] level of exposure” may not be necessary. 895 F. Supp. 2d at 739 (citing *Westberry*, 178 F.3d at 264). On the other hand, where there is “no direct evidence of the plaintiff’s level of exposure to the chemical at issue,” the expert’s opinion may be excluded as unreliable. *Zellers*, 895 F. Supp. 2d at 740 (citing *Allen*, 102 F.3d at 199). Likewise, where the expert did not review medical records, perform any tests or calculations, or seek to learn any specifics about the environment in which the alleged exposure took place, the expert’s opinion as to causation based on exposure level was excluded as being “not based on sufficient information about the level of the plaintiff’s exposure to the alleged toxin.” 895 F. Supp. 2d at 740 (citing *Wintz v. Northrop Corp.*, 110 F.3d 508, 510–13 (7th Cir. 1997)). In *Zellers*, the expert opinions were ultimately excluded because the experts “did not consider the extent of Plaintiffs’ exposure,” rendering their opinions “speculative at best.” 895 F. Supp. 2d at 741, *aff’d sub nom.* *Zellers v. NexTech Ne., LLC*, 533 F. App’x 192, 198 (4th Cir. 2013). For a discussion of general issues

mathematical modeling, in which one uses a variety of physical factors to estimate the transport of the pollutant from the source to the individual. For example, mathematical models take into account such factors as wind variations to allow calculation of the transport of radioactive iodine from a federal atomic research facility to nearby residential areas. Second, exposure can be directly measured in the medium in question—air, water, food, or soil. When the medium of exposure is water, soil, or air, hydrologists or meteorologists may be called upon to contribute their expertise to measuring exposure. The third approach directly measures human individuals through some form of biological monitoring, such as blood tests to determine blood lead levels or urinalyses to check for a urinary metabolite indicative of pollutant exposure. Ideally, both environmental testing and biological monitoring are performed; however, this is not always possible, particularly in instances of past exposure (unless the chemical(s) had very long half-lives (e.g., greater than three or four years), in which case blood levels may be useful to demonstrate significant exposures that occurred many years earlier).⁹⁶

The toxicologist must go beyond understanding exposure to determine if the individual was exposed to the compound in a manner that can result in absorption into the body. The absorption of the compound is a function of its physiochemical properties, its concentration, and the presence of other agents or conditions that assist or interfere with its uptake. For example, inhaled lead is absorbed almost totally, whereas ingested lead is taken up only partially into the body. Of toxicological relevance is the finding that children absorb ingested lead substantially more efficiently than adults, which may contribute to the enhanced susceptibility of children to the neurotoxic effects of lead.⁹⁷ Iron deficiency and low nutritional calcium intake, both common conditions of children living in impoverished urban environments, increase the amount of ingested lead that is absorbed in the gastrointestinal tract and passes into the bloodstream.⁹⁸

regarding assessment of exposure of toxic substances see M. Elizabeth Marder & Joseph V. Rodricks, *Reference Guide on Exposure Science and Exposure Assessment*, in this manual.

96. See sections titled “Toxicology and the Law” and “Use of Biomarkers in Toxicology Exposure Assessment” above.

97. Alan R. Abelsohn & Margaret Sanborn, *Lead and Children: Clinical Management for Family Physicians*, 56 Canadian Fam. Physician 531 (2010), <https://perma.cc/M6S4-P2L7>.

98. The term *bioavailability* is used to describe the extent to which a compound, such as lead, is taken up into the body. In essence, bioavailability is at the interface between exposure and absorption into the organism. See, e.g., *In re Denture Cream Prods. Liab. Litig.*, No. 09-2051-MD, 2015 WL 392021 (S.D. Fla. Jan. 28, 2015) (expert’s analysis of in vitro studies failed to demonstrate bioavailability of zinc in denture cream); *Ridings v. Maurice*, No. 15-00020-CV-W-JTM, 2019 WL 13159921, at *4 (W.D. Mo. Aug. 12, 2019) (permitting expert to testify regarding bioavailability of drug alleged to have caused, at least in part, the plaintiff’s injuries). Under certain circumstances bioavailability is not a necessary condition to establish general causation, however. *Adkisson v. Jacobs Eng’g Grp., Inc.*, 342 F. Supp. 3d 791, 805–07 (E.D. Tenn. 2018) (“Biological plausibility and bioavailability are important scientific concepts. But it does not appear that either is strictly

Were Other Factors Present That Can Affect the Distribution of the Compound Within the Body?

Once a compound is absorbed into the body through the skin, lungs, or gastrointestinal tract, it is distributed throughout the body via the bloodstream. Thus, the rate of distribution depends on the rate of blood flow to various organs and tissues. Distribution and resulting toxicity also are influenced by other factors, including the dose, the route of entry, tissue solubility, lymphatic supplies to the organ, metabolism, and the presence of specific receptors or uptake mechanisms within body tissues.

What Is Known About How Metabolism in the Human Body Alters the Toxic Effects of the Compound?

Metabolism is the alteration of a chemical by bodily processes. It does not necessarily result in less toxic compounds being formed. In fact, many of the organic chemicals that are known human cancer-causing agents require metabolic transformation before they can cause cancer. A distinction often is made between direct-acting agents, which cause toxicity without any metabolic conversion, and indirect-acting agents, which require metabolic activation before they can produce adverse effects. Metabolism is complex, because a variety of pathways compete for the same agent; some produce harmless metabolites, and others produce toxic agents.⁹⁹

What Excretory Route Does the Compound Take, and How Does This Affect Its Toxicity?

Excretory routes are urine, feces, sweat, saliva, expired air, and lactation. Many inhaled volatile agents are eliminated primarily by exhalation. Small water-soluble compounds are usually excreted through urine. Higher-molecular-weight

necessary for an association between a particular toxic agent and a particular disease to be considered causal. Accordingly, neither is required to establish proof of general causation.”).

99. Courts have explored the relationship between metabolic transformation and carcinogenesis. See, e.g., *In re E.I. Du Pont De Nemours & Co. C-8 Personal Inj. Litig.*, No. 2:13-md-2433, 2016 WL 3064124, at *4 (S.D. Ohio May 30, 2016) (“For example, one pound of a toxic, cancer-causing chemical that biopersist in humans for decades and bioaccumulates in the environment for millennia may cause more harm than 100 pounds of a toxic, cancer-causing chemical that metabolizes and/or degrades quickly.”).

compounds are often excreted through the biliary tract into the feces. Certain fat-soluble, poorly metabolized compounds, such as PCBs, may persist in the body for decades, although they can be excreted in the milk fat of lactating women, with potential effects in their infants.

Does the Temporal Relationship Between Exposure and the Onset of Disease Support or Contradict Causation?

In acute toxicity, there is usually a short time period between cause and effect. However, in some situations, the length of basic biological processes necessitates a longer period of time between initial exposure and the onset of observable disease. For example, in AML (acute myelogenous leukemia), the adult form of acute leukemia, at least one to two years must elapse from initial exposure to radiation, benzene, or cancer chemotherapy before the manifestation of a clinically recognizable case of leukemia, and the period of significantly higher risk from the last exposure usually persists for no more than about fifteen years. A toxic tort claim alleging a shorter or longer time period between cause and effect is scientifically highly debatable. Much longer latency periods are necessary for the manifestation of solid tumors caused by agents such as asbestos and arsenic.¹⁰⁰

100. The temporal relationship between exposure and causation is discussed in many cases. See, e.g., *Johnson v. Arkema, Inc.*, 685 F.3d 452, 466–67 (5th Cir. 2012) (quoting *Curtis v. M&S Petroleum, Inc.*, 174 F.3d 661, 670 (5th Cir. 1999)) (“[T]emporal connection standing alone is entitled to little weight in determining causation[.]” but may be “entitled to greater weight when there is an established scientific connection between exposure and illness or other circumstantial evidence supporting the causal link.”) (internal citations omitted); *In re Paulsboro Derailment Cases*, 746 F. App’x 94, 99 (3d Cir. 2018) (citing *Kannankeril v. Terminix Int’l, Inc.*, 128 F.3d 802, 808–09 (3d Cir. 1997)) (noting that an expert may only rely on a temporal relationship analysis if the expert uses that relationship within the greater methodology of a differential diagnosis); *C.W. ex rel. Wood v. Textron, Inc.*, 807 F.3d 827, 838 (7th Cir. 2015) (quoting *Ervin v. Johnson & Johnson*, 492 F.3d 901, 904–05 (7th Cir. 2007)) (rejecting expert methodology relying on the relationship between the time of exposure and the onset of injury, explaining that “[t]he mere existence of a temporal relationship between taking a medication and the onset of symptoms does not show a sufficient causal relationship”); *Arias v. DynCorp*, 928 F. Supp. 2d 10, 8 (D.D.C. 2013), *aff’d*, 752 F.3d 1011 (D.C. Cir. 2014) (discussing the relationship between temporal evidence and specific causation); *Leake v. United States*, 843 F. Supp. 2d 554, 561–62 (E.D. Pa. 2011) (noting that “even a strong temporal relationship between exposure and injury, in and of itself,” may not be “sufficient to establish a reliable general causation opinion”).

When Exposure to the Substance Is Associated with the Disease, Is There a Benchmark Dose or No Observed Adverse Effect Level, and If So, Was the Individual Exposed Above This Level?

As discussed in the section titled “In Vivo Research: Use of Live Animals in Toxicity Testing and Safety Assessment” above, for agents that produce effects other than through mutations, it is assumed that there is some level below which no toxic effects will occur—the so-called threshold. Many chemicals may have multiple different toxic effects, and the dose–response relationship for each adverse outcome (toxic effect) may be different. Typically, regulatory agencies use the most sensitive toxic effect (the effect associated with the lowest dose, or threshold). In toxic tort litigation related to a specific effect (e.g., a particular type of birth defect, liver or kidney disease, etc.), experts may argue that the dose of the agent was below the threshold and thus insufficient to have caused or substantially contributed to the disease. If the level of exposure was below this level, a relationship between the exposure and disease cannot be established.¹⁰¹ When only laboratory animal data are available, the expert extrapolates the BMD, NOAEL, or other metric of a threshold level based on available experimental data. Occasionally, the lowest dose used has an observable effect, and thus no NOAEL can be established. In those circumstances, the lowest dose used is called the Lowest Observed Adverse Effect Level (LOAEL). As discussed in the section noted above, in regulatory toxicology, if using a NOAEL value to estimate a threshold dose, the expert decreases this level by one or more safety factors (usually a factor of ten for each one) to ensure no human effect.¹⁰² As discussed in the section titled “Benchmark Dose (BMD),” if using a BMD, the lower statistical confidence level (usually tenth percentile) of the BMD (called

101. See, e.g., *Wyman v. U.S. Surgical Corp.*, No. 1:18-cv-00095-JAW, 2020 WL 1932338, at *21 (D. Me. Apr. 21, 2020) (In the context of mercury, benchmark dose is “the amount . . . associated with the threshold for a health effect on sensitive populations according to epidemiological studies.”); *Kolakowski v. Sec’y of Health & Hum. Servs.*, No. 99-0625V, 2010 WL 5672753, at *11 (Fed. Cl. Nov. 23, 2010) (Benchmark dose “is a dose at which some statistical interval, measured from a percentage of the population with a physical response to the dose.”); *In re Valsartan, Losartan, and Irbesartan Prods. Liab. Litig.*, No. 2022 WL 807343, at *2 (D.N.J. Mar. 17, 2022) (permitting an expert to testify using benchmark-dose methodology, acknowledging that while “this is not the methodology used by many scientists,” it “is nonetheless used by some in the relevant scientific community”).

102. See, e.g., *supra* note 54 & accompanying text; Robert G. Tardiff & Joseph V. Rodricks, *Toxic Substances and Human Risk: Principles of Data Interpretation* 391 (1987); Joseph V. Rodricks, *Calculated Risks* 230–39 (2d ed. 2006). For regulatory toxicology, NOAEL is being replaced by a more statistically robust approach known as the benchmark dose. See *supra* note 55 & accompanying text. For example, the EPA’s use of the benchmark dose takes into account comprehensive dose–response information, unlike NOAEL.

the BMDLow, or BMDL, or BMDL₁₀) can also be calculated from animal data or from human toxicity data if they exist. The estimation of a threshold dose using either NOAEL or BMD data, however, is generally not applied to substances that exert toxicity by causing DNA damage and mutations that may lead to cancer. Theoretically, any exposure at all to mutagens may increase the risk of cancer, although the risk may be very small and not achieve statistical significance.¹⁰³

Although the concept of the non-threshold response is generally used only for genotoxic carcinogens or other outcomes associated with gene mutations (e.g., development of some types of birth defects), it is sometimes claimed that other toxic responses, such as the effects of lead on children's IQ, also follow a linear response at low doses. However, it is biologically likely that there are thresholds for such responses, but if the threshold is below background levels of exposure (such as may be the case with lead), the dose–response would appear to be linear since a threshold dose could not be established and background exposures exceed the putative threshold level.

What Is the Likelihood That the Disease Would Have Occurred Without the Specific Exposure?

In coming to an expert opinion as to whether the exposure to a known cause of a disease is likely to be responsible for the case observed in the plaintiff, the expert must consider other potential causes of the same disease. Some may be

103. See sources cited *supra* notes 57 and 65. See also *Myers v. United States*, No. 02cv1349–BEN, 2014 WL 6611398, at *39 (S.D. Cal. Nov. 20, 2014) (explaining that although thallium may be harmful at certain levels, “[s]ince we are exposed to thallium on a daily basis, there must be a level that does not cause adverse health effects”). U.S. regulatory approaches aimed at protecting the general population tend to avoid setting a standard for a known human carcinogen, because any allowable level below the standard is at least theoretically capable of causing cancer. However, exposure to many chemical carcinogens, including benzene and arsenic, cannot be eliminated. Thus, agencies and Congress have developed a number of ingenious means to regulate carcinogens while not seeming to acquiesce in exposure of the general population to a carcinogen. These include the FDA's approach to de minimis risk and the EPA's setting of a zero maximum contaminant level goal for carcinogens in drinking water while setting a maximum contaminant level above zero that is set as closely as possible to the MCLG, taking technology and cost data into account. In contrast, occupational standards, which also take into account feasibility, permit exposure to known human carcinogens. A generally outmoded approach for environmental or indoor air guidelines has been to divide the permissible OSHA standard by a factor accounting for the presumed lifetime exposure to the environmental chemical compared with forty-five years at a forty-hour workweek. Plaintiff's experts in a toxic court case must rely on more than exposure levels established by regulatory agencies, as those levels “often build in considerable cushion to account for the most sensitive members of the population.” *Williams v. Mosaic Fertilizer, LLC*, 889 F.3d 1239, 1246–47 (11th Cir. 2018) (affirming exclusion of expert opinion for, inter alia, relying on regulatory standards of exposure levels).

due to other known causal factors, such as lung cancer in a uranium miner who is also a cigarette smoker. In addition, with rare exceptions, almost all diseases have some anticipated background causes that appear related to human biology, particularly aging. An additional challenge comes in unraveling the contribution of a specific substance when exposure may have been to multiple agents. There are numerous examples where the effect of two combined exposures to two substances both known to cause the same disease is greater than the sum of the individual effects (synergism). The example above of lung cancer in uranium miners who also smoke is a good illustration. Another example of such synergism is the incidence of liver cancer in people who are exposed to the dietary contaminant aflatoxin B1, and also are infected with hepatitis B virus. Both are known causes of liver cancer (relative risk for hepatitis B virus antigen positivity is approximately tenfold; relative risk for aflatoxin B1 alone is approximately threefold) but the presence of both risk factors increased the risk of developing liver cancer by approximately sixty times.¹⁰⁴

Not surprisingly, cancer has received the most attention in research aimed at disentangling external and internal causes. For some cancers, such as lung cancer, smoking is an obvious predominant external cause, and the extent to which other known causes contribute to overall lung cancer incidence also can be estimated. But these known external causes do not currently account for all cases of lung cancer. For other cancers, such as pancreatic cancers, it has been very difficult to find any external cause. There are, however, a few instances in which the exposure to a specific chemical is nearly uniquely associated with a particular (usually rare) type of cancer. For example, the industrial chemical vinyl chloride, widely used in the synthesis of certain plastics, is associated with a rare form of cancer of the blood vessels in the liver (angiosarcoma).¹⁰⁵ Likewise, certain types of mesothelioma (a cancer of the lining of the chest cavity or stomach/intestine) are associated with prior exposure to asbestos, especially among smokers, suggesting a synergistic interaction between smoking and asbestos exposure.¹⁰⁶

That mutations in the DNA of stem cells of virtually every tissue accumulate with age is now generally recognized. Upwards of thousands of mutations

104. John D. Groopman et al., *Aflatoxin and Hepatitis B Virus Biomarkers: a Paradigm for Complex Environmental Exposures and Cancer Risk*, 1 *Cancer Biomarkers* 5 (2005), <https://doi.org/10.3233/cbm-2005-1103>. See also Joshua Jin et al., *Synergism in Actions of HBV with Aflatoxin in Cancer Development*, 499 *Toxicology* 153652 (2023), <https://doi.org/10.1016/j.tox.2023.153652>.

105. The relative risk (RR) of angiosarcoma of the liver was ninety-seven in one of the first occupational cohort studies to demonstrate the association between occupational exposure to vinyl chloride and this very rare form of liver cancer. There is also suggestive evidence that vinyl chloride can contribute to the more common form of liver cancer (hepatocellular carcinoma), although the relative risks are much lower. See Ugo Fedeli et al., *Occupational Exposure to Vinyl Chloride and Liver Diseases*, 25 *World J. Gastroenterology* 4885 (2019), <https://doi.org/10.3748/wjg.v25.i33.4885>.

106. Sonja Klebe et al., *Asbestos, Smoking and Lung Cancer: An Update*, 17 *Int'l J. Env't Rsch. & Pub. Health* 258 (2019), <https://doi.org/10.3390/ijerph17010258>.

per cell are not uncommon in the cells of the elderly. Certain of these mutations, often called driver mutations, are more commonly associated with cancer.

A major cause for the accumulation of mutations as we age is related to the frequency of mistakes made in copying DNA. These reflect the fallibility of normal cell DNA replication as well as the increasing failure with age of DNA repair enzymes to successfully carry out appropriate copy editing of the replicated DNA.

There is increasing evidence that many cancers are associated with heritable genetic differences among individuals. For example, women who inherit one mutated copy of the so-called “breast cancer genes,” *BRCA1* and *BRCA2*, are at substantially greater risk of developing breast cancer when compared to women who have the common (“wild type”) genetic form.¹⁰⁷ The study of gene–environment interactions is of growing importance in the field of toxicology as well as medicine, as there is now substantial evidence that many diseases result from a combination of certain genetic variants and exposure to specific chemicals.¹⁰⁸ For many cancers, genetic variants that decrease the efficiency and accuracy of DNA repair are widely recognized as “susceptibility genes.” The evidence suggests that individuals with genetic deficiency in a DNA repair gene are likely to be more susceptible to the mutagenic effects of chemicals that cause the specific type of mutation repaired by the deficient DNA repair gene.

Estimates of what percent of individual cancer types are due to external versus internal factors are beginning to appear and can be expected to improve with advances in stem cell biology. (Unfortunately, cancers due to intrinsic factors, such as the failure of DNA repair, have been described as “bad luck” to distinguish them from cancers due to external factors.) This information will likely become increasingly important in considering the differential causation of individual cancer types.¹⁰⁹ It is likely that the introduction of potential genetic

107. Women who have mutated copies of BRCA genes have a lifetime risk of developing breast cancer of 45–75%, compared with a “background” lifetime risk of ~10–15%. About 5–10% of all breast cancers can be attributed to genetic risk. See Zora Baretta et al., *Effect of BRCA Germ-line Mutations on Breast Cancer Prognosis: A Systematic Review and Meta-Analysis*, 95 *Medicine* e4975 (2016), <https://doi.org/10.1097/MD.00000000000004975>.

108. See Nat’l Inst. Env’t Health Scis., *Gene and Environment Interaction*, <https://perma.cc/X5HB-39TV>, for a general discussion of how genes and the environment can interact to produce certain diseases.

109. A readily understandable account of the chemistry and biological implications of DNA repair is in the Popular Science Background piece accompanying the award of the 2015 Nobel Prize for Chemistry, DNA Repair—Providing Chemical Stability for Life, <https://perma.cc/S9VL-9KRH>. See also *McManaway v. KBR, Inc.*, No. H-10-1044, 2012 WL 13059744 (S.D. Tex. Aug. 22, 2012) (expert failed to take into account whether alleged genetic transformation injuries caused by sodium dichromate were repaired, rendering his opinion on persistence of these injuries unreliable). A brief overview of the literature on the extent of estimated external and internal causes in different human cancer types is in Bernard D. Goldstein & Varun Patel, *Controversy About the “Bad Luck” Cancer Hypothesis Could Lead to a Useful Tool for Planning Primary Prevention Cancer*

susceptibility factors to environmental/occupational exposures to certain chemicals will become more common in toxic tort litigation, potentially used by plaintiff and defense lawyers alike to address the likelihood of a causal association between an exposure and a disease.

A relatively new and important area of genetic research, called epigenetics, has identified that there can be heritable changes (passed on from one generation to the next) in the functions of DNA that are not associated with a change in the DNA sequence (i.e., not the result of a mutation). Epigenetics (literally translated as “above genetics”) describes how the expression of DNA is regulated by several different biological processes.¹¹⁰ Importantly, there are a growing number of examples where chemicals found in the diet, workplace, and general environment can cause epigenetic changes that may contribute to a wide variety of adverse effects, including many types of cancers, diabetes and metabolic syndrome, neurological and cognitive dysfunction, as well as alterations in the functions of important organs such as the lung, the heart, the immune system, and reproductive organs. Indeed, a search of the scientific literature today shows over 127,000 scientific papers published in the general field of epigenetics. Although much of this scientific literature is focused on the normal (endogenous) functioning of epigenetic phenomena in chronic disease processes, there is growing recognition that many environmental and dietary factors can alter epigenetic processes, including some heavy metals, certain pesticides, some chemicals used in plastics, diesel exhaust, tobacco

Research, 32 Chem. Rsch. Toxicology, 949 (2019), <https://doi.org/10.1021/acs.chemrestox.8b00390>. For a discussion of methodologies for ruling out idiopathic (unknown) causes of a disease, see *Hardeman v. Monsanto Co.*, 997 F.3d 941, 953 (9th Cir. 2021) (quoting *Wendell v. GlaxoSmithKline LLC*, 858 F.3d 1227, 1233–34 (9th Cir. 2017)) (ruling out idiopathy for disease with 70% idiopathy rate where expert relied on clinical experience, literature, and medical records).

110. For example, many of the nucleotide bases that are strung together to make up DNA can have methyl ($-\text{CH}_3$) groups attached to them in specific positions by enzymes known as DNA methyl transferases. DNA methylation functions somewhat like a switch, providing critical information on when a gene is “turned on” or “turned off.” In a similar manner, certain enzymes can modify proteins called chromatin that are intimately associated with DNA and help to regulate when specific genes are turned on or off (gene expression). One group of these chromatin proteins, called histones, can be modified by attaching, or detaching, acetyl groups on the histone proteins (histone acetylases and histone deacetylases), which then modulate whether the gene is expressed or not. This epigenetic process is known as histone modification (histone acetylation or deacetylation). Several other biological processes that also modify the expression of genes via epigenetic processes include protein phosphorylation, ubiquitination, and sumoylation of chromatin proteins. Similar to histone acetylation, adding these different chemical entities to proteins that are involved in regulation of DNA function can modify how genes are expressed, without changing the actual sequence of the DNA, and thus are referred to as epigenetic effects. Other forms of RNA called short non-coding RNA and microRNAs have been found to be important epigenetic regulators of expression of DNA. See Lian Zhang et al., *Epigenetics in Health and Disease*, in *Epigenetics in Allergy and Autoimmunity* (Christopher Chang & Qianjun Lu eds., 2020), https://doi.org/10.1007/978-981-15-3449-2_1.

smoke, polycyclic aromatic hydrocarbons, hormones, radioactivity, viruses and bacteria, to name a few.¹¹¹

As the role of epigenetic factors in cancer and in other diseases unfolds, these might also be grist for the mill of both plaintiff and defense lawyers.

Medical History

Is the Medical History of the Individual Consistent with the Toxicologist's Expert Opinion Concerning the Injury?

One of the basic and most useful tools in diagnosis and treatment of disease is the patient's medical history.¹¹² A thorough, standardized patient information questionnaire would be particularly useful for identifying the etiology, or causation, of illnesses related to toxic exposures; however, there is currently no validated or widely used questionnaire that gathers all pertinent information.¹¹³ Nevertheless, it is broadly recognized that a thorough medical history involves the questioning and examination of the patient as well as appropriate medical testing. The patient's written medical records also should be examined.

The following information is relevant to a patient's medical history: past and present occupational and environmental history and exposure to toxic agents; lifestyle characteristics (e.g., use of nicotine and alcohol); family medical history (i.e., medical conditions and diseases of relatives); and personal medical history (i.e., present symptoms and results of medical tests as well as past injuries, medical conditions, diseases, surgical procedures, and medical test results).

111. See Bob Weinhold, *Epigenetics: The Science of Change*, 114 *Env't Health Perspectives* A160 (2006), <https://doi.org/10.1289/ehp.114-a160>; Giacomo Cavalli & Edith Heard, *Advances in Epigenetics Link Genetics to the Environment and Disease*, 571 *Nature* 489 (2019), <https://doi.org/10.1038/s41586-019-1411-0>.

112. For a thorough discussion of the methods of clinical diagnosis, see John B. Wong et al., *Reference Guide on Medical Testimony*, in this manual. A number of cases have considered the admissibility of the treating physician's opinion based, in part, on medical history, symptomatology, and laboratory and pathology studies. See, e.g., *Morrow v. Brenntag Mid-South, Inc.*, 505 F. Supp. 3d 1287, 1290 (M.D. Fla. 2020) (declining to find expert testimony reliable where the expert, a physician, had not reviewed any "prior medical history or treatment records"); cf. *Galvez v. KLLM Transp. Servs., LLC*, 575 F. Supp. 3d 748, 760–61 (N.D. Tex. 2021) (finding expert testimony reliable where causation opinion was supported by a review of the patient's medical history, part of "the well-established 'scientific method' of diagnosis in the medical community").

113. Office of Tech. Assessment, U.S. Congress, *Reproductive Health Hazards in the Workplace* 8 (1985), at 365–89.

In some instances, the reporting of symptoms in itself can be diagnostic of exposure to a specific substance, particularly in evaluating acute effects.¹¹⁴ For example, individuals acutely exposed to organophosphorus pesticides report headaches, nausea, and dizziness accompanied by anxiety and restlessness. Other reported symptoms are muscle twitching, weakness, and hypersecretion with sweating, salivation, and tearing.¹¹⁵

Are the Complaints Specific or Nonspecific?

Acute exposure to many toxic agents produces a constellation of nonspecific symptoms, such as headaches, nausea, lightheadedness, and fatigue. These types of symptoms are part of human experience and can be triggered by a host of medical and psychological conditions. They are almost impossible to quantify or document beyond the patient's report. Thus, these symptoms can be attributed mistakenly to an exposure to a toxic agent or discounted as unimportant, when in fact they reflect a significant exposure.¹¹⁶

114. See *McManaway v. KBR, Inc.*, No. H-10-1044, 2012 WL 13059744, at *6 (S.D. Tex. Aug. 22, 2012) (expert review of medical records and in-person interviews, including review of acute symptoms, supports a finding of reliability); *Coene v. 3M Co.*, No. 10-CV-6546-FPG, 2017 WL 1046749, at *3, *9 (W.D.N.Y. Mar. 20, 2017) (finding toxicologist's opinion regarding causation of silicosis to be reliable when the opinion was based on a review of the plaintiff's medical records as well as conversations with the plaintiff, the MSDS sheets for the chemicals the plaintiff worked with that allegedly caused the injury, and technical literature); *Ledbetter v. Blair Corp.*, No. 3:09-CV-843-WKW, 2012 WL 2464000 (M.D. Ala. June 27, 2012) (finding medical toxicologist's opinion as to impairment caused by certain prescription drugs to be reliable when it was based, in part, on a review of medical and prescription records). *Contra* *Gilbert v. Lands' End Inc.*, No. 19-cv-823-jdp, 2022 WL 2643514, at *12-13 (W.D. Wis. July 8, 2022) (in a case alleging injury from required work uniforms, finding expert's opinion unreliable when it was based only on a review of partial medical records and when the expert did not talk to the plaintiffs, "attempt to link any particular plaintiffs' symptom to any particular garment," or "rule out other potential causes").

115. EPA, *Recognition and Management of Pesticide Poisonings* 45 (6th ed. 2013), <https://perma.cc/Z4UL-9NCQ>.

116. Complex issues of exposure to oil and dispersants, chemicals, fumes, and odors and reported adverse health effects are addressed in a medical settlement establishing a Periodic Medical Consultation Program and a Specified Physical Conditions Matrix as discussed in *In re Oil Spill by Oil Rig Deepwater Horizon*, 295 F.R.D. 112 (E.D. La. 2013) (medical class certified for settlement purposes only). An example of a disease that may be caused by exposure to toxins but may present only with nonspecific symptoms is Legionnaires' Disease, explored at length in *Mueller v. Chugach Federal Solutions, Inc.*, No. 12-S-00624-NE, 2014 WL 2891030 (N.D. Ala. June 25, 2014). There, the decedent's wife alleged that her husband had been exposed to *Legionella pneumophila* at his workplace. *Id.* at *1. The court noted that the "disease may present early in the illness with non-specific symptoms, so it can be difficult to diagnose." *Id.* at *20. Indeed, the decedent in *Mueller* had been hospitalized for pneumonia and treated for the same prior to finally being diagnosed with Legionnaires' Disease after a urine antigen test. *Id.* at *4. In opining that that decedent's illness was

In taking a careful medical history, the expert focuses on the time pattern of symptoms and disease manifestations in relation to any exposure and on the constellation of symptoms to determine causation. It is easier to establish causation when symptoms or a specific diagnosis are unusual and rarely caused by anything other than the suspect chemical (e.g., blue lips and shortness of breath caused by dyes that produce methemoglobinemia) or rare cancers such as hemangiosarcoma, associated with vinyl chloride exposure, and mesothelioma, associated with asbestos exposure. However, many cancers and other conditions are associated with several extrinsic or intrinsic causative factors, complicating proof of causation.¹¹⁷

Do Laboratory Tests Indicate Exposure to the Compound?

Two types of laboratory tests can be considered: tests that are routinely used in medicine to detect changes in normal body status, and specialized tests, which are used to directly or indirectly detect the presence of the chemical or physical agent.¹¹⁸ For the most part, tests used to demonstrate the presence of a toxic agent are frequently unavailable from clinical laboratories. Even when available from a hospital or a clinical laboratory, a test such as that for carbon monoxide bonded to hemoglobin (carboxyhemoglobin) is done so rarely that there may be concerns regarding its accuracy. Other tests, such as the test for blood lead levels, are required for routine surveillance of potentially exposed workers.¹¹⁹

caused by exposure in the workplace, the expert was permitted to base his opinions on various materials produced during litigation, his own experience, and the fact that other employees also exhibited symptoms consistent with Legionnaires' Disease. *Id.* at *6.

117. Failure to rule out other potential causes of symptoms may lead to a ruling that the expert's report is inadmissible. *See, e.g.,* *Hardeman v. Monsanto Co.*, 997 F.3d 941, 953, 965 (9th Cir. 2021) (expert's specific causation opinion was admissible where hepatitis C was ruled out as a cause of plaintiff's non-Hodgkins lymphoma based on research studies and a temporal analysis of exposures and active disease); *Pluck v. BP Oil Pipeline Co.*, 640 F.3d 671, 678–81 (6th Cir. 2011) (affirming district court's conclusion that expert's opinion was unreliable when the expert failed to rule out alternative causes of the plaintiff's non-Hodgkins lymphoma); *Scott v. Dyno Nobel, Inc.*, No. 4:16-CV-1440 HEA, 2021 WL 1750238, at *10–11 (E.D. Mo. May 4, 2021) (finding expert opinion reliable when it ruled out other possible causes of symptoms and noting that another expert's opinion was found inadmissible for failure to do the same).

118. *See, e.g.,* *Myers v. United States*, No. 02cv1349–BEN, 2014 WL 6611398, at *35–38 (S.D. Cal. Nov. 20, 2014) (explaining at length the necessity of reliable laboratory testing and reasons why tests may be found unreliable).

119. However, if a laboratory is certified for the testing of blood lead levels in workers, for which the OSHA action level is 40 micrograms per deciliter (µg/dl), it does not necessarily mean that it will give reliable data on blood lead levels at the much lower CDC Reference Level of 3.5

What Other Causes Could Lead to the Given Complaint?

With few exceptions, acute and chronic diseases, including cancer, can be caused by either a single toxic agent or a combination of agents or conditions. In taking a careful medical history, the expert examines the possibility of competing causes, or confounding factors, for any disease, which leads to a differential diagnosis. In addition, ascribing causality to a specific source of a chemical requires that a history be taken concerning other sources of the same chemical. The failure of a physician to elicit such a history or of a toxicologist to pay attention to such a history raises questions about competence and leaves open the possibility of competing causes of the disease.¹²⁰

Is There Evidence of Interaction with Other Chemicals?

An individual's simultaneous exposure to more than one chemical may result in a response that differs from that which would be expected from exposure to only one of the chemicals.¹²¹ When the effect of multiple agents is that which would be predicted by the sum of the effects of individual agents, it is called an additive effect; when it is greater than this sum, it is known as a synergistic effect; when one agent causes a decrease in the effect produced by another, the result is termed antagonism; and when an agent that by itself produces no effect leads to an

µg/dl (defined as the blood level used “to identify children with blood lead levels that are higher than most children’s levels,” CDC, *Blood Lead Levels in Children*, <https://perma.cc/XY53-3A7K>).

120. See, e.g., *McManaway v. KBR, Inc.*, No. H-10-1044, 2012 WL 13059744 (S.D. Tex. Aug. 12, 2012) (expert conducted a differential diagnosis for each plaintiff, in which he ruled out other causes for their injuries, and also conducted blood testing to assist with differential diagnoses regarding sodium dichromate exposure); *In re E.I. du Pont de Nemours & Co. C-8 Personal Inj. Litig.*, 348 F. Supp. 3d 680, 696 (S.D. Ohio 2016) (differential diagnosis is an “appropriate method for making a determination of causation for an individual instance of disease”) (citing *Hardyman v. Norfolk & W. Ry. Co.*, 243 F.3d 255, 260 (6th Cir. 2001)); see also *Milward v. Rust-Oleum Corp.*, 820 F.3d 469, 476 (1st Cir. 2016) (affirming exclusion of expert testimony as unreliable for failure to rule out an idiopathic diagnosis); *Kovach v. Wheeling & Lake Erie Ry. Co.*, 556 F. Supp. 3d 762, 771 (N.D. Ohio 2021) (quoting *Best v. Lowe’s Home Ctrs., Inc.*, 563 F.3d 171, 181 (6th Cir. 2009)) (noting that “doctors need not rule out every conceivable cause for their differential-diagnosis-based opinions to be admissible[.]” but they must at least consider and rule out alternative causes).

121. See generally Angelo Moretto et al., *A Framework for Cumulative Risk Assessment in the 21st Century*, 47 *Critical Revs. Toxicology* 85 (2017), <https://doi.org/10.1080/10408444.2016.1211618>; Devon C. Payne-Sturges et al., *Methods for Evaluating the Combined Effects of Chemical and Nonchemical Exposures for Cumulative Environmental Health Risk Assessment*, 15 *Int’l J. Env’t Rsch. & Pub. Health* 2797 (2018), <https://doi.org/10.3390/ijerph15122797>.

enhancement of the effect of another agent, the response is termed potentiation.¹²² These interactions can often be explained if the metabolic pathways of the agent or the toxicological mechanism by which the individual agents cause their effects are known.

Three types of toxicological approaches are pertinent to understanding the effects of mixtures of agents. One is based on the standard toxicological evaluation of common commercial mixtures, such as gasoline. The second approach is from studies in which the known toxicological effect of one agent is used to explore the mechanism of action of another agent, such as using a known specific inhibitor of a metabolic pathway to determine whether the toxicity of a second agent depends on this pathway. The third approach is based on an understanding of the basic mechanism of action of the individual components of the mixture, thereby allowing prediction of the combined effect, which can then be tested in an animal model.¹²³

The toxicologist may also need to consider whether the mixture contains agents whose effects would allow estimation of exposure to a putative causative agent that was also part of the mixture. For example, the upper boundary for exposure to benzene present at a level of 0.1% in commercial grade toluene can be based on the level of toluene that causes central nervous system effects, including coma. A worker's daily exposure of 1 part per million (ppm) benzene to this mixture would have imposed a concomitant exposure of approximately 1,000 ppm toluene—incompatible with the National Institute for Occupational Safety and Health (NIOSH) rating of Immediately Dangerous to Life and Health level for toluene of 500 ppm for fifteen minutes. Conversely, in a situation in which the worker did become woozy or comatose following exposure to a toluene-containing mixture, the toxicologist could use information about the level of toluene that caused such symptoms as a means to estimate the extent to which there was exposure to benzene or another contaminant of concern.

122. Courts have been called on to consider the issue of synergy. See *Russell v. U.S. Dep't of Labor*, No. 3:15-CV-320-DCP, 2018 WL 2054566, at *8–9 (E.D. Tenn. May 2, 2018) (finding that the Department of Labor properly considered synergistic effects of four substances in arriving at its conclusion that plaintiff's chronic obstructive pulmonary disease was not caused by exposure to the substances "individually or in combination"); but see *In re E.I. Du Pont De Nemours & Co. C-8 Personal Inj. Litig.*, 337 F. Supp. 3d 728, 747 (S.D. Ohio 2015) (noting that the expert's opinion on synergistic action between C-8 and obesity was "mere speculation" and, in this context, "synergism as a theory is unreliable and inadmissible under *Daubert* and Rule 702").

123. See generally Moretto et al., *supra* note 121; Payne-Sturges et al., *supra* note 121. The EPA has been addressing the issue of multiple exposures to different agents within a community under the heading of cumulative risk assessment. This approach is particularly of importance in dealing with environmental justice concerns. See Michael A. Callahan & Ken Sexton, *If Cumulative Risk Assessment Is the Answer, What Is the Question?*, 115 *Env't Health Persps.* 799 (2007), <https://doi.org/10.1289/ehp.9330>.

Do Humans Differ in the Extent of Susceptibility to the Particular Compound in Question? Are These Differences Relevant in This Case?

Individuals who exercise inhale more than sedentary individuals and therefore are exposed to higher doses of airborne environmental toxicants. Similarly, differences in metabolism, which are inherited or caused by external factors, such as the levels of carbohydrates in a person's diet, may result in differences in the delivery of a toxic product to the target organ.¹²⁴

Moreover, for any given level of a toxic agent that reaches a target organ, damage may be greater because of a greater response of that organ. In addition, for any given level of target-organ damage, there may be a greater impact on particular individuals. For example, an elderly individual or someone with pre-existing lung disease is less likely to tolerate a small decline in lung function caused by an air pollutant than is a healthy individual with normal lung function.

Advances in human genetics research and interactions between genetics and environmental factors are providing information about susceptibility that may be relevant to determining the likelihood that a given exposure has a specific effect on an individual.¹²⁵

Nongenetic factors may also alter the metabolism of a carcinogen. For example, an increased risk of certain cancers has been associated with obesity.¹²⁶ Obesity also can alter the metabolism of chemicals, for example through the increased levels of cytochrome P450 2E1 found in humans and laboratory animals with fatty livers.¹²⁷ A person's level of physical activity, age, sex, and genetic makeup, as well as exposure to therapeutic agents (such as prescription or over-the-counter drugs), may affect the metabolism of the compound and hence its toxicity, making the individual more susceptible to the toxic effects of a chemical exposure.

124. See generally Moretto et al., *supra* note 121; Payne-Sturges et al., *supra* note 121; see also Marissa B. Kosnik & David M. Reif, *Determination of Chemical-Disease Risk Values to Prioritize Connections Between Environmental Factors, Genetic Variants, and Human Diseases*, 379 *Toxicology & Applied Pharmacology* 114674 (2019), <https://doi.org/10.1016/j.taap.2019.114674>.

125. See, e.g., Supratim Choudhuri et al., *From Classical Toxicology to Tox21: Some Critical Conceptual and Technological Advances in the Molecular Understanding of the Toxic Response Beginning from the Last Quarter of the 20th Century*, 161 *Toxicological Scis.* 5 (2018), <https://doi.org/10.1093/toxsci/kfx186>.

126. See, e.g., Sarkees v. E.I. DuPont de Nemours & Co., 15 F.4th 584, 592–93 (2d Cir. 2021) (expert identified numerous factors that can elevate risk of bladder cancer and then sufficiently ruled them out, thereby establishing differential etiology); see also Cooper v. Smith & Nephew, Inc., 259 F.3d 194, 202 (4th Cir. 2001).

127. See, e.g., Mohamed A. Abdelmegeed et al., *Role of CYP2E1 in Mitochondrial Dysfunction and Hepatic Injury by Alcohol and Non-Alcoholic Substances*, 10 *Current Molecular Pharmacology* 207 (2017), <https://doi.org/10.2174/1874467208666150817111114>.

Has the Expert Considered Data That Contradict Their Opinion?

Multiple avenues of deductive reasoning based on scientific data lead to acceptance of causation in any field, particularly in toxicology. However, the basis for this deductive reasoning is also one of the most difficult aspects of causation to describe quantitatively. If animal studies, pharmacological research on mechanisms of toxicity, in vitro tissue studies, and epidemiological research all document toxic effects of exposure to a compound, an expert's opinion about causation in a particular case is much more likely to be true.¹²⁸

The more difficult problem is how to evaluate conflicting research results. When different research studies reach different conclusions regarding toxicity, the expert must be asked to explain how those results have been taken into account in the formulation of the expert's opinion.

Expert Qualifications

The basis of the toxicologist's expert opinion in a specific case is a thorough review of the research literature and treatises concerning effects of exposure to the chemical at issue. To arrive at an opinion, the expert assesses the strengths and weaknesses of the research studies. The expert also bases an opinion on fundamental concepts of toxicology relevant to understanding the actions of chemicals in biological systems.

As the following series of questions indicates, no single academic degree, research specialty, or career path qualifies an individual as an expert in

128. See, e.g., *Waite v. All Acquisition Corp.*, 194 F. Supp. 3d 1298, 1313, 1315 (S.D. Fla., 2016) (holding that the weight-of-evidence approach used by the expert was “thoroughly reasoned and based on sound methodology” and explaining that the approach “requires consideration of all available scientific evidence, including epidemiology, toxicology (animal studies), cellular studies (in vitro), and molecular biology”); *In re Flint Water Cases*, No. 17-10164, 2021 WL 5631706, at *7–8 (E.D. Mich. Dec. 1, 2021) (finding expert's opinion on general causation reliable where the opinion was based on “reasonable scientific inferences” from “the great weight of the evidence” and where the expert “cite[d] to peer-reviewed, epidemiological studies which account for confounding variables”); *In re Abilify (Aripiprazole) Prods. Liab. Litig.*, 299 F. Supp. 3d 1291, 1311 (N.D. Fla. 2018) (explaining that the “‘weight of the evidence’ approach to analyzing causation can be considered reliable, provided the expert considers all available evidence carefully and explains how the relative weight of the various pieces of evidence led to his conclusion . . . , it is crucial that the expert describe each step in the process by which he gathered and assessed the scientific evidence”). But see *Daniels-Feasel v. Forest Pharms., Inc.*, No. 17 CV 4188-LTS-JLC, 2021 WL 4037820, at *5 (S.D.N.Y. Sept. 3, 2021), *aff'd*, No. 22-146, 2023 WL 4837521 (2d Cir. July 28, 2023) (quoting *In re Abilify*, 299 F. Supp. 3d at 1311) (expert's opinion that relies on cherry-picked data is not reliable). See generally Liesa L. Richter & Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual.

toxicology. Toxicology is a heterogeneous field. A number of indicia of expertise can be explored, however, that are relevant to both the admissibility and weight of the proffered expert opinion.

Does the Proposed Expert Have an Advanced Degree in Toxicology, Pharmacology, or a Related Field? If the Expert Is a Physician, Are They Board Certified in Toxicology or in a Field Such as Occupational Medicine?

A graduate degree in toxicology demonstrates that the proposed expert has a substantial background in the basic issues and tenets of toxicology. Many universities have established graduate programs in toxicology. These programs are administered by the faculties of medicine, pharmacology, pharmacy, or public health.

In addition to toxicologists with a specific Ph.D. in toxicology, many highly qualified toxicologists are physicians or hold doctoral degrees in related disciplines (e.g., veterinary medicine, pharmacology, biochemistry, environmental health, or industrial hygiene). For a person with this type of background, a single course in toxicology is unlikely to provide sufficient background for developing expertise in the field. Additional specific training and board certification in toxicology is highly relevant to evaluating the credentials of a toxicologist.

A proposed expert should be able to demonstrate an understanding of the discipline of toxicology, including statistics, toxicological research methods, and disease processes. A physician without particular training or experience in toxicology is unlikely to have sufficient background to evaluate the strengths and weaknesses of toxicological research. Most practicing physicians have little knowledge of environmental and occupational medicine.¹²⁹ Subspecialty physicians may have particular knowledge of a cause-and-effect relationship (e.g., pulmonary physicians have knowledge of the relationship between asbestos exposure and asbestosis); anesthesiology is largely focused on the effects of certain chemicals; and certified addiction medicine physicians focus on chemical agents that are not pharmaceuticals or are illegally used pharmaceuticals, such as

129. For recent documentation of how rarely an occupational history is obtained, see Barry J. Politi et al., *Occupational Medical History Taking: How Are Today's Physicians Doing? A Cross-Sectional Investigation of the Frequency of Occupational History Taking by Physicians in a Major U.S. Teaching Center*, 46 J. Occupational Env't Med. 550 (2004), <https://doi.org/10.1097/01.jom.0000128153.79025.e4>.

fentanyl.¹³⁰ Physicians who receive additional training in classic toxicology include those who are certified by the American Board of Preventive Medicine in medical toxicology, addiction medicine, or occupational and environmental medicine.¹³¹ Knowledge of toxicology is particularly strong among occupational health specialists who work in the chemical, petrochemical, and pharmaceutical industries, in which the surveillance of workers exposed to chemicals is a major responsibility.¹³²

130. Courts look at specific circumstances in determining whether a treating physician may testify as a fact witness or an expert witness. *See, e.g.,* *Mueller v. Chugach Fed. Solutions, Inc.*, No. 12-S-00624-NE, 2014 WL 2891030, at *3–4 (N.D. Ala. June 25, 2014) (permitting treating physician to testify as fact witness and offer his “opinion regarding the cause of death . . . based upon his personal experience of treating” the decedent); *but see* N.K. by Bruestle-Kumra v. Abbott Lab’s, 731 F. App’x 24, 26 (2d Cir. 2018) (noting that a treating physician may not testify as a fact witness and must “be admitted as a Rule 702 expert witness to provide expert testimony on specific causation”). Some courts have allowed treating physicians to testify regarding causation because it could have been formed within the scope of treatment); *Burton v. Am. Cyanamid*, 362 F. Supp. 3d 588, 599 (E.D. Wis. 2019) (allowing treating physician to testify regarding lead exposure and causation because “his professional training and his experience treating . . . patients with elevated levels are sufficient to qualify him to give testimony”). *Contra* *Zellers v. NexTech Ne., LLC*, 533 F. App’x 192, 198 (4th Cir. 2013) (excluding testimony of treating physician as to causation because, *inter alia*, the physician was a neurologist who did not have “specialized training in the field of toxicology”); *Higgins v. Koch Dev. Corp.*, 794 F.3d 697, 704–05 (7th Cir. 2015) (excluding treating physician opinion regarding causation because the treating physician had no “training in toxicology”).

Treating physicians also become involved in considering cause-and-effect relationships when they are asked whether a patient can return to a situation in which an exposure has occurred. The answer is obvious if the cause-and-effect relationship is clearly known. However, this relationship is often uncertain, and the physician must consider the appropriate advice. In such situations, the physician will tend to give advice as though the causality was established, both because it is appropriate caution and because of fears concerning medicolegal issues.

131. Before 1990, the American Board of Medical Toxicology certified physicians. But beginning in 1990, medical toxicology became a subspecialty board under the American Board of Emergency Medicine, the American Board of Pediatrics, and the American Board of Preventive Medicine, as recognized by the American Board of Medical Specialties.

132. Clinical ecologists, another group of physicians, have offered opinions regarding multiple chemical hypersensitivity and immune system responses to chemical exposures. These physicians generally have a background in the field of allergy, not toxicology, and their theoretical approach is derived in part from classic concepts of allergic responses and immunology. This theoretical approach has often led clinical ecologists to find cause-and-effect relationships or low-dose effects that are not generally accepted by toxicologists. Clinical ecologists often belong to the American Academy of Environmental Medicine.

In 1991, the Council on Scientific Affairs of the American Medical Association concluded that until “accurate, reproducible, and well-controlled studies are available . . . multiple chemical sensitivity should not be considered a recognized clinical syndrome.” Council on Sci. Affairs, Am. Med. Ass’n, Council Report on Clinical Ecology 6 (1991). Multiple chemical sensitivity has been held by courts to be “a controversial diagnosis that has been excluded under *Daubert* as unsupported

Has the Proposed Expert Been Certified by the American Board of Toxicology, or Do They Belong to a Professional Organization, Such as the Academy of Toxicological Sciences or the Society of Toxicology?

As of August 2022, more than 2,500 individuals had received board certification from the American Board of Toxicology, Inc., and thus can use the title of “Diplomate of the American Board of Toxicology” (DABT). To sit for the examination, the candidate must be involved full time in the practice of toxicology, including designing and managing toxicological experiments or interpreting results and translating them to identify and solve human and animal health problems. Diplomates must be recertified every five years. The Academy of Toxicological Sciences (ATS) was formed to provide credentials in toxicology through peer review only. It does not administer examinations for certification. As of 2022, approximately 290 individuals had been elected as Fellows of ATS.

The Society of Toxicology (SOT), the major professional organization for the field of toxicology, was founded in 1961 and has grown dramatically in recent years. In 2022 the SOT had approximately 800 members.¹³³ Criteria for membership is based either on peer-reviewed publications or on the active practice of toxicology. Physician toxicologists can join the American College of Medical Toxicology and the American Academy of Clinical Toxicology as well as the SOT. There are also societies of forensic toxicology, such as the International Association of Forensic Toxicologists. Other organizations in the field are the American College of Toxicology, for which experience in the active practice of toxicology is the major membership criterion; the International Society of Regulatory Toxicology and Pharmacology; and the Society for Occupational and Environmental Health. For membership, the last two organizations require only the payment of dues.

by sound scientific reasoning or methodology.” *Madej v. Maiden*, 951 F.3d 364, 374–75 (6th Cir. 2020) (quoting *Summers v. Mo. Pac. R.R. Sys.*, 132 F.3d 599, 603 (10th Cir. 1997)) (collecting cases). The *Madej* court recognized that the “mountain of precedent” regarding multiple chemical sensitivity consists mostly of cases “over a decade old[.]” but reiterated that it has not been “shown that more recent scientific advancements have led the scientific community to come to accept a multiple-chemical-sensitivity diagnosis.” 951 F.3d at 375. The “diagnosis remains unrecognized by the American Medical Association and unlisted in the World Health Organization’s International Classification of Diseases.” *Id.*

133. As of 2024, there are twenty-nine specialty sections of the SOT that represent the different specialty areas involved in understanding the wide range of toxic effects associated with exposure to chemical and physical agents. These sections include Mechanisms, Molecular and Systems Biology, Inhalation and Respiratory, Metals, Neurotoxicology, Carcinogenesis, Risk Assessment, Biological Modeling, Immunotoxicology, and Sustainable Chemicals through Contemporary Toxicology, to name a few.

What Other Criteria Does the Proposed Expert Meet?

Toxicology, like many other disciplines that transcend both basic and applied science, has in recent decades gone through professionalization. This includes development of organizations that have different levels of expertise and recognition in the field. Understanding these organizations, including their criteria for membership, is pertinent to evaluating expertise in the field.

The success of academic scientists in toxicology, as in other biomedical sciences, usually is measured by the following types of criteria: the quality and number of peer-reviewed publications, the ability to compete for research grants, service on scientific advisory panels, and university appointments.

Publication of articles in peer-reviewed journals indicates an expertise in toxicology. The number of articles, their topics, and whether the individual is the principal or senior author are important factors in determining the expertise of a toxicologist.¹³⁴

Most research grants from government agencies and private foundations are highly competitive. Successful competition for funding and publication of the research findings indicate competence in an area.

Selection for local, national, and international regulatory advisory panels usually implies recognition in the field. Examples of such panels are the NIH Study Sections considering toxicology-related grant proposals, and panels convened by the EPA, FDA, WHO, and IARC. Recognized industrial organizations, including the American Petroleum Institute and the Electric Power Research Institute; public interest groups, such as the Environmental Defense Fund and the Natural Resources Defense Council; and public-private nonprofit partnerships, such as the Health and Environmental Sciences Institute (HESI) and the Health Effects Institute (HEI), employ toxicologists directly and as consultants, and enlist academic toxicologists to serve on advisory panels. Because of a growing interest in environmental issues, the demand for scientific advice has outgrown the supply of available toxicologists. It is thus common for reputable toxicologists to serve on advisory panels.

Finally, a tenured or tenure-track university appointment in toxicology, risk assessment, or a related field signifies substantial expertise, particularly if the

134. Examples of reputable, peer-reviewed journals are the *Journal of Toxicology and Environmental Health*; *Toxicological Sciences*; *Toxicology and Applied Pharmacology*; *Science*; *British Journal of Industrial Medicine*; *Clinical Toxicology*; *Archives of Environmental Health*; *Journal of Occupational and Environmental Medicine*; *Annual Review of Pharmacology and Toxicology*; *Teratogenesis, Carcinogenesis and Mutagenesis*; *Fundamental and Applied Toxicology*; *Inhalation Toxicology*; *Biochemical Pharmacology*; *Toxicology Letters*; *Environmental Research*; *Environmental Health Perspectives*; *International Journal of Toxicology*; *Human and Experimental Toxicology*; *Regulatory Toxicology and Pharmacology*; and *American Journal of Industrial Medicine*.

university has a graduate education program in that area. However, some universities offer adjunct or affiliate faculty positions to local professionals (consultants, government employees, etc.), often to assist in teaching entry-level toxicology courses. Although many well-qualified toxicologists working in the private sector or government agencies often have adjunct academic appointments, such an appointment does not necessarily confer the same level of expertise or toxicology credentials as a regular faculty appointment.

Acknowledgments

The authors gratefully appreciate the excellent research assistance provided by Stephanie N. Patton, associate, Buchanan Ingersoll & Rooney, P.C.; Lyndsey Arneson Field, Wake Forest Law School class of 2024; and Marvin Astrada, senior research associate, Federal Judicial Center, in the preparation of this fourth edition of the reference guide.

Glossary of Terms

absorption. The biological process of taking up of a chemical into the body orally, through inhalation, or through skin exposure.

acute toxicity. An immediate toxic response following a single or short-term exposure to a toxic substance.

additive effect. When exposure to more than one toxic agent results in the same effect as would be predicted by the sum of the effects of exposure to the individual agents.

antagonism. When exposure to one toxic agent causes a decrease in the effect produced by another toxic agent.

benchmark dose (BMD). The benchmark dose is determined on the basis of dose–response modeling and is defined as the exposure associated with a specified low incidence of risk, generally in the range of 1% to 10%, of a health effect, or the dose associated with a specified measure or change of a biological effect. Frequently, the statistical lower 10% confidence limit on the estimate of the BMD is used for regulatory standard setting, and is referred to as the Benchmark Dose Low 10%, or BMDL₁₀.

bioassay. A test for measuring the toxicity of an agent by exposing laboratory animals to the agent and observing the effects.

biological monitoring. Measurement of toxic agents or the results of their metabolism in biological materials, such as blood, urine, expired air, or biopsied tissue, to test for exposure to the toxic agents, or the detection of physiological changes that are due to exposure to toxic agents.

biologically plausible theory. A biological explanation for the relationship between exposure to an agent and adverse health outcomes. This is usually associated with an understanding of how the chemical causes its toxic effect (see note 49 above and accompanying text).

carcinogen. A chemical substance or other agent that causes cancer.

carcinogenicity bioassay. Limited or long-term tests using laboratory animals to evaluate the potential carcinogenicity of an agent.

chronic toxicity. A toxic response to long-term exposure or dosing (typically more than six months and up to two years for laboratory animal studies) with an agent.

clinical ecologists. Physicians who believe that exposure to certain chemical agents can result in damage to the immune system, causing multiple-chemical hypersensitivity and a variety of other disorders. Clinical ecologists often have a background in the field of allergy, not toxicology, and their theoretical approach is derived in part from classic concepts of allergic

responses and immunology. There has been much resistance in the medical community to accepting their claims.

clinical toxicology. The study and treatment of humans exposed to chemicals and the quantification of resulting adverse health effects. Clinical toxicology includes the application of pharmacological principles to the treatment of chemically exposed individuals and research on measures to enhance elimination of toxic agents.

compound. In chemistry, the combination of two or more different elements in definite proportions, which when chemically combined acquire properties different from those of the original elements.

confounding factors. Variables that are related to both exposure to a toxic agent and the outcome of the exposure. A confounding factor can obscure the relationship between the toxic agent and the adverse health outcome associated with that agent.

developmental toxicology. The processes by which a chemical agent causes toxic effects to the developing embryo and fetus and also during early life stages after birth when the brain and endocrine system continue to develop.

differential diagnosis. A physician's consideration of alternative diagnoses that may explain a patient's condition.

direct-acting agents. Agents that cause toxic effects without metabolic activation or conversion.

distribution. Movement of a toxic agent throughout the organ systems of the body (e.g., the liver, kidney, bone, fat, and central nervous system). The rate of distribution is usually determined by the blood flow through the organ and the ability of the chemical to pass through the cell membranes of the various tissues.

dose, dosage. A product of both the concentration of a chemical or physical agent and the duration and frequency of exposure.

dose–response curve. A graphic representation of the relationship between the dose of a chemical administered and the effect(s) produced. Each specific endpoint of toxicity may have its own dose–response curve.

dose–response relationships. The extent to which a living organism responds to specific doses of a toxic substance. The more time spent in contact with a toxic substance, or the higher the dose, the greater the organism's response. For example, a small dose of carbon monoxide will cause drowsiness; a large dose can be fatal.

epidemiology. The study of the occurrence and distribution of disease among people. Epidemiologists study groups of people to discover the cause of a disease, or where, when, and why disease occurs.

epigenetic. The study of how cells control gene activity without changing the DNA sequence. Epigenetics research has identified heritable changes in the functions of DNA that are not associated with a change in the DNA sequence. Chemicals found in the diet, workplace, and environment have been found to cause epigenetic changes that may contribute to adverse effects, including cancers.

etiology. A branch of medical science concerned with the causation of diseases.

excretion. The process by which toxicants are eliminated from the body, including through the kidneys and urinary tract, the liver and biliary system, fecal excretion, exhalation of the agent via the lungs, and secretion into sweat, saliva, and breast milk (lactation, which can result in an important route of exposure for nursing infants).

exposure. The intake into the body of a hazardous material. The main routes of exposure to substances are through the skin, mouth, and lungs. Exposure via injection (intravenous, intramuscular, subcutaneous) can occur for some drugs, especially drugs of abuse.

exposure assessment. The second step in the process of chemical risk assessment, in which quantitative estimates of the potential dose and duration of exposure to a specific chemical or chemical mixture will occur during a specified set of circumstances. It includes the consideration of concentration of a chemical in specific media (air, food, water, skin contact), amount of contact (food consumption, water consumption, inhalation rate), and frequency and duration of exposure for each route.

extrapolation. The process of estimating unknown values from known values.

genome, genomics. The genetic content of a cell, composed of DNA and related proteins that make up the twenty-three pairs of chromosomes in every living human cell. The human genome is composed of approximately 24,000 genes, each consisting of thousands of individual nucleotides (the building blocks of DNA). The sequence of the DNA in a gene dictates its function. The DNA of a gene is used by a cell to make proteins, which are the functional units of a cell. Changes in DNA sequence (a mutation) can result in irreversible changes in the function of a cell, leading to a wide variety of pathology, including cancers and birth defects.

good laboratory practice (GLP). Codes developed by the federal government in consultation with the laboratory testing industry that govern many aspects of laboratory standards.

hazard. The inherent ability of a chemical to cause (a) specific type(s) of toxic effect on biological organisms. Hazard differs from risk in that there is no quantitative consideration of dose.

hazard assessment. The first step in the process of risk assessment, which evaluates the potential of a specific chemical, or mixture of chemicals, to cause harm.

hazard identification. In risk assessment, the qualitative analysis of all available experimental animal and human data to determine whether and at what dose an agent is likely to cause toxic effects.

hydrologists, hydrogeologists. Scientists who specialize in the movement of ground and surface waters and the distribution and movement of contaminants in those waters.

immunotoxicology. A branch of toxicology concerned with the effects of toxic agents on the immune system.

indirect-acting agents. Agents that require metabolic activation or conversion before they produce toxic effects in living organisms.

inhalation toxicology. The study of the effect of toxic agents that are absorbed into the body through inhalation, including their effects on the respiratory system.

in silico methodology. Computational models that investigate toxicological and pharmacological hypotheses using tools such as data mining, homology models, machine learning, pharmacophores, quantitative structure–activity relationships, and network analysis tools.

in vitro. A research or testing methodology that uses living cells in an artificial or test tube system, or that is otherwise performed outside of a living organism.

in vivo. A research or testing methodology that uses living organisms.

lethal dose 50 (LD₅₀). The dose at which 50% of laboratory animals die within days to weeks, generally after the administration of a single dose.

lifetime bioassay. A bioassay in which doses of an agent are given to experimental animals throughout their lifetime. (See bioassay.) For carcinogenicity and most chronic toxicity studies, the standardized period for a lifetime bioassay in rats and mice is two years.

linearized non-threshold (LNT) model. A mathematical modeling approach that is used to extrapolate dose–response data to doses below the observed range, with assumptions that (1) the cancer risk is directly proportional to the dose at all doses, and thus (2) there is no threshold (a dose below which the response is zero).

lowest observed adverse effect level (LOAEL). The lowest dose or concentration of a chemical that causes observable adverse effects in experimental toxicology studies that use multiple doses.

maximum tolerated dose (MTD). The highest dose of an agent to which an organism can be exposed without it causing death or significant overt toxicity.

mechanism (or mode) of action. The specific molecular, biochemical, and cellular processes that are altered by the toxic substance, giving rise to the observed adverse effect(s). (See also biologically plausible theory.)

metabolism. The sum total of the biochemical reactions that a chemical produces in an organism.

metabolome. The total number of small molecules, both endogenous and exogenous, that can be measured in the blood. Metabolomics is useful to identify the presence of multiple potentially toxic substances in the blood, including the metabolites of the toxic substances.

molecular toxicology. The study of how toxic agents interact with cellular molecules, including DNA, proteins, and lipids (fats).

multiple-chemical hypersensitivity. A physical condition whereby individuals react to many different chemicals at extremely low exposure levels.

multistage model. A biochemical and statistical model for understanding certain diseases, including some cancers, based on the postulate that more than one event is necessary for the onset of disease.

mutagen. A substance that causes physical changes in chromosomes or biochemical changes in genes.

mutagenesis. The process by which agents cause changes in chromosomes and genes.

neurotoxicology. A branch of toxicology concerned with the effects of exposure to toxic agents on the central nervous system.

no observed adverse effect level (NOAEL). The highest level of exposure to an agent at which no effect is observed. It is the experimental equivalent of a threshold. See threshold.

one-hit hypothesis. A hypothesis of cancer risk in which each molecule of a chemical mutagen has a possibility, no matter how tiny, of mutating a gene in a manner that may lead to tumor formation or cancer. See also linearized non-threshold model.

PFAS. A widely used abbreviation to represent a class of chemicals called per- and polyfluoroalkyl substances. Such compounds provide a nonstick and stain-resistant coating to a wide variety of consumer products, such as nonstick cookware, carpeting, apparel, upholstery, personal care products, and cosmetics, and were also used in firefighting foams.

pharmacokinetics. A mathematical approach that expresses the movement of a toxic agent through the organ systems of the body, including the distribution to the target organ and to its ultimate fate via excretion pathways. It measures rate constants for each step in the process.

point of departure (POD). A term used to identify a point on the lower portion of a dose–response curve from which extrapolations are used to identify a hypothetical response level at lower doses. PODs are usually either a NOAEL, LOAEL, or BMD. These values, which are experimentally derived within the range of observations of a specified effect (e.g., birth defect, liver injury, tumor occurrence), are then divided by specified safety or uncertainty factors to arrive at a Reference Dose (RfD) or Acceptable Daily Intake (ADI).

potentiation. The process by which the addition of one agent, which by itself has no toxic effect, increases the toxicity of another agent when exposure to both agents occurs simultaneously.

reference dose (RfD). A term used by some regulatory agencies, such as the EPA, to identify a daily dose that is expected to be without harm. It is conceptually identical to the phrase acceptable daily intake (ADI), which is the amount of a chemical to which a person can be exposed on a daily basis over an extended period of time (usually a lifetime) without suffering a deleterious effect.

reproductive toxicology. The study of the effect of toxic agents on male and female reproductive systems, including sperm, ova, and offspring.

risk assessment. The use of scientific evidence to estimate the likelihood of adverse effects on the health of individuals or populations from exposure to hazardous materials and conditions. Chemical risk assessment includes: (1) hazard assessment, (2) exposure assessment, (3) dose–response modeling, and (4) risk characterization.

risk characterization. The final step in the risk assessment process, which summarizes information about an agent, including the strengths and limitations of the available toxicity data, and evaluates it in order to estimate the risks it poses.

safety assessment. Toxicological research that tests the toxic potential of a chemical in vivo or in vitro using standardized techniques required by governmental regulatory agencies or other organizations. The term is similar to risk assessment of chemical hazards, but is most often used in association with pharmaceuticals, food additives, and other chemicals for which public benefits are expected. It considers both the risks and the benefits of the chemical in deriving an acceptable level of risk (i.e., a “safe” dose).

safety factor (SF). See uncertainty factor.

structure–activity relationships (SAR). An in silico method used by toxicologists to predict the toxicity of new chemicals by comparing their chemical structures with those of compounds with known toxic effects.

synergistic effect. An effect by which two toxic agents acting together have an effect greater than that predicted by adding together their individual effects.

target organ. The organ system that is affected by a particular toxic agent.

target-organ dose. The dose to the organ that is affected by a particular toxic agent.

teratogen. An agent that changes eggs, sperm, or embryos, thereby increasing the risk of birth defects.

teratogenic. The ability to produce birth defects. Teratogenic effects do not pass to future generations. See teratogen.

threshold. The dose level above which effects will occur and below which no effects are expected to occur. See no observed adverse effect level.

toxic. Of, relating to, or caused by a poison—or a poison itself.

toxic agent or toxicant. An agent or substance that causes disease or injury.

toxicokinetics. Toxicokinetics is the description of the rate at which a chemical will enter an organism, and what occurs in terms of absorption, distribution, metabolism, and excretion (ADME). The term is used principally in describing ADME characteristics for chemicals that are not used as pharmaceuticals. The term pharmacokinetics (see above) describes this same process for chemicals used for therapeutic benefit (drugs).

toxicology. The science of the nature and effects of poisons, their detection, and the treatment of their adverse effects.

toxins. Toxic substances that are produced by biological organisms (plants, animals, fungi, bacteria, etc).

uncertainty factor (UF). These are values, usually a factor of ten, which are used to provide ample public health protection in determining “safe doses” (e.g., ADIs, RfDs) when extrapolating dose information obtained in experimental animals to human populations.

xenobiotic. A chemical that is foreign to the body. Sometimes used synonymously with “toxicant” or “toxic chemical.”

Introduction

Physicians are a common sight in today's courtroom. A survey of federal judges published in 2002 found that medical and mental health experts constitute more than 40% of testifying experts.¹ Medical evidence is a common element in product-liability suits,² workers' compensation disputes,³ medical malpractice suits,⁴ and personal-injury cases.⁵ Medical testimony may also be critical in certain kinds of criminal cases.⁶ This reference guide introduces types of evidence that physicians use to make judgments as treating physicians or as experts retained by one of the parties in a case for federal and state judges, emphasizing the tools and basic concepts of diagnostic reasoning and clinical decision-making and highlighting the challenges in testifying as medical experts. The "Medical Care" and "Medical Decision-Making" sections of this guide explain in detail the practice of medicine, including medical education and training, the structure and organization of healthcare, the elements of patient care, and, most importantly,

1. Joe S. Cecil, *Ten Years of Judicial Gatekeeping Under Daubert*, 95 Am. J. Pub. Health S74–S80 (2005), <https://doi.org/10.2105/AJPH.2004.044776>.

2. See, e.g., *In re Bextra & Celebrex Mktg. Sales Pracs. & Prod. Liab.*, 524 F. Supp. 2d 1166 (N.D. Cal. 2007) (thoroughly reviewing the proffered testimony of plaintiff's expert cardiologist and neurologist in a products-liability suit alleging that defendant's arthritis pain medication caused serious cardiovascular injury).

3. See, e.g., *AT&T Alascom v. Orchitt*, 161 P.3d 1232 (Alaska 2007) (affirming the decision of the state workers' compensation board and rejecting appellant's challenges to worker's experts); *Butts v. Dept. of Labor & Workforce Dev.*, 467 P.3d 231 (Alaska 2020) (reviewing the use of medical evidence to determine compensation).

4. See, e.g., *Schneider ex rel. Est. of Schneider v. Fried*, 320 F.3d 396 (3d Cir. 2003) (allowing a physician to testify in a malpractice case regarding whether administering a particular drug during angioplasty was within the standard of care); *Ellison v. United States*, 753 F. Supp. 2d 468 (E.D. Pa. 2010) (holding that oral surgeon's testimony was relevant and reliable); *Hemsley v. Langdon*, 909 N.W.2d 59 (Neb. 2018) (holding that the district court did not abuse its discretion by admitting doctor's expert testimony); *Gonzales v. Neb. Pediatric Prac., Inc.*, 955 N.W.2d 696 (Neb. 2021) (admitting the testimony of a family and emergency-room physician to prove another physician's misdiagnosis).

5. See, e.g., *Epp v. Lauby*, 715 N.W.2d 501 (Neb. 2006) (detailing the opinions of two physicians regarding whether plaintiff's fibromyalgia resulted from an automobile accident with two defendants); *Marsh v. Valyou*, 977 So. 2d 543 (Fla. 2007) (analyzing expert testimony linking a car accident to fibromyalgia); *Britt v. Wal-Mart Stores E., LP*, 599 F. Supp. 3d 1259 (S.D. Fla. 2022) (deciding that a surgeon could testify competently as to his opinions on whether or not plaintiff had sustained a permanent injury based on the information disclosed during the course of plaintiff's treatment).

6. See *State v. Price*, 171 P.3d 1223 (Mont. 2007) (discussing an assault case in which a physician testified regarding the potential for a stun gun to cause serious bodily harm); *People v. Unger*, 749 N.W.2d 272 (Mich. Ct. App. 2008) (a second-degree murder case involving testimony of a forensic pathologist and neuropathologist); *State v. Greene*, 951 So.2d 1226 (La. Ct. App. 2007) (regarding a child-sexual-battery and child-rape case involving the testimony of a board-certified pediatrician); *Unger v. Bergh*, 742 F. App'x 55 (6th Cir. 2018) (discussing the handling of expert testimony by trial counsel).

the processes of diagnostic reasoning and medical judgment that physicians use to diagnose and treat their patients. Special attention is given to the physician-patient relationship and to the types of evidence that physicians use to make medical judgments. Following the introduction, the section titled “Medical Testimony Introduction” identifies a few overarching theoretical issues that courts face in translating the methods and techniques customary in the medical profession in a manner that will serve the court’s inquiry. In an effort to make each issue more salient, examples from case law are offered when they are illustrative.

Medical Testimony Introduction

Medical Versus Legal Terminology

Because medical testimony is common in the courtroom generally and is indispensable to certain cases, courts have employed some medical terms in ways that differ from their use by the medical profession. Differential diagnosis, for example, is an accepted method that a medical expert may employ to offer expert testimony that satisfies Federal Rule of Evidence 702.⁷ In the legal context it refers to a technique “in which a physician first rules in all scientifically plausible causes of plaintiff’s injury, then rules out least plausible causes of injury until the most likely cause remains, thereby reaching a conclusion as to whether defendant’s product caused injury.”⁸ But in the medical context, differential diagnosis

7. See Liesa L. Richter & Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual.

8. *Wilson v. Taser Int’l, Inc.*, 303 F. App’x 708 (11th Cir. 2008) (“[N]onetheless, Dr. Meier did not perform a differential diagnosis or any tests on Wilson to rule out osteoporosis and these corresponding alternative mechanisms of injury. Although a medical expert need not rule out every possible alternative in order to form an opinion on causation, expert opinion testimony is properly excluded as unreliable if the doctor ‘engaged in very few standard diagnostic techniques by which doctors normally rule out alternative causes and the doctor offered no good explanation as to why his or her conclusion remained reliable’ or if ‘the defendants pointed to some likely cause of the plaintiff’s illness other than the defendants’ action and [the doctor] offered no reasonable explanation as to why he or she still believed that the defendants’ actions were a substantial factor in bringing about that illness.’”); *Williams v. Allen*, 542 F.3d 1326, 1333 (11th Cir. 2008) (“Williams also offered testimony from Dr. Eliot Gelwan, a psychiatrist specializing in psychopathology and differential diagnosis. Dr. Gelwan conducted a thorough investigation into Williams’ background, relying on a wide range of data sources. He conducted extensive interviews with Williams and with fourteen other individuals who knew Williams at various points in his life.”) (involving a capital murder defendant petitioning for habeas corpus offering a supporting expert witness); *Bland v. Verizon Wireless, L.L.C.*, 538 F.3d 893, 897 (8th Cir. 2008) (“Bland asserts Dr. Sprince conducted a differential diagnosis which supports Dr. Sprince’s causation opinion. We have held, ‘a medical opinion about causation, based upon a proper differential diagnosis, is sufficiently reliable to satisfy *Daubert*.’ A ‘differential diagnosis [is] a technique that identifies the cause of a medical condition by eliminating the likely causes until the most probable cause is isolated.’”) (citations

refers to a set of diseases that physicians consider as possible causes for the symptoms a patient is suffering or signs that a patient exhibits.⁹ By identifying the likely potential causes of a patient's disease or condition and weighing the risks of harms and benefits of additional testing or treatment, physicians then try to determine the most appropriate approach—testing, medication, or surgery, for example.¹⁰

Courts have used the term differential etiology interchangeably with differential diagnosis.¹¹ In medicine, etiology starts with the study of causation in disease,¹² but differential etiology is a legal invention not used by physicians. In general, both differential etiology and differential diagnosis are concerned with establishing or refuting causation between an external cause and a plaintiff's condition. Depending on the type of case and the legal standard, a medical expert may testify regarding specific causation, general causation, or both. Keep in mind that physicians typically make decisions about treatment and make

omitted) (stating expert's incomplete execution of differential diagnosis procedure rendered expert testimony unsatisfactory for *Daubert* standard); *Lash v. Hollis*, 525 F.3d 636, 640 (8th Cir. 2008) ("Further, even if the treating physician had specifically opined that the Taser discharges caused rhabdomyolysis in Lash Sr., the physician offered no explanation of a differential diagnosis or other scientific methodology tending to show that the Taser shocks were a more likely cause than the myriad other possible causes suggested by the evidence.") (finding lack of expert testimony with differential diagnosis enough to render evidence insufficient for jury to find causation in personal-injury suit); *Feit v. Great West Life & Annuity Ins. Co.*, 271 F. App'x 246, 254 (3d Cir. 2008) ("However, although this Court generally recognizes differential diagnosis as a reliable methodology the differential diagnosis must be properly performed in order to be reliable. To properly perform a differential diagnosis, an expert must perform two steps: (1) 'Rule in' all possible causes of Dr. Feit's death and (2) 'Rule out' causes through a process of elimination whereby the last remaining potential cause is deemed the most likely cause of death.") (citations omitted) (ruling that district court was not in error for excluding expert medical testimony that relied on an improperly performed differential diagnosis); *Saldana v. Delta Airlines, Inc.*, 1:19 CIV. 027 (CAK), 2021 WL 4710811 (D.V.I. Oct. 8, 2021) (quoting *Feit*, also considering that differential diagnosis had been properly performed in the case to form the opinion that the plaintiff had suffered a heart attack as a result of hurrying to catch the connecting flight).

9. *Stedman's Medical Dictionary* 531 (28th ed. 2006) (defining differential diagnosis as "the determination of which of two or more diseases with similar symptoms is the one from which the patient is suffering, by a systematic comparison and contrasting of the clinical findings.").

10. *The Concise Dictionary of Medical-Legal Terms* 36 (1998) (definition of differential diagnosis).

11. See *Proctor v. Fluor Enters., Inc.*, 494 F.3d 1337 (11th Cir. 2007) (testifying medical expert employed differential etiology to reach a conclusion regarding the cause of plaintiff's stroke). But see *McClain v. Metabolife Int'l, Inc.*, 401 F.3d 1233, 1252 (11th Cir. 2005) (distinguishing differential diagnosis from differential etiology, with the former closer to the medical definition and the latter employed as a technique to determine external causation); *Brown v. Burlington N. Santa Fe Ry. Co.*, 765 F.3d 765 (7th Cir. 2014) (indicating that differential diagnosis focuses on the identity of an ailment, while differential etiology focuses on the cause of the ailment).

12. *Stedman's Medical Dictionary* 675 (28th ed. 2006) (defining etiology as "the science and study of the causes of disease and their mode of operation"). For a discussion of the term etiology in epidemiology studies, see Steve C. Gold et al., *Reference Guide on Epidemiology*, section titled "Specific Causation," in this manual.

inferences about the possible diseases (different diagnoses) that may cause the presenting symptoms or signs to arrive at an appropriate treatment based on potential diagnoses when the diagnosis alters the optimal treatment. For example, stroke symptoms (the disease) can be caused by a variety of etiologies, mechanisms by which oxygen to the brain is disturbed (e.g., a burst brain aneurysm, a blood clot or an atherosclerotic plaque traveling to the brain, or other causes), thereby motivating further diagnostic testing to identify the etiology and treat appropriately. Physicians also use inference to help narrow potential diseases by identifying associated symptoms and risk factors—for example, chest pain due to coronary artery disease with a history of high blood pressure, high cholesterol, smoking, or occurring with exertion. The focus, however, is on diagnosis, typically with residual uncertainty and a weighing of the likelihood of that disease and the benefits and harms of treatment in a patient’s particular health context—age, sex, gender, past medical history, health behaviors and exposures (e.g., smoking, alcohol, occupational hazards, toxins), and family history—sometimes requiring revisiting the patient’s response to treatment over time and possibly ordering additional tests or treatments in an iterative approach. Most treating physicians will less commonly be familiar with differential etiology. General causation refers to whether the plaintiff’s injury could have been caused by the defendant or a product produced by the defendant, while specific causation is established only when the defendant’s actions or product actually caused the harm.¹³ An opinion by a testifying physician may be offered in support of both types of causation.¹⁴

Courts also refer to medical certainty or probability in ways that differ from their use in medicine. The standards of “reasonable medical certainty”¹⁵ and “reasonable medical probability” are also terms of art in the law that have no analog for a practicing physician.¹⁶ As detailed in the “Medical Decision-Making”

13. See *Amorgianos v. Nat’l R.R. Passenger Corp.*, 303 F.3d 256, 268 (2d Cir. 2002).

14. See, e.g., *Ruggiero v. Warner-Lambert Co.*, 424 F.3d 249 (2d Cir. 2005) (excluding testifying expert’s differential diagnosis in support of a theory of general causation because it was not supported by sufficient evidence); *Milward v. Rust-Oleum Corp.*, 820 F.3d 469 (1st Cir. 2016) (establishing that the plaintiffs had the burden of establishing, through expert testimony, general and specific causation, and analyzing the admissibility of an expert witness to establish the latter).

15. See, e.g., the official reporter’s note in *Restatement (Third) of Torts: Liability for Physical and Emotional Harm* § 28 cmt. e (Am. L. Inst. 2010), which exhaustively reviews the case law and law-review articles on this topic and finds that at least thirty-eight states have concluded that expert testimony otherwise admissible need not be expressed to a “reasonable degree of medical or scientific certainty.”

16. See, e.g., *Dallas v. Burlington N., Inc.*, 689 P.2d 273, 277 (Mont. 1984) (“[R]easonable medical certainty’ standard; the term is not well understood by the medical profession. Little, if anything, is ‘certain’ in science. The term was adopted in law to assure that testimony received by the fact finder was not merely conjectural but rather was sufficiently probative to be reliable.”); *Laue v. Voyles*, CV 13-31-BU-CSO, 2014 WL 12888669 (D. Mont. Apr. 18, 2014) (quoting the same passage from *Dallas*). This reference guide will not probe substantive legal standards in any detail, but there are substantive differences in admissibility standards for medical evidence between federal

section below, diagnostic reasoning and medical evidence are aimed at recommending the best therapeutic option for a patient. Although most courts have interpreted “reasonable medical certainty” to mean a preponderance of the evidence,¹⁷ physicians often work with multiple hypotheses while diagnosing and treating a patient without any “standard of proof” to satisfy.

Courts also use standard of care as a legal term that varies from state to state. In healthcare, medical-specialty societies use terms such as standards (high degree of certainty), guidelines (varying degrees of certainty), and consensus statements (expert opinion where controversy exists).¹⁸ Per the Institute of Medicine (IOM), “*Practice Guidelines* are systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances”; “*Medical Review Criteria* are systematically developed statements that can be used to assess the appropriateness of specific health care decisions, services, and outcomes”; “*Standards of Quality* are authoritative statements of (1) minimum levels of acceptable performance or results, (2) excellent levels of performance or results, or (3) the range of acceptable performance or results”; and “*Performance Measures* are methods or instruments to estimate or monitor the extent to which the actions of a health care practitioner or provider conform to practice guidelines, medical review criteria, or standards of quality.”¹⁹ In 2011, the Institute of Medicine updated the definition: “Clinical practice guidelines are statements that include recommendations intended to optimize

and state courts. See Robin Kundis Craig, *When Daubert Gets Erie: Medical Certainty and Medical Expert Testimony in Federal Court*, 77 Denv. U. L. Rev. 69 (1999).

17. See, e.g., *Sharpe v. United States*, 230 F.R.D. 452, 460 (E.D. Va. 2005) (“It is not enough for the plaintiff’s expert to testify that the defendant’s negligence might or may have caused the injury on which the plaintiff bases her claim. The expert must establish that the defendant’s negligence was ‘more likely’ or ‘more probably’ the cause of the plaintiff’s injury . . .”); *W.C. v. Sec’y of Health & Hum. Servs.*, 100 Fed. Cl. 440 (2011), *aff’d*, 704 F.3d 1352 (Fed. Cir. 2013) (finding that claimant had not established by preponderant evidence a medical theory causally connecting his significantly worsened multiple sclerosis to his flu vaccination).

18. In *Adams v. Lab. Corp. of Am.*, 760 F.3d 1322 (11th Cir. 2014), the issue was whether a litigation review of Pap smear slides needed to be done “blinded,” with the plaintiff’s specimen reviewed alongside others and with the expert not knowing which specimen was being challenged in the lawsuit. The court pointed out that there were plenty of times in pathology when retrospective reviews were done without such an elaborate “blinded” process, which seemed more suited to making it difficult to pursue litigation. As the Eleventh Circuit found, “As far as we are aware, this is the first time that an industry group has promulgated a set of guidelines that attempts to define and limit the evidence courts should accept when the group’s members are sued. The members of the CAP and ASC have a substantial interest in making it more difficult for plaintiffs to sue based on alleged negligence in their Pap smear screening, and their guidelines do just that.” *Id.* at 1331.

19. Comm. to Advise Pub. Health Serv. on Clinical Prac. Guidelines, Inst. Med., *Clinical Practice Guidelines: Directions for a New Program* 8 (Marilyn J. Field & Kathleen N. Lohr eds., 1990), <https://doi.org/10.17226/1626>. [hereinafter 1990 CAPHSCPG Report]. The Institute of Medicine is now the National Academy of Medicine.

patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options.”²⁰

Statutes and administrative regulations may also contain terms that are borrowed, often imperfectly, from the medical profession. In these cases, the court may need to examine the intent of the legislature and the term’s usage in the medical profession. If no intent is apparent, the court may need to determine whether the medical definition is the most appropriate one to apply to the statutory language. Whether the language is a medical term of art or a question of law will often dictate the admissibility and weight of evidence.²¹

Testimony by Physicians

Federal Rule of Civil Procedure 26(a)(2) requires various disclosures regarding expert witnesses. In 2010, the expert disclosure requirements were expanded to include disclosure of anticipated testimony by non-retained experts, including treating physicians, even if those opinions were confined entirely to opinions formed during treatment. Law professor Steven Gensler summarizes the disclosure requirements in this way:

In summary, the disclosures that must be made for a treating physician depend on the nature of the testimony he or she will give. Unless the treating physician is going to be limited to testifying about facts in a lay person capacity, the physician must be disclosed as an expert and must provide either the summary disclosures or an expert report. Whether the treating physician must file a written report or is subject only to summary disclosures depends on the role of the expert. If the treating physician’s expert opinions stay within the scope of treatment and diagnosis, then the physician would not be considered “retained” to provide expert testimony and only summary disclosures would be needed. But if a treating physician is going to offer opinions formed outside the course of treatment and diagnosis, then as to those further opinions the physician is being used in a “retained expert” role and the Rule 26(a)(2)(B)’s report requirement will apply to the extent of that further testimony.²²

Thus, the level of disclosure required by Rule 26 turns on whether the treating physician confines his or her testimony to facts and opinions in the context of

20. Comm. on Standards for Developing Trustworthy Clinical Prac. Guidelines, Inst. Med., Clinical Practice Guidelines We Can Trust 4 (Robin Graham et al. eds., 2011), <https://doi.org/10.17226/13058>. [hereinafter 2011 CSDTCGP Report].

21. See, e.g., *Coleman v. Workers’ Comp. Appeal Bd. (Ind. Hosp.)*, 842 A.2d 349 (Pa. 2004) (holding that since the legislature did not define the medical term *physical examination*, the common usage of the term is more appropriate than the strict medical definition).

22. Steven S. Gensler, 1 Federal Rules of Civil Procedure: Rules and Commentary, Rule 26 (2023).

determining the treatment, or ventures into opinions formed apart from treatment. In practice, parties rarely object on Rule 702 grounds to a doctor's testimony confined to treatment, even if it includes opinions formed during treatment. But when a treating clinician gives opinions beyond those formed during treatment, such as an opinion on future costs of treatment, *Daubert* objections are more common.

Although testifying medical experts often will need to tailor their opinions in a way that conforms to the legal standard of causation, the treating physicians generally are more concerned about accurate diagnosis and treatment and are less familiar with differential etiology. As the section titled "Medical Decision-Making" below will demonstrate, when analyzing the patient's symptoms and making a judgment based on the available medical evidence, a treating physician may not expressly identify a "proximate cause" or "substantial factor." For example, in order to recommend treatment, a physician does not necessarily need to determine whether a patient's lung ailment was more likely the result of a long history of tobacco use or prolonged exposure to asbestos if the optimal treatment is the same. In contrast, when testifying as an expert in a case in which an employee with a long history of tobacco use is suing his employer for possible injuries from asbestos exposure in the workplace, physicians may need to make judgments regarding the likelihood that either tobacco or asbestos—or both—could have contributed to the injury.²³

Physicians may be asked to testify about patients they have never examined or from whom they have never taken a medical history and make assessments of the proximate cause, increased risk of injury, or likely future injuries.²⁴ A doctor may even need to make medical judgments about a deceased litigant.²⁵ Testifying in all such cases requires making judgments that physicians do not ordinarily make in their profession and adapting their opinion to take into account the appropriate legal standard.²⁶

23. Physicians will testify as experts in cases in which the plaintiff's condition may be the result of multiple causes. In these cases, the divergence between medical reasoning and legal reasoning is very apparent. See, e.g., *Tompkin v. Philip Morris USA, Inc.*, 362 F.3d 882 (6th Cir. 2004) (affirming district court's conclusion that testimony offered by defendant's expert regarding the decedent's work-related asbestos exposure was not prejudicial in a suit against a tobacco company on behalf of plaintiff's deceased husband); *Mobil Oil Corp. v. Bailey*, 187 S.W.3d 265 (Tex. Ct. App. 2006) (involving claims from a worker who had a long history of tobacco use that exposure to asbestos increased his risk of cancer).

24. Visual and verbal information about patients suspected of having acute heart disease influenced a physician's estimates of the likelihood of disease by 35% (from a mean of 51%, with an absolute change of 18%). See C.P. Friedman et al., *Visual Information and the Diagnosis of Chest Pain*, 69 Acad. Med. S28–S30 (1994), <https://doi.org/10.1097/00001888-199410000-00032>.

25. See, e.g., *Tompkin*, 362 F.3d 882.

26. More than thirty medical specialty societies have issued statements about ethical requirements for their members to testify in court. That also deserves discussion. A prominent example is the American Academy of Orthopedic Surgeons (AAOS), which has an "expert witness affirmation statement," available at <https://perma.cc/H7TA-LC9T>.

Medical Expertise and Admissibility

As the “Medical Testimony Introduction” section above suggested, the goal that guides the physician—recommending the best therapeutic options for the patient—means that diagnostic reasoning involves probabilistic judgments concerning several working hypotheses, often considered simultaneously. Legal standards for physician testimony include Federal Rule of Civil Procedure 26(a)(2) requiring various disclosures regarding expert witnesses. The 1993 Advisory Committee Note to Rule 26—when expert disclosure requirements in the absence of a discovery request were added to Rule 26—specifically states that experts as used in Rule 26 are those who testify under Rule 702. Before 2010, the only expert disclosures required of parties were the detailed reports required for experts “retained or specially employed” to give testimony in the case.²⁷ This usually did not include treating physicians, who were testifying because they provided treatment and not because they were hired by a party. In 2010, the expert disclosure requirements were expanded to include non-retained experts who testify at trial.²⁸ This was specifically done to address treating-physician testimony, which normally was not subject to the report requirement but often was pivotal at trial.

Therefore, treating doctors who do more than recite basic facts are giving testimony subject to Rule 702, but the admissibility of their testimony is typically more of an issue—and *Daubert* challenges are more common—when they provide opinions not formed during the course of their treatment. The “Medical Care” and “Medical Decision-Making” sections below explain in great detail the practice of medicine, including medical education, the structure of health-care, and, most importantly, the methods that physicians use to diagnose and treat their patients. Special attention is given to the physician-patient relationship and to the types of evidence that physicians use to make medical judgments.

Medical Care

Medical Education and Training

Medical School

The Association of American Medical Colleges (AAMC) oversees accredited U.S. medical schools, as well as 197 Canadian medical schools.²⁹ The Liaison Committee on Medical Education performs the accreditation for AAMC and

27. Fed. R. Civ. P. 26(a)(2)(B).

28. Fed. R. Civ. P. 26(a)(2)(A), (C).

29. Ass’n Am. Med. Colls., Membership, <https://perma.cc/49NB-MLXW>.

assesses the quality of post-secondary education by determining whether each institution or program meets established standards for function, structure, and performance. All physicians who wish to be licensed must pass the U.S. Medical Licensing Examination Steps 1, 2, and 3.³⁰

In the United States, the bulk of physicians are allopathic medical doctors (M.D.s) while 11% are doctors of osteopathy (D.O.s).³¹ The Commission on Osteopathic College Accreditation accredits osteopathic medical schools. Training is similar to that for allopathic physicians but with “special training in the musculoskeletal system, your body’s interconnected system of nerves, muscles and bones.”³² About 25% of current U.S. physicians are foreign medical graduates that

30. U.S. Medical Licensing Examination, *General Common Questions*, <https://perma.cc/P67R-EESM>.

Rule 702 requires an expert to be qualified by “knowledge, skill, experience, training, or education.” *Planned Parenthood Cincinnati Region v. Taft*, 444 F.3d 502, 515 (6th Cir. 2006) (“The State has not appealed the district court’s order refusing to recognize Dr. Crockett as an expert in the critical review of medical literature. Although that order has not been placed before us, the only reason the district court gave for her ruling was that Dr. Crockett did not have any specific training in the critical review of medical literature beyond the training incorporated in her general medical school and residency training. This ruling ignored Dr. Crockett’s testimony that her residency program at Georgetown University put particular emphasis on training residents in the critical review of medical literature, that she had taught classes on the subject, that she had done extensive reading and self-education on the subject, and that she had critically reviewed medical literature for the FDA. If these qualifications are not sufficient to demonstrate expertise, this court is hard-pressed to imagine what qualifications would suffice.”); *Davis v. Houston Cnty., Ala. Bd. of Educ.*, No. 1:06-CV-953-MEF, 2008 WL 410619, at *4 (M.D. Ala. Feb. 13, 2008), *aff’d sub nom. Davis v. Houston Cnty., Ala. Bd. of Educ.*, 291 F. App’x 251 (11th Cir. 2008) (“The Board has moved to exclude all evidence of Freet’s opinions and conclusions related to the cause of Joshua Davis’s behavior at the football game contained in his deposition as well as Freet’s letter to Malcolm Newman. The Board argues that Freet is not qualified to give expert testimony, and that Plaintiff failed to comply with Fed. R. Civ. 26(a)(2)(B) by not providing a report of Freet’s testimony that includes all of the information required by Rule 26(a)(2)(B). . . . In order to consider Freet’s expert opinions, this Court must find that Freet meets the requirements of Fed. R. Evid. 702. . . . Freet is not a medical doctor and never attended medical school. The only evidence of Freet’s qualifications are: approximately five years working for the Department of Veterans Affairs in the vocational rehabilitation program, followed by approximately seven years working in private practice as a ‘licensed professional counselor.’ There is no evidence in the record of Freet’s educational background, or any details of the exact nature of Freet’s work experience.”); *Therrien v. Town of Jay*, 489 F. Supp. 2d 116, 117 (D. Me. 2007) (“Citing *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579, 113 S. Ct. 2786, 125 L. Ed. 2d 469 (1993) and Rule 702 of the Federal Rules of Evidence, Officer Gould’s first objection is that Dr. Harding does not possess sufficient expertise to express expert opinions about ‘the mechanism and timing of Plaintiff’s injuries.’ This objection is not well taken. Dr. Harding was graduated from Dartmouth College and Georgetown Medical School; he completed a residency in internal medicine, is board certified in internal medicine, and has been licensed to practice medicine in the state of Maine since 1978.”).

32. *Id.*

include both U.S. citizens and foreign nationals.³³ Because educational standards and curricula outside the United States and Canada vary, the Education Commission for Foreign Medical Graduates administers a certification exam to determine eligibility for Accreditation Council for Graduate Medical Education (ACGME) accredited U.S. residency and fellowship programs.³⁴

Postgraduate Training

Most medical school graduates seek additional training through residency programs in their chosen specialty.³⁵ Residencies range from three to seven years at teaching hospitals and academic medical centers. In training, residents care for patients while being supervised mostly by board-certified physicians. They also have opportunities to pursue educational and research activities.³⁶ Physician licensure in many states requires the completion of a residency program accredited by the ACGME, which is responsible for all allopathic and osteopathic graduate medical education programs, including over 13,000 residency and fellowship programs in 182 specialties and subspecialties.³⁷ After residency, eligible physicians can take their board certification examinations (see below), and some opt for additional subspecialty fellowship training.

Licensure and Credentialing

Medical practice acts defining the practice of medicine and delegating enforcement to state medical boards exist for each of the fifty states, the District of Columbia, and the U.S. territories. State medical boards award medical licenses, investigate complaints, discipline physicians who violate the law, and evaluate and rehabilitate physicians.

The hospital credentialing process defines physicians' scope of practice and hospital privileges, that is, the clinical inpatient and outpatient services and procedures they may provide. The process involves verifying medical education, postgraduate training, board certification, professional experience, state licensure, prior credentialing outcomes, medical-board actions, malpractice, and adverse clinical

events. Re-credentialing involves an assessment of a physician's professional or technical competence and performance by evaluating and monitoring the quality of patient care. Licensing and credentialing is identical for allopathic medical doctors and doctors of osteopathy.

The American Board of Medical Specialties (ABMS) provides certification in twenty-four medical boards, forty specialties, and eighty-eight subspecialties³⁸ to maintain and evaluate standards in the profession and to help “physicians and specialists demonstrate their competence and professionalism throughout their careers.”³⁹ Although criteria vary by field, board eligibility requires completing medical school, passing the United States Medical Licensing Examination, finishing an appropriate residency, and evaluation generally with computer-based and, in some cases, oral examinations. ABMS Standards for Continuing Certification, effective January 1, 2024, seek to promote integrated, specialty-specific programs by member boards to support an individual physician's or medical specialist's (i.e., diplomate's) continuing professional development.⁴⁰ In some cases, specialty organizations have developed their own certification process outside of the ABMS (e.g., the American Board of Bariatric Medicine).⁴¹ The American Osteopathic Association (AOA) certifies osteopathic physicians in sixteen specialty boards, issues certificates in twenty-seven primary specialties and forty-eight subspecialties,⁴² and has a continuous certification process.⁴³

Continuing Medical Education

For relicensure, state medical boards require continuing medical education so that physicians can acquire new knowledge and maintain clinical competence. The Accreditation Council for Continuing Medical Education (ACCME) identifies, develops, and promotes quality standards for organizations providing continuing

38. Am. Bd. Med. Specialties, <https://perma.cc/4DSJ-48HJ>.

39. Although specialization is a hallmark of modern medical practice, courts have not always required that medical testimony come from a specialist. *See, e.g., Gaydar v. Sociedad Instituto Gineco-Quirurgico y Planificacion Familiar*, 345 F.3d 15, 24–25 (1st Cir. 2003) (“The proffered expert physician need not be a specialist in a particular medical discipline to render expert testimony relating to that discipline.”); *Keller v. Feasterville Fam. Health Care Ctr.*, 557 F. Supp. 2d 671 (E.D. Pa. 2008) (holding that the expert opinion that patient did not have Alzheimer's disease was admissible in medical malpractice action, even though treating physicians were internal and family-care physicians, and expert was board certified in family medicine, but never received any specialized education, training, or experience in neuropathology, neurodegenerative diseases, or Alzheimer's disease).

medical education for physicians⁴⁴ to help assure physicians, state medical boards, medical societies, state legislatures, continuing medical education providers, and the public that the education meets certain quality standards. For osteopathic physicians, the AOA Board of Trustees also oversees accreditation for osteopathic continuing medical education sponsors through the Council on Continuing Medical Education (CCME).⁴⁵

Organization of Medical Care

The delivery of healthcare in the United States is highly decentralized and fragmented.⁴⁶ Healthcare is provided through clinics, hospitals, managed-care organizations, medical groups, multispecialty clinics, integrated delivery systems, specialty standalone hospitals, imaging facilities, skilled-nursing facilities, rehabilitation hospitals, emergency departments, and pharmacy-based and other walk-in clinics. Transitions in care settings involve multiple handoffs among different healthcare professionals and care providers with the need for accurate, timely, and complete transfer of information. As hospitals increasingly belong to a network or system, physicians too have shifted toward larger practices. For the first time, fewer than half of patient-care physicians were in private practice in 2020; therefore, “[n]o single practice type, ownership structure, or size can or should be considered the typical physician practice.”⁴⁷ The Covid-19 pandemic has accelerated practice changes including telemedicine visits, home hospitalizations, and ambulatory surgery and procedure centers with their own specialty organizations, accreditation bodies, and state regulatory oversight, besides possible federal certification.

Per W. Edwards Deming, “Every system is perfectly designed to get the result that it does.” As a consequence, the U.S. healthcare system yields a life expectancy 5.9 years shorter than the average of comparable countries in 2021, yet it spends nearly twice as much per capita.⁴⁸ Driven by social and economic inequities, the healthcare system has substantial disparities by race/ethnicity, but also by “socioeconomic status, age, geography, language, gender, disability

status, citizenship status, and sexual identity and orientation.” For example, “[b]lack infants in America are now more than twice as likely to die as white infants, a disparity that is wider than it was in 1850, 15 years before the end of slavery.”⁴⁹

Since a Harvard Medical Practice study found a high incidence of adverse events in hospitalizations and highly publicized errors (fatal medication overdoses and amputation of the limb on the wrong side), there have been safety concerns about the organization of medical care. The Harvard study indicated that adverse events occurred in 3.7% of hospitalizations and that 27.6% of adverse events were due to negligence.⁵⁰ A report by the IOM estimated that negligence errors resulted in as many as 98,000 deaths in patients hospitalized annually.^{51,52} The report further highlighted system issues leading to safety events: “The decentralized and fragmented nature of the healthcare delivery system (some would say ‘nonsystem’) also contributes to unsafe conditions for patients and serves as an impediment to efforts to improve safety.” While recognizing that “not all errors result in harm,” the report defined safety as “freedom from accidental injury” and specified two types of error: “the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim.”⁵³

The IOM recommended the development of a learning healthcare–delivery system—“a system that both prevents errors and learns from them when they occur. The development of such a system requires, first, a commitment by all stakeholders to a culture of safety and, second, improved information systems.”⁵⁴

Government and nongovernment institutions have adopted as parts of their mission the assessment and promotion of safety at the healthcare-system level.

Besides patients and their families,⁵⁵ the work system for healthcare delivery and diagnosis includes organizational characteristics (culture, rules and procedures, leadership, and management), technologies and tools (health information technology and electronic health records), physical environment (layout, distractions, lighting, and noise), and external factors (payment, care-delivery system, legal system, and reporting environment).⁵⁶ Beyond physicians, medical delivery systems have increasingly incorporated allied health professions, including nurses, nurse practitioners, physician assistants, pharmacists, and therapists. The term *clinicians* will be used to be inclusive of this expanded diagnostic and care-delivery team.

Patient Care

Goals

The translated classical version of the Hippocratic Oath (c. 400 B.C.), “abstain from whatever is deleterious,” was abbreviated into “first do no harm,” or in Latin, *primum non nocere*. The IOM describes quality healthcare delivery as “[t]he degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.” The six aims for improving the healthcare system assert that healthcare should be

- *Safe*—avoiding injuries to patients from the care that is intended to help them.
- *Effective*—providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit (avoiding underuse and overuse, respectively).
- *Patient-centered*—providing care that is respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions.
- *Timely*—reducing waits and sometimes harmful delays for both those who receive and those who give care.
- *Efficient*—avoiding waste, including waste of equipment, supplies, ideas, and energy.
- *Equitable*—providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.⁵⁷

In *Crossing the Quality Chasm*, the IOM emphasized that care delivery should accommodate individual patient choices and preferences and be customized on the basis of a patient's needs and values.⁵⁸ The Charter on Medical Professionalism specifies three fundamental principles: (1) patient welfare or serving the interest of the patient, (2) patient autonomy or empowering patients to make informed decisions, and (3) social justice or fair distribution of healthcare resources.⁵⁹ When faced with limited resources, such as when a patient gets an intensive care bed during the Covid-19 pandemic, clinicians are faced with the dilemma of choosing between patient care and societal goals.⁶⁰

Diagnostic Process

The diagnostic problem begins with patients experiencing a health problem that leads to a healthcare system encounter (Figure 1).⁶¹ Initial information gathering then leads to information integration and interpretation in which a set of working diagnoses are formed and revised until sufficient information has been gathered in the clinical reasoning process. The sources of information include the clinical history and interview, physical examination, diagnostic testing, and possible referral and consultation.⁶²

The clinical history and interview identify the chief complaint as the specific symptom that led the patient to seek medical attention. The history of the present illness describes the onset and progression of symptoms over time and may include eliciting the presence or absence of symptoms as “pertinent positives or pertinent negatives” that increase or decrease the likelihood of potential diseases under consideration. The past medical history includes prior illnesses, hospitalizations, surgeries, current medications, drug allergies, and lifestyle habits (smoking, alcohol use, illicit drug exposure, dietary habits, and exercise habits). Family history captures illnesses diagnosed in related family members. Social history includes education, employment, and social relationships. These provide a context for the chief complaint. Finally, the review of systems is a comprehensive inquiry of symptoms from various organ systems.

Figure 1. The diagnostic process.

Source: From National Academies of Sciences, Engineering, and Medicine, *Improving Diagnosis in Health Care* 33 (National Academies Press 2015), <https://doi.org/10.17226/21794>.

Distinct from symptoms that are described by patients, physical-examination findings are considered as signs. Directed physical examination refers to inspecting only the relevant organ systems that may be causing the symptoms.

Based on the set of working diagnoses, diagnostic testing may be ordered to confirm or rule out possible diagnoses. Diagnostic testing is distinguished from surveillance testing or screening because the patient has a symptom whose cause the diagnostic team is seeking to identify for treatment. Depending on residual diagnostic uncertainty, patients may be referred for further consultation with specialists or subspecialists for their diagnostic or therapeutic opinion.

Patients also may seek care to monitor chronic conditions. This places an emphasis on collaborative and continuous care that involves patients, their families, clinicians, long-term care goals and plans, self-management training, and support⁶³ with organizational needs that differ substantially from those necessary for acute episodic complaints. The clinical history and physical examination involve assessing whether the symptoms or signs of that condition have progressed, improved, or stabilized. Surveillance may involve repeating tests at some recommended frequency for a known health risk—for example, a colonoscopy in three years for someone found to have premalignant polyps previously, instead of ten years for someone with a negative colonoscopy.

63. 2001 CQHCA Report, *supra* note 46, at 27.

Patients may seek preventive health visits. Screening involves testing asymptomatic, otherwise-healthy patients to find a disease earlier, presumably when it may be more treatable (e.g., cancer) or preventable (e.g., preventing stroke by treating hypertension, a risk factor for stroke). Screening for a population requires that (1) the condition affects quality and length of life in the population; and (2) has a sufficiently high incidence or prevalence to justify any risk of harms associated with the test; (3) a preventive or early treatment is available; (4) an asymptomatic period for early detection is present; (5) an accurate, acceptable, and affordable screening test exists; and (6) as applied to a population, screening benefits should exceed harms. Screening for disease in asymptomatic, otherwise healthy patients has become widely accepted and promulgated.⁶⁴ In contrast to diagnostic testing prompted by a complaint from a patient, screening involves apparently healthy individuals without any complaint,⁶⁵ so “every adverse outcome of screening is iatrogenic and entirely preventable” by not screening, including overdiagnosis and overtreatment (diagnoses that never would have been made, e.g., never cause symptoms or mortality resulting in over treatment with potential adverse effects).⁶⁶

Medical Decision-Making

Uncertainty in defining when a disease is present makes diagnosis, and therefore treatment decisions, difficult: (1) the difference between normal and abnormal is not always well demarcated; (2) many diseases do not progress with certainty (e.g., progression of lobular carcinoma in situ of the breast to invasive breast cancer occurs less than 50% of the time), but rather increase the risk of a poor outcome (e.g., hypertension raises the risk of developing heart disease or stroke); and (3) symptoms, signs, and findings for one disease overlap with others.⁶⁷ Variation also exists in the ability of physicians to elicit particular symptoms (e.g., in a group of patients interviewed by many physicians, 23% to 40% of the physicians reported cough as being present), observe signs (e.g., only 53% of physicians detected cyanosis—a blue or purple discoloration of the skin resulting from lack of oxygen—when present), or interpret tests (e.g., only 51% of pathologists agreed with each other when examining Pap smear slides with abnormal cells taken from

a woman's cervix to look for signs of cervical cancer).⁶⁸ And prognosis (response to disease or treatment) with alternative therapies is in many cases uncertain. A report by the Royal College of Physicians puts it this way:

The practice of medicine is distinguished by the need for judgement in the face of uncertainty. Doctors take responsibility for these judgements and their consequences. A doctor's up-to-date knowledge and skill provide the explicit scientific and often tacit experiential basis for such judgements. But because so much of medicine's unpredictability calls for wisdom as well as technical ability, doctors are vulnerable to the charge that their decisions are neither transparent nor accountable.⁶⁹

Note that a key piece of the diagnostic process in Figure 1 involves communication of the diagnosis and the care-path plan for the diagnosis.

Clinical-Reasoning Process

Studies of clinical problem solving suggest that physicians employ combinations of two diagnostic approaches ranging from hypothetico-deductive reasoning (deliberative and analytical, or thinking slow) to heuristic pattern recognition (quick and intuitive, or thinking fast).⁷⁰

Hypothetico-Deductive Reasoning

In the hypothetico-deductive approach, based on initial information such as age, gender, and chief complaint, clinicians begin to generate an initial list of potential diseases (hypothesis generation) based on their potential to explain the patient's observed signs and symptoms (Figure 2)⁷¹ within the known capacity

limitations in human short-term memory.⁷² This initial working list of diagnoses provides a context used to evaluate subsequent information. Based on their disease knowledge, clinicians expect the presence or absence of certain symptoms, risk factors, disease course, signs, or test results for each diagnosis (deductive inference).

As further information emerges (Figure 3), those data are evaluated and interpreted for their consistency with the working list of possibilities and whether those data would increase or decrease the likelihood of each possibility (hypothesis refinement). If the data are inconsistent, those diseases may be dropped and other diagnostic possibilities may be considered (hypothesis modification). The information gathering continues iteratively over time, including possible referral to another clinician. The final cognitive step (diagnostic verification) involves testing the validity of the diagnosis for its coherency (consistency with predisposing risk factors, physiological mechanisms, and resulting manifestations), its adequacy (the ability to account for all normal and abnormal findings and the disease time course), and its parsimony (the simplest single explanation as opposed to requiring the simultaneous occurrence of two or more diseases to explain the findings).⁷³

Figure 3. Clinical-reasoning process from chief complaint to therapeutic decisions.

Heuristics: Intuitive Pattern Recognition

Alternatively, heuristics are quick, automatic “rules of thumb” or cognitive shortcuts. In such cases, pattern recognition leads to rapid recognition and a reflexive diagnosis with little cognitive effort.⁷⁴ For example, a black woman with large shadows from enlarged lymph nodes in her chest X-ray would trigger a presumptive diagnosis of sarcoidosis for many clinicians. The simplifying assumptions involved in heuristics, however, are subject to cognitive biases. For instance, episodic headache, sweating, and a rapid heartbeat form the classic triad seen in patients with a rare adrenal tumor known as a pheochromocytoma that also can cause hypertension. Physicians finding those three symptoms in a patient with hypertension may overestimate the patient’s likelihood of having pheochromocytoma based on representativeness bias, overestimating the likelihood of a less common disease just because case findings resemble those found in that disease.⁷⁵ Other cognitive errors include availability (overestimating the likelihood of memorable diseases in a subsequent patient because of vivid experience with a prior patient or media attention, and thus underestimating common or routine diseases) and

74. Stephen G. Pauker & John B. Wong, *How (Should) Physicians Think?: A Journey from Behavioral Economics to the Bedside*, 304 JAMA 1233, 1233–34 (2010), <https://doi.org/10.1001/jama.2010.1336>.

75. For additional discussion and definition of terms, see section titled “Diagnostic Reasoning” below. Applying Bayes’ rule, about 100 in 100,000 patients with hypertension have pheochromocytoma; this symptom triad occurs in 91% of patients with pheochromocytoma (sensitivity), and does not occur in 94% of those without pheochromocytoma (specificity), and so 6% of those without pheochromocytoma would have this symptom triad. Based on Bayes’ rule, 91 of the 100 individuals with pheochromocytoma (91% times 100) would have this triad, and 5,994 without a pheochromocytoma (6% times 99,900) will have this triad. Thus, among the 100,000 hypertensive patients, 6,085 will have the classic triad, suggesting the possibility of pheochromocytoma, but only 91 out of the 6,085 or 1.5%, will indeed have pheochromocytoma.

anchoring (insufficient adjustment of the initial likelihood of disease following a positive or negative test).⁷⁶

Clinical intuition refers to rapid, unconscious processes that select the pertinent findings from the multitude of available data.⁷⁷ Such expertise results from multiple exposures to patients with similar symptoms and their final diagnosis, is context sensitive, and cannot always be reduced to cause and effect.⁷⁸ Cognitive research into the development of expertise suggests two competing hypotheses. In instance- or exemplar-based memory, physicians store scripts or stories of prior recalled case examples—for example, visual information such as that in pathology, dermatology, or radiology—and match new cases to those stories. The alternative prototype memory hypothesis is based on a mental model of disease wherein experts store structured clinical “facts” to create abstractions of patients with the disease. These “prototypes” enable experts to link findings to one another, to connect findings to the possible diagnoses, and to predict additional findings necessary to confirm the diagnosis, even in the absence of prior experience with exactly such a case.⁷⁹

Physicians typically apply hypothetico-deductive approaches when seeing patients with problems outside of their expertise or patients with difficult problems with atypical features within their expertise and apply intuitive pattern recognition for cases within their expertise or less challenging cases. However, diagnostic accuracy appears to depend more on mastery of domain knowledge than on the particular problem-solving method.⁸⁰

Diagnostic Reasoning

There is no correlation between physicians’ ability to collect data thoroughly and their ability to interpret the data accurately.⁸¹ As a decision scientist describes,

You can’t think unless you’ve got distinctions, and we talk about powerful distinctions. I say an expert in anything is an expert because that expert has powerful distinctions. And we don’t mean he or she has memorized the glossary. It’s that you really have a working knowledge of why they’re important and why that distinction was a very valuable one in the history of the subject and in your thinking.⁸²

Symptoms and Signs

Although a test is commonly thought of as a sample from a bodily fluid, tissue, or image, a test also could be the presence or absence of a symptom or physical sign. For example, both influenza and the ancestral Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) can present with similar symptoms. However, a distinguishing symptom is the absence of a runny nose, which is nine times more likely with SARS-CoV-2 (95% vs. 11%). Thus, a runny nose occurs in only 5% of patients with SARS-CoV-2 but 89% of patients with influenza, making influenza 18 times more likely in those with a runny nose.⁸³

Bayes' Rule

Over 200 years ago, Reverend Thomas Bayes first wrote a paper, published posthumously, that now forms a critical concept in modern medicine: how to estimate the likelihood of disease following a test result using the likelihood of disease prior to testing and the specific test result obtained. Bayesian analysis refers to a method of combining existing evidence or a pretest probability with additional evidence, for example, from the presence or absence of a positive symptom, sign, test, or research-study result to calculate a posterior probability.⁸⁴

The pretest suspicion of disease or, equivalently, the likelihood or prior probability of disease may be objective, that is, related to incidence (new cases over a specified period of time) or prevalence (existing cases at a particular point in time); based on clinical-prediction rules (e.g., mathematical predictive models to estimate the likelihood of having a stroke or heart attack over the next ten years); or subjective, that is, based on a clinician's subjective estimated likelihood of disease prior to any testing.⁸⁵ Bayes' rule then combines that pretest suspicion with the observed test result. Tests, however, are almost never perfectly accurate. Not everyone with disease has a positive test (i.e., false negatives), and not

85. See *Gonzalez v. Metro. Transp. Auth.*, 174 F.3d 1016, 1023 (9th Cir. 1999) (describing the implications of Bayes' rule for drug testing and noting that a test with the same false-positive rate will generate a higher proportion of false positives to true positives in a population with fewer drug users); see generally Michael O. Finkelstein & William B. Fairley, *A Bayesian Approach to Identification Evidence*, 83 *Harv. L. Rev.* 489 (1970), <https://doi.org/10.2307/1339656>. For a discussion of Bayesian statistics, see David H. Kaye & Hal S. Stern, *Reference Guide on Statistics and Research Methods*, "Appendix: Conditional Probability and Bayes' Rule," in this manual.

everyone who does not have disease has a negative test (i.e., false positives), which can lead to misestimation of the likelihood of disease.

For example, consider the interpretation of a positive mammogram among women who may have cancer but most do not.⁸⁶ Suppose 1% or 10 of 1,000 40-year-old women have breast cancer. The mammogram will be truly positive in 80% or 8 of the 10 women with breast cancer but falsely positive in 10% or 99 of the 990 women without breast cancer. Among the 107 (8 plus 99) women with a positive mammogram, 8 have breast cancer, so the positive mammogram increases the likelihood of breast cancer from 1% (10 per 1,000) to 7% (8 per 107). The 7% is the probability of breast cancer among 40-year-old women after a positive mammogram, that is, post-test probability of disease after a positive test or predictive-value positive. The above is described as a natural-frequency format for Bayes' rule. When presented as probabilities as in Table 1: There is a 1% probability of breast cancer for these 10,000 women with an 80% probability of a positive mammogram for those with breast cancer and a 10% probability of a positive mammogram without breast cancer. Table 1 shows the calculation of Bayes' rule using probabilities with column C showing the natural frequencies as probabilities and column D multiplying the two probability columns. Column E then divides the column D entries by the total frequency of positive mammograms.

Table 1. A Tabular Form of Bayes' Rule for Test Interpretation

A	B	C	D	E
	Prior Probability	Probability of a Positive Mammogram Given the Condition in Column A	Multiply Columns B and C	Post-test Probability (Column D Divided by Sum)
Breast Cancer	1% = 10/1,000	80% = 8/10	0.8% = 8/1,000	7% = 8/107
No Breast Cancer	99% = 990/1,000	10% = 1/10	9.9% = 99/1,000	93% = 99/107
			Sum = 10.7% = 107/1,000	

Probabilistic Reasoning

There are two types of medical reasoning to infer the likely diagnosis (Figure 2). Traditional medical education teaches disease manifestations by understanding

86. Among 48 physicians, 10% receiving probability data achieved the correct answer versus 46% when given the natural frequency format. Ulrich Hoffrage & Gerd Gigerenzer, *Using Natural Frequencies to Improve Diagnostic Inferences*, 73 Acad. Med. 538 (1998), <https://doi.org/10.1097/00001888-199805000-00024>.

the mechanistic pathways by which the disease causes specific symptoms and signs. For deductive medical inference (deduction), one hypothesizes a specific disease and determines if the manifestations of that disease (e.g., from the literature) account for all of the patient’s observed symptoms and signs.⁸⁷ Deduction, however, assumes the diseases hypothesized contain the most likely set of diagnoses in a specific patient, yet a set of different diseases may have overlapping manifestations and have varying underlying likelihoods in different contexts. In contrast to deduction, inductive medical inference (induction) goes from observing symptoms and signs (what is known) to quantifying the likelihood of each of the possible diagnoses, allowing for a possibly broader consideration of diseases but with uncertainty attached to the likelihood of each disease.

For example, both influenza and SARS-CoV-2 can cause fever, cough, sore throat, nasal congestion, headache, fatigue, muscle and joint aches, chills, nausea, vomiting, and diarrhea. How might Bayes’ rule help distinguish the cause of the symptoms? To illustrate probabilistic inference, the table below presents another tabular form of Bayes’ rule that starts with two diseases (column A) and then the pretest probability of each disease (column B) (e.g., the observed ratio of the incidence of SARS-CoV-2 versus influenza based on prevailing epidemiologic data) followed by the published likelihood of the observing nasal congestion for each disease.⁸⁸ Column D multiplies the numbers in columns B and C to calculate the joint likelihood of those results and the prior probability of each disease. Column E shows that the presence of nasal congestion changes the higher epidemiologic likelihood of SARS-CoV-2 to making influenza much more likely. Bayes’ rule provides the only quantitative approach to incorporate findings to calculate revised likelihoods of diseases given a symptom, sign, or test result through induction (in contrast to the deduction).

Table 2. A Tabular Form of Bayes’ Rule for Diagnosis

A	B	C	D	E
	Prior Probability	Probability of Nasal Congestion Given the Condition in Column A	Multiply Columns B and C	Post-test Probability (Column D Divided by Sum)
SARS-CoV-2	0.75	0.05	0.037	0.14
Influenza	0.25	0.89	0.222	0.86
			Sum = 0.259	

87. This is analogous to assuming the null hypothesis between the intervention and control arm in a randomized trial. One can then deduce the likelihood of the observed results based on that assumption.

88. Guan et al., *supra* note 83, at 1713; Hupert et al., *supra* note 83, at 340.

How well does a symptom distinguish SARS-CoV-2 from influenza? The informative or discriminating ability of a test can be succinctly summarized as a likelihood ratio. The likelihood-ratio positive is the ratio of true-positive rate (sensitivity) to the false-positive rate (one minus the specificity) and expresses how much more likely disease is to be present following a positive test result. Considering influenza as the disease, the likelihood-ratio positive for nasal congestion is 18 ($0.89 \div 0.05$). Likelihood-ratio positives should always exceed one because they increase the likelihood of disease, and likelihood-ratio negatives should always be less than one. Likelihood ratios exceeding 10 or falling below 0.1 are strong discriminators causing “large” changes in the likelihood of disease; those between 5 and 10 or 0.1 and 0.2 cause “moderate” changes; and those between 2 and 5 or 0.2 and 0.5 cause “small” changes.⁸⁹ The likelihood ratios succinctly capture the combined effects of sensitivity and specificity to express the impact of a finding on the likelihood of a disease.

Probabilistic inductive reasoning using Bayes’ rule not only applies to interpreting symptoms and signs for differential diagnosis but also to selection and interpretation of diagnostic tests to exclude or confirm the presence of a disease, thereby avoiding faulty information gathering and processing, for example, faulty interpretation of a test. It also explicitly accounts for varying disease prevalence in different contexts due to patient or population characteristics. For example, a patient with chest pain will have different likelihoods of atherosclerotic disease in the heart if they are being seen in primary care or had been referred by primary care to cardiology outpatient settings. This is because the latter often requires a referral from another doctor who judges the risk of heart disease to be higher, so those patients will have a higher likelihood of worrisome chest pain. This influences the interpretation of a test result as well as the likelihood of disease and the perceived benefit of treatment in the consulting cardiologist.⁹⁰ Beyond differential diagnosis, the prevalence (or pretest probability) of disease in different patient populations affects how well mathematical predictive models perform in other populations (i.e., their generalizability). For example, a logistic regression model that captures the four physical findings that predict strep throat does not perform as well in other populations because the prevalence of strep throat varies by setting.⁹¹

Poses et al., *The Importance of Disease Prevalence in Transporting Clinical Prediction Rules: The Case of Streptococcal Pharyngitis*, 105 *Annals Internal Med.* 586, 586 (1986), <https://doi.org/10.7326/0003-4819-105-4-586> (prediction of streptococcal pharyngitis improved when adjusted for the disease prevalence in the specific clinical setting, e.g., by changing the constant in the logistic regression).

Prosecutor's Fallacy

The prosecutor's fallacy involves the misinterpretation of probabilistic information, such as when a prosecutor argues that if the defendant is guilty, then the probability is high that the compelling evidence will be found, and given presentation of that evidence during the trial, the defendant must be guilty. For example, in a highly publicized British case, solicitor Sally Clark was convicted of double homicide of her first two children in part based on testimony from then-eminent pediatrician Professor Sir Roy Meadow, known for Meadow's law that "one cot death [the British term for sudden infant death syndrome or SIDS] is a tragedy, two cot deaths is suspicious and, until the contrary is proved, three cot deaths is murder."⁹² The Confidential Enquiry for Stillbirths and Deaths in Infancy (CESDI) in Britain estimated a SIDS risk at the time of the testimony of 1 in 1,300 live births overall; Sir Meadow applied a lower risk of a SIDS death of 1 in 8,543 births to account for two characteristics of the Clark family that made SIDS death less likely (nonsmoking and affluent parents), but ignoring ecologic bias when accounting for those characteristics and also assuming the same likelihood for both deaths. By squaring 1 in 8,543 births, he testified that the likelihood of two natural SIDS deaths was "one in 73 million" with the potential implication that all other deaths were all by homicide. With 700,000 births annually in the United Kingdom, Sir Meadow testified that a double SIDS death would be expected to occur "once in a hundred years."⁹³

In a commentary, Ray Hill, a professor of mathematics, wrote that some infants die from SIDS and some from homicides. Double SIDS and double infant homicides deaths in the same family are both rare events, so what matters are the "relative chances of these." Using the 700,000 births annually and the incidence data, 538 deaths would be expected from SIDS and 32 from homicide, so on average, SIDS mortality was 17-fold more likely than homicide death. Based on data (albeit sparser data), Hill then estimated the likelihood of a second SIDS death to be 1/228 and a second homicide death to be 1/123, resulting in 2.36 double SIDS deaths and 0.26 double homicide deaths or a 9:1 ratio of double SIDS to double homicide (Table 3).⁹⁴ Hill wondered "whether the *Clark* jury would have

93. *Id.* at 325.

94. Bayes' rule demonstrates how motive in a trial is critical. If the prior probability of an individual committing a crime is zero, despite whatever evidence is presented, the posterior probability of crime by that individual, regardless of the evidence, remains zero. A motive, even if weak, moves the prior probability to be more than zero so that convincing evidence can then raise the likelihood of crime to be more likely than not (i.e., greater than 50%) or, alternatively, beyond a reasonable doubt, e.g., for homicide. For example, if the prior probability of homicide is zero due to the absence of a motive for murder in Table 3, then that zero is multiplied throughout the Homicide row, so the posterior probability for SIDS will always be 1.00 or 100%.

Table 3. Probability of Two Deaths from SIDS vs. Homicides

A	B	C	D	E
	Infant Deaths in 1 Year from Column A	Probability of Second Death	Multiply Columns B–C	Posterior Probability
SIDS	538	1/228	2.36	0.90
Homicide	32	1/123	0.26	0.10
			Sum = 2.62	

convicted if, instead of being given the ‘once in a hundred years figure,’ they had been told that second cot deaths occur about four or five times a year and indeed happen more frequently than second infant murders in the same family.”⁹⁵

Sally Clark was convicted of murder and, after losing her first appeal, won on second appeal in 2003 that would have also allowed appeal based on “flawed statistical evidence” (she died in 2007).⁹⁶ The president of the Royal Statistical Society urged that “statistical evidence be presented only by appropriately qualified statistical experts.”⁹⁷ Nobles and Schiff argued for a simpler approach: “[O]ne does not compensate for the misleading evidence; one simply excludes it.”⁹⁸

The *Clark* case led a Queen’s Counsel to raise the issues of susceptibility toward systematic distortion in forensic science, evident in two forms: “inherent bias towards producing a positive outcome or result” and “the tendency for an adversarial system of investigation and trial to lead to partisan behavior,” particularly “when the experts used in the course of investigation are also the experts used in the trial.”⁹⁹ In the 2003 second appeal of the *Clark* case, the pathologist who changed the cause of death for the first brother after the second death and who also withheld evidence that bacteria were found in the cerebral spinal fluid of the second child stated, “‘It is not my practice to refer to additional results in my post mortem unless they are relevant to the cause of death, as the specimens were referred to another consultant.’ The Court did not consider this approach acceptable. . . . It is in effect the expert trying the case and deciding what is relevant evidence, not the court.”¹⁰⁰

Multiple Diseases and Multiple Tests

The terms sensitivity and specificity apply to a simple situation in which disease is present or absent, and a test can be positive or negative, but terminology and interpretation become more complicated when multiple diseases are under consideration and when multiple test results may occur.¹⁰¹ For example, consider blood in the urine (hematuria), which could be caused by a urinary tract infection, a kidney stone, or a bladder cancer, among many other diseases. The terms sensitivity and specificity are no longer appropriate because disease is not simply present or absent. Instead, they are replaced by the term conditional probabilities; that is, sensitivity is replaced by the likelihood of blood in the urine with a urinary tract infection, or with a kidney stone, or with a bladder cancer. Similarly, a very positive test has a different interpretation than a weakly positive test, and Bayes' rule can quantify the difference. Results from multiple tests can be combined with Bayes' rule by applying Bayes' rule to the first test result and then reapplying Bayes' rule to subsequent test results with the post-test probability after the first test becoming the pretest for the second test. This approach assumes that the result of the first test does not affect the test characteristics (sensitivity or specificity) of the second test (i.e., that there is conditional independence of each test). When two tests are available, the screening will usually occur first with the high-sensitivity test to detect a high proportion of those with disease (true positives, or "ruling in" disease). Those with a positive first test will then undergo a high-specificity test to reduce the number of individuals who do not have disease ("ruling out" disease) in those with a false-positive first test.

The choice of whether to do a test will depend on the pretest probability. The basic rule of thumb is to do a test only if it could change the action you would take. With a high pretest probability, you would treat unless a test result would drive the probability to such a low level that you wouldn't treat, which would require a very sensitive test (few false negatives). If the pretest probability is low, you wouldn't treat unless the post-test probability was high, which requires a very specific test (few false positives).

Genomic Analyses

Bayes' rule becomes even more relevant in the genomic-medicine era.¹⁰² Suppose a genetic test has a sensitivity and specificity of 99.9%, and suppose the probability of disease is 1 in 1,000 if a positive family history is present and 1 in 100,000 if no

102. Isaac S. Kohane et al., *The Incidentalome: A Threat to Genomic Medicine*, 296 JAMA 212, 213 (2006), <https://doi.org/10.1001/jama.296.2.212>.

family history is present. Screening 1,000 individuals with a positive family history for the gene results in two positive tests: one individual truly has a disease, and in the other, the test is a false positive. Screening 10 million individuals without a family history results in 10,100 positive tests, of which 100 individuals have a disease and 10,000 do not. Even with a specificity of 99.99%, if a test screens for 10,000 genes simultaneously, then 63% of individuals will have at least one false-positive test result. Based simply on the genetic test results alone, neither individuals nor physicians would be able to distinguish those with true-positive results from those with false-positive results, thereby potentially leading to inappropriate monitoring or treatment for all with positive test results.

Positivity Criterion

The sensitivity and specificity of a quantitative test rely on setting a positivity criterion, a level for determining what is negative or positive for disease. When the criterion is made stricter (a higher level) for a test where higher is more positive, then sensitivity falls and specificity increases, and if the criterion is made laxer (a lower level), then sensitivity rises, and specificity falls. Depending on the context of the testing, it may be more appropriate to choose a laxer criterion (e.g., screening donated blood for HIV infection where the benefit is reducing transfusion-associated HIV transmission, and the harm is discarding some uninfected units of donated blood) or a stricter one (e.g., screening a low-prevalence population for HIV infection where the benefit is reducing false-positive diagnoses from higher specificity, and the harm is missing some truly HIV-infected individuals from lower sensitivity).¹⁰³ Thus the benefits of finding and treating a person with disease versus the risk of harm from mislabeling or treating a person without disease should help establish what should be considered negative or positive.

Bayesian vs. Frequentist Statistics

In a randomized trial, frequentist statistics involve assuming a null hypothesis (no difference between an intervention and control) and then calculating the likelihood of the outcomes observed. For example, using a fair coin (null hypothesis), the likelihood of two heads in a row occurring would be 25% (HT, HH, TH, TT), of three heads in a row 12.5%, of four heads in a row 6.25%, and of five heads in a row 3.125%. The alpha or *p*-value for statistical significance is typically 5%, and some argue that four or five heads in a row would make some suspicious of the coin being unfair. The American Statistical Association has, for

103. Klemens M. Meyer & Stephen G. Pauker, *Screening for HIV: Can We Afford the False Positive Rate?*, 317 NEJM 238, 240 (1987), <https://doi.org/10.1056/NEJM198707233170410>.

the first time, made a statement about statistical practice methods to move away from $p < 0.05$:

Don't believe that an association or effect exists just because it was statistically significant. Don't believe that an association or effect is absent just because it was not statistically significant. Don't believe that your p -value gives the probability that chance alone produced the observed association or effect or the probability that your test hypothesis is true.¹⁰⁴

One of the most highly cited papers in medicine, titled *Why Most Published Research Findings Are False*, states, "It can be proven that most claimed research findings are false. . . . a consequence of the . . . ill-founded strategy of claiming conclusive research solely on the basis of a single study assessed by formal statistical significance, typically for a p -value less than 0.05."¹⁰⁵ When a study finds a surprising result with $p = 0.05$, the overwhelming majority of physicians "will confidently state there is a 95% or greater chance that the null hypothesis is incorrect . . . an understandable but categorically wrong interpretation because the P value" assumes "the null hypothesis is true. It cannot, therefore, be a direct measure of the probability that the null hypothesis is false."¹⁰⁶

Bayesian inference is often described as showing "how belief is altered by data" or "belief calculus" and being subjective, especially when no prior evidence exists, whereas others term it "evidential calculus" by combining the prior odds of the null hypothesis with a Bayes factor as the "weight of the evidence,"¹⁰⁷ for example, from a randomized trial.

The Bayes factor differs in many ways from a P value. First, the Bayes factor is not a probability itself but a likelihood ratio of probabilities, i.e., Probability of the Data, given the null hypothesis divided by the Probability of the Data, given the alternative hypothesis, so it can vary from zero to infinity. It requires two hypotheses, making it clear that for evidence to be against the null hypothesis, it must be for some alternative. Second, the Bayes factor depends on the probability of the observed data alone . . . so we begin to understand what represents strong evidence, and weak evidence . . .¹⁰⁸

Standard frequentist statistical and Bayesian methods have tradeoffs, with standard frequentist methods weakest when drawing conclusions from a single

108. Goodman, *supra* note 107, at 1006.

experiment, whereas Bayesian methods make inductive inference from that experiment. Bayesian methods, however, use prior probability distributions and are imperfect subjective estimates of what is known or unknown, so that over multiple experiments, Bayesians cannot guarantee that their 95% credible intervals (the Bayesian analog of the 95% confidence interval) will hold up. Thus, frequentist criteria can and have been used to evaluate Bayesian and likelihood methods. “Putting *P* values aside, Bayesian and frequentist approaches each provide an essential perspective that the other lacks. The way in which we balance their sometimes conflicting demands is what makes the process of learning from nature creative, exciting, uncertain, and, most of all, human.”¹⁰⁹

Causal Reasoning

While considering risk factors (e.g., age, gender, exposures such as smoking, family history, or medical conditions), physicians will often use any type of evidence¹¹⁰ that might support causation—for example, biological plausibility,¹¹¹ physiological drug effects, case reports, or temporal proximity¹¹² to an exposure.¹¹³ Although physicians use epidemiological studies in their decision-making, “they are accustomed to using *any* reliable data to assess causality, no matter what their source” because they must make care decisions (e.g., treat or not) even in the face of uncertainty.¹¹⁴ This is in contrast to the courts, which require a higher standard than clinicians or regulators; causation cannot just be “possible,” rather “a ‘preponderance of evidence’ establishes that an injury was caused by an alleged exposure.”¹¹⁵ For physicians, causal reasoning typically involves understanding how abnormalities in physiology, anatomy, genetics, or biochemistry lead to the clinical manifestations of disease. Through such reasoning, physicians develop a causal cascade or “chain or web of causation” linking a sequence of plausible cause-and-effect mechanisms to arrive at the pathogenesis or pathophysiology of a disease. For example, kidney failure leads to poor drug

excretion, resulting in symptoms or signs of drug toxicity.¹¹⁶ These causal-reasoning pathways center on disease manifestations to help treating clinicians, who are commonly less concerned with distinguishing causation from association, with diagnosis and treatment (e.g., Sir Austin Bradford Hill's considerations for inferring causation).¹¹⁷

Pattern recognition of concomitant symptoms and signs can trigger a diagnosis. For example, cough, lung lesions, and enlarged breasts (gynecomastia) in a thirty-seven-year-old man could spark the diagnosis of metastatic germ cell cancer.¹¹⁸ More typically, physicians use causal reasoning in diagnostic refinement and verification to examine a diagnosis for its coherency, namely, asking whether its physiological mechanism would be expected to lead to the observed manifestations and whether it adequately accounts for all normal and abnormal findings and the disease time course. Once treatment has been implemented, clinicians must make causal judgments to determine whether alteration in patient status is the result of progression of disease or an adverse consequence of treatment, or whether the absence of improvement results should prompt a change in therapy or even reconsideration of the diagnosis.

Pathophysiological reasoning, however, also can lead to incorrect conclusions. In patients with heart failure with a weakened heart, a class of medications called beta blockers had been thought to be contraindicated because beta blockers would decrease the strength of the heart muscle contraction and slow the then thought to be compensatory increase in heart rate. Subsequent studies found that beta blockers in patients with heart failure actually increased survival without ill effect. Similarly, physicians once thought that atherosclerotic blockages in heart arteries slowly progressed to cause a heart attack, so that revascularizing those plaques through heart bypass surgery would prevent heart attacks.¹¹⁹ Over the past twenty-five years, however, scientific evidence has emerged that small vulnerable atherosclerotic plaques (not amenable to revascularization because of their small size) can suddenly rupture and cause heart attacks. Not surprisingly, revascularization trials involving either bypass surgery or percutaneous interventions such as stenting or angioplasty do relieve symptoms but do not diminish the risk of having a heart attack or improve survival for most patients.¹²⁰

Although treating physicians¹²¹ may testify on both general and specific causation, as with use of evidence for causation, their standards for evidence vary.¹²² For example, some physicians may stop using a drug after the first reports of adverse effects, and others may continue to use a drug despite evidence of harm from randomized controlled trials. Determining whether an effect is a class effect or is drug-specific can be difficult. In a randomized trial limited to patients with documented weakened hearts, one particular beta blocker was found not to confer a survival benefit, and as a result, the heart failure guidelines limited their recommendation to three beta-blocker drugs with documented mortality benefit in trials.¹²³

Treating physicians may be aware of patient-specific risk factors such as smoking or family history but may not routinely review specialized aspects of such data, for example, toxicology, industrial hygiene, environment, and some aspects of epidemiology. Additional experts may assist in distinguishing general from specific causation by using specialized knowledge to weigh the relative contribution of each putative causative factor to determine “reasonable medical certainty” or “reasonable medical probability.” The determination of general causation involves medical and scientific literature review and the evaluation of epidemiological data, toxicological data, and dose–response relationships.

Causal Inference Methods

It is important to recognize that

[S]cientists report that an evaluation of data and scientific evidence to determine whether an inference of causation is appropriate requires judgment and interpretation. Scientists are subject to their own value judgments and preexisting biases . . . although one scientist or group of scientists comes to one conclusion about factual causation, they recognize that another group that comes to a contrary conclusion might still be “reasonable.” Courts, thus, should be cautious about adopting specific “scientific” principles, taken out of context, to

Analysis of Individual Patient Data from Ten Randomised Trials, 373 *Lancet* 1190, 1192 (2009), [https://doi.org/10.1016/S0140-6736\(09\)60552-3](https://doi.org/10.1016/S0140-6736(09)60552-3).

Heidenreich et al., *2022 AHA/ACC/HFSA Guideline for the Management of Heart Failure: A Report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines*, 145 *Circulation* e895, e931 (2022), <https://doi.org/10.1161/CIR.0000000000001062>.

formulate bright-line legal rules or conclude that reasonable minds cannot differ about factual causation.¹²⁴

In an emerging area, “[b]ecause identifying individual causal effects is generally not possible, we now turn our attention to an aggregated causal effect: the average causal effect in a population of individuals.”¹²⁵ Consider, for example, hormone replacement therapy for postmenopausal women. Multiple observational studies using methods such as case-control, cross-sectional, and cohort designs¹²⁶ suggested an association between hormone therapy and reduction in heart attack, but such designs are subject to confounding and bias and are particularly weak for causation because in case-control and cross-sectional studies, the sequence of the exposure and outcome is unknown.

To resolve the question, the Women’s Health Initiative (WHI) study randomized women to hormone replacement therapy or placebo and found a statistically significant increase in harmful clot-related disorders—heart attack, stroke, and heart-related mortality—over five years, but evident in the first year after initiation of hormone therapy.¹²⁷ Heart attacks are caused by blood clots and plaque rupture, and so the results were consistent with the known biological mechanism of estrogens in the clotting cascade. However, patients in the WHI study were, on average, sixty-three years old and therefore not perimenopausal, as were the participants analyzed in the observational studies. In a novel approach, researchers emulated the design and intention-to-treat (ITT) analysis aspect of the WHI randomized trial in the prospective observational Nurses’ Health Study and found that hormone-replacement treatment effects were similar to those from the randomized trial, suggesting that “the discrepancies between WHI and the Nurses’ Health Study ITT estimates could be largely explained by differences in the distribution of time since menopause and length of follow-up.”¹²⁸ These emerging methods for analyzing non-randomized study designs address “[t]he fundamental problem of causal inference . . . that at most one of the potential outcomes can be realized and thus observed” as a consequence of an action (e.g., taking a pill).¹²⁹

Treatment Decision-Making

Treatment Thresholds

Sir William Osler describes medicine as “a science of uncertainty and an art of probability.”¹³⁰ Through diagnostic reasoning, clinicians seek to identify the cause of a patient’s complaints and findings to determine the most appropriate therapy to alleviate symptoms or prolong life—including no therapy, as ineffective therapy carries risk for harm. In 1975, Pauker and Kassirer described the threshold approach to treatment decisions.¹³¹ For a likelihood of a disease ranging from zero (absent) to one (certainty), they determined that the threshold probability of disease above which patients should be treated depended on the benefits and harms of treating patients with and without disease (Figure 4). The benefit (B) equaled the difference in outcomes of treatment in patients with disease minus their outcomes without treatment; the harm (H) equaled the outcomes in patients without disease who are not treated minus their outcomes if treated. The threshold probability equals H divided by (H + B). If the benefit is high, then the threshold for treatment is low (e.g., antibiotics for pneumonia); if the harm is high, greater diagnostic certainty must exist before treatment (e.g., chemotherapy for cancer usually requires tissue diagnosis). For the diagnostic dilemma of a sarcoidosis or tuberculosis case, tuberculosis (TB) treatment would confer a 30% survival benefit with a 0.15% risk of mortality from TB treatment, so the threshold for TB treatment equals $0.15\% / (0.15\% + 30\%) = 0.15\% / 30.15\% = 0.5\%$, far below the 70% estimated likelihood prior to testing by the discussant.¹³²

Testing Decision-Making

Testing Thresholds

When should a test be done? A guiding principle is that a test should be performed only if the test result could change the care plan. Thus, if a positive test moves the post-test probability of disease across the treatment threshold from a pretest probability falling in the no-treat range, it should change the plan from no treat to treat (or conversely with a negative test when the pretest probability falls in the treat range). The no-treat-test threshold is the lowest pretest probability at which the post-test probability equals the treatment threshold. When a post-test probability does not cross an action threshold, generally it should not be done.

In 1980, Pauker and Kassirer extended their threshold approach to treatment decisions by defining conceptual thresholds for testing (Figure 5).¹³³ They determined that the threshold probabilities at which patients should be tested or treated (or neither) depended on treatment benefit (B) and harm (H) in patients with and without disease but also the sensitivity and specificity of the test as calculated by the likelihood-ratio positive ($LR+ = \text{sensitivity} / (1 - \text{specificity})$) and likelihood-ratio negative ($LR- = (1 - \text{sensitivity}) / \text{specificity}$). The test threshold above which testing should be done equals $H / (H + (LR+) \times B)$. Because $LR+$ increases the likelihood of disease, it always exceeds one, so it magnifies the benefit of treatment and makes the test threshold lower than the treat threshold. Similarly, the $LR-$ is always less than one, so it reduces benefit, thereby raising the test-treatment threshold above the treatment threshold.¹³⁴ In the diagnostic dilemma of TB or sarcoidosis, the $LR-$ for a negative TB skin test (for TB) is 0.26 (0.25/0.95), yielding a test-treatment threshold of 1.9%, and the $LR-$ for an abnormal angiotensin-converting enzyme (ACE) blood test is 0.06 (0.05/0.8), yielding a test-treatment threshold of 7.4%, and even with both $LR-$ tests, the test-treatment threshold rises only to 23% with the discussant's 70% estimate exceeding all three of these thresholds, supporting empiric TB treatment. In summary, the treatment-threshold probability and the $LR-$ and $LR+$ of the test divide the probability scale into three parts: no treat, test, and treatment. If the pretest probability is known, the preferred next step can be identified.

$$\text{Test–Treatment Threshold} = \frac{\text{Harm}}{\text{Harm} + (\text{LR}–) \times \text{Benefit}}$$

Screening

As articulated by Wilson and Jungner for the World Health Organization in 1968,

[t]he object of screening for disease is to discover those among the apparently well who are in fact suffering from disease. They can then be placed under treatment and, if the disease is communicable, steps can be taken to prevent them from being a danger to their neighbours. In theory, therefore, screening is an admirable method of combating disease, since it should help detect it in its early stages and enable it to be treated adequately before it obtains a firm hold on the community.¹³⁵

But as they also note, “[i]n practice, there are snags.”¹³⁶

Decades ago, routine screening tests included ordering anywhere from six to twelve blood tests as part of an annual visit in asymptomatic patients. Normal ranges for biochemical tests are often based on the 95% confidence intervals in a healthy population. By convention, values outside the 2.5% lower and upper extremes are considered to be abnormal, so ordering six blood tests in a healthy individual yields a 74% chance that all six tests will be normal (0.95⁶), that is, a 26% chance that one or more tests may be abnormal, assuming each test is independent of the others. Similarly, when ordering twelve tests in a normal person, there is a 54% chance that all twelve will be normal, so a 46% chance that one or more will be abnormal. Simply ordering tests in healthy individuals in the absence of clinical suspicion of a disease may result in many false-positive test

135. J.M.G. Wilson & G. Jungner, Principles and Practice of Screening for Disease No. 34, at 7, https://iris.who.int/bitstream/handle/10665/37650/WHO_PHP_34.pdf.

136. *Id.*

results that can lead to false alarms, anxiety, additional testing, and possible morbidity or mortality from subsequent testing or interventions.¹³⁷

Even a valueless screening test may appear to be beneficial because of lead-time bias. That is, if screened and unscreened patients have the same prognosis from the time of onset of symptoms to death, screened patients only appear to live longer because the time elapsed from diagnosis by screening to death exceeds the time elapsed from time of symptom onset to death.¹³⁸ A second bias, length bias, also leads to overestimating the benefit from screening.¹³⁹ A randomized trial of screening or no screening is conducted over a limited duration from study initiation to termination. Among the unscreened patients, disease only becomes evident through the development of symptoms, which would be more likely with the aggressive form of the disease, conferring a poorer prognosis for these patients. Among the screened patients, the screening test detects patients with both aggressive and indolent forms of the disease. Some of the patients with indolent cancer may not develop symptoms until after the trial ends. These slower growing cases can make the patients detected by screening appear to live longer, enriching the prognosis of the screening group with those patients with indolent cancers.

Screening can also result in pseudo-disease or overdiagnosis, such as the identification of slow-growing cancers that, even if untreated, would never cause symptoms or reduce survival.¹⁴⁰ Although lung cancer is commonly thought to be one of the more aggressive cancers, an autopsy study found that one-third of lung cancers were unsuspected prior to autopsy, and nearly all of these patients with unsuspected lung cancer prior to autopsy died from other causes.¹⁴¹ The lifetime risk of dying from prostate cancer is about 3%, yet 60% of men in their sixties have prostate cancer, and so, screening and detecting all men with prostate cancer in their sixties would lead to the treatment of many men who would not have died from prostate cancer.¹⁴²

137. A radiologist described his own experience to illustrate the clinical aphorism that “the only ‘normal’ patient is one who has not yet undergone a complete work-up.” He had a negative CT scan of the colon, but the CT scan also provided images outside the colon with radiologists identifying lesions in the kidneys, liver, and lungs. This resulted in additional CT scans, a liver biopsy, PET scan, video-aided thoracoscopy (a flexible scope inserted into the chest), and three wedge resections of the lung leading to multiple tubes, medications, and “excruciating pain” that required five weeks for recovery. William J. Casarella, *A Patient’s Viewpoint on a Current Controversy*, 224 *Radiology* 927 (2002), <https://doi.org/10.1148/radiol.2243020024>.

Diagnostic Testing

Based on patients' history and physical examination, clinicians establish diagnostic possibilities. They may then request additional tests to reduce uncertainty and to confirm the diagnosis as part of diagnostic verification. Although theoretically all tests could be ordered, tests should be chosen based on a clinical suspicion because of possible morbidity or even mortality from inappropriate testing. Normative, prescriptive decision models for reasoning in the presence of uncertainty suggest that whether and which tests get ordered should depend on test sensitivity and specificity and the benefit and harm of treatment as discussed in the section titled "Diagnostic Reasoning" above; when testing carries risks for morbidity or mortality harms, the probabilities of disease for which testing should be done become narrower, and so physicians should be more likely to treat empirically or neither test nor treat.¹⁴³ As sensitivity and specificity increase, the range of probabilities in which testing should be done expands.

Although an abnormal test result may be found, that abnormality may not be causing symptoms. For example, herniated lower back (lumbar spine) discs are found in approximately 25% of healthy individuals without back pain as an incidental finding. If signs such as a foot drop develop, additional muscle and nerve conduction studies could confirm evidence of nerve compromise from the herniated disc, but such tests are painful. Over time, sequential images show that herniated discs have a partial or complete resolution after six months without surgery as the disc shrinks. Therefore, a herniated disc may be seen with CT or MRI scanning in patients with or without symptoms, so just having symptoms and evidence of a herniated disc would not be a sufficient indication for back surgery.¹⁴⁴ In the absence of severe or progressive neurological deficits, elective disc surgery could be considered for patients with probable herniated discs who have persistent symptoms and findings consistent with sciatica (not just low back pain) for four to six weeks, but such "patients should be involved in decision making" (see section titled "Patient care" below).¹⁴⁵

Tests initially felt to be useful may be found to be less valuable over time.¹⁴⁶ Among other potential biases,¹⁴⁷ this may occur because of the choice of the

study population used to determine the test's sensitivity and specificity. For example, an FDA-approved rapid test for HIV infection has a reported specificity of 100%, implying that any positive tests must indicate truly infected individuals, yet one of the populations in which testing is recommended is women who have had prior children and are in labor but have not yet had an HIV test during the pregnancy.¹⁴⁸ In fifteen multiparous women, this rapid HIV test resulted in one false-positive test result, yielding a specificity of 93%,¹⁴⁹ and so not all pregnant women with positive rapid HIV tests can be assumed to be truly infected.

Biomarker or Image Testing

Once a diagnosis has been established, additional biomarker testing may be performed to establish the extent of disease (e.g., staging of cancer), monitor response to therapy, or direct treatment. In women with breast cancer, for example, finding a genetic marker called the human epidermal growth factor receptor type 2 (HER2, also called HER2/neu) gene identified patients who responded poorly to any of the standard chemotherapeutic agents resulting in a poor prognosis. Illustrative of the era of pharmacogenomics, adjuvant chemotherapy combined with a monoclonal antibody in HER2-positive breast cancer patients has been found to delay progression and prolong survival.¹⁵⁰ For the treatment of lymphomas, monitoring of disease response can be done through imaging. The lack of response has been used to indicate treatment failure and to recommend a change in chemotherapy.

Variation and Standards in Medicine

Variation in Medical Care

Studies over the past several decades show substantial geographic variation in the utilization rates for medical care within small areas or local regions (e.g., a twelve-fold variation in the use of tonsillectomy in rural Vermont) and between large areas or widespread regions (e.g., a four- to five-fold variation in the performance of other discretionary surgical procedures such as hip replacement, coronary

bypass surgery, and prostatectomy, among others).¹⁵¹ Even when limiting the analysis to seventy-seven U.S. hospitals with reputations for high-quality care in managing chronic illness, the care that patients received in their last six months of life varied extensively, ranging from hospital stays of nine to twenty-seven days (three-fold variation), intensive-care unit stays of two to ten days (five-fold variation); and physician visits of eighteen to seventy-six (four-fold variation), depending on the hospital at which patients received their care.¹⁵²

Four categories of variation are recognized: (1) underuse of effective care, (2) issues of patient safety, (3) concern for preference-sensitive care, and (4) notions of supply-sensitive services.¹⁵³ Effective care refers to treatments that are known to be beneficial and that nearly all patients should receive with little influence of patient preferences—for example, the use of beta blockers following myocardial infarction. The underuse of effective care was illustrated by one prominent study that identified 439 high-quality process measures for 30 conditions and preventive care. In assessing the use of measures that were clearly recommended (i.e., clearly beneficial), they found that only about 50% of patients received these highly recommended care processes.¹⁵⁴ Issues of patient safety refer to the execution of care and the occurrence of iatrogenic complications (i.e., complications resulting from healthcare interventions). The IOM emphasized that “[g]etting the right diagnosis is a key aspect of healthcare: it provides an explanation of a patient’s health problem and informs healthcare decisions,” yet “[i]t is likely that most of us will experience at least one diagnostic error in our lifetime, sometimes with devastating consequences.”¹⁵⁵ Concern for preference-sensitive care refers to treatment choices that should depend on patient health goals or preferences.¹⁵⁶ Prostate surgery helps relieve symptoms of an enlarged prostate (such as frequent urination and waking up at night to urinate) but carries a risk of losing sexual function. Separate from the probability of losing sexual function, in preference-sensitive care, the decision to have prostate surgery depends on how much the enlarged prostate symptoms bother the patient and on how important sexual function is to them, that is, it depends on their preferences and values.¹⁵⁷ Finally,

supply-sensitive services refer to care that depends not on evidence of effectiveness or patient preferences but rather on the availability of services. Specifically, patients living in areas with more doctors or more hospitals experience more office visits, tests, and hospitalizations.¹⁵⁸

Evidence-Based Medicine

The variation in the delivery of medical care led to a careful reexamination of diagnostic strategies, therapeutic decision-making, and the use of medical evidence, but it was not the only factor. Other circumstances that set the stage for an intense focus on medical evidence included (1) the development of medical research, including randomized controlled trials and other observational study designs; (2) the growth of diagnostic and therapeutic interventions;¹⁵⁹ (3) interest in understanding medical decision-making and how physicians reason;¹⁶⁰ and (4) the acceptance of meta-analysis as a method to combine data from multiple randomized trials.¹⁶¹ In response to the above conditions, evidence-based medicine gained prominence in 1992,¹⁶² defined by Sackett et al. as “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of the individual patient. It means integrating individual clinical expertise with the best available external clinical evidence from systematic research.”¹⁶³

Evidence-based medicine contrasts with the traditional informal method of practicing based on anecdotes, applying the most recently read articles, doing what a group of eminent experts recommend, or minimizing costs.¹⁶⁴ Rather,

per Greenhalgh, it is “the use of mathematical estimates of the risks of benefit and harm, derived from high-quality research on population samples, to inform clinical decision making in the diagnosis, investigation or management of individual patients.”¹⁶⁵ In a paper from a joint workshop held by the IOM and the Agency for Healthcare Research and Quality that addressed what clinicians consider to be sufficient evidence to justify their clinical practice and treatment decisions, Mulrow and Lohr wrote, “evidence-based medicine stresses a structured critical examination of medical research literature; relatively speaking, it deemphasizes average practice as an adequate standard and personal heuristics.”¹⁶⁶

Hierarchy of Medical Evidence

With the explosion of available medical evidence, increased emphasis has been placed on assembling, evaluating, and interpreting medical research evidence. A fundamental principle of evidence-based medicine is that the strength of medical evidence supporting a therapy or strategy is hierarchical (see also section titled “Uncertainty and Tradeoffs in Therapeutic Decision-Making Evidence” below). When ordered from strongest to weakest, a systematic review of randomized trials (meta-analysis) is at the top, followed by single randomized trials, systematic reviews of observational studies, single observational studies, physiological studies, and unsystematic clinical observations.¹⁶⁷ An analysis of the frequency with which various study designs are cited by others provides empirical evidence supporting the influence of meta-analysis followed by randomized controlled trials in the medical evidence hierarchy.¹⁶⁸ Although they are at the bottom of the evidence hierarchy, unsystematic clinical observations or case reports may be the first signals of adverse events or associations that are later confirmed with larger or controlled epidemiological studies (e.g., aplastic anemia caused by chloramphenicol¹⁶⁹ or lung cancer caused by asbestos¹⁷⁰). Nonetheless, subsequent studies may not confirm initial reports (e.g., the putative

novel association between coffee consumption and pancreatic cancer published in a prominent medical journal).¹⁷¹

Just as basic science findings require repeated confirming experiments, evidence about the benefits and harms of medical interventions arise through repetitive observations. A single randomized controlled trial relies on hypothesis testing, specifically assuming the null hypothesis that a new drug is equivalent to the comparator (e.g., placebo). As conceived about 100 years ago, interpreting a trial involves calculating the likelihood of the alpha error (p -value) wherein the study suggests that the drug or device is beneficial, but the “truth” is that it is not, that is, a false-positive study result. Similarly, a beta error is the likelihood of a study finding that the drug or device is not beneficial when the “truth” is that it is, that is, a false-negative study result (1 minus power, where power is the likelihood of a study finding that the drug or device is not beneficial and the truth aligns with that finding).

The choice of which specific error rates to use (e.g., false-positive or p -value or alpha of 0.05) was supposed to depend on a judgment of the relative consequences of the two errors, missing an effective drug (Type II beta error) or considering an ineffective drug to be effective (Type I alpha error) with a stricter (lower) error rate for the latter.¹⁷² The null hypothesis, however, assumes equivalence, and so it does not provide any measure of evidence outside of the particular study (e.g., prior studies or biological mechanism or plausibility). Thus, the null hypothesis assumption necessitates abandoning the ability to measure evidence or determine “truth” from a single experiment so that hypothesis testing is thereby “equivalent to a system of justice that is not concerned with which individual defendant is found guilty or innocent (that is, ‘whether each separate hypothesis is true or false’) but tries instead to control the overall number of incorrect verdicts” over time in the long run.¹⁷³

Cumulative meta-analysis of treatments enables the accumulation of randomized trial evidence to examine trends in efficacy or risks, overcoming issues of underpowered trials with insufficient numbers of patients enrolled to reliably detect a benefit.¹⁷⁴ For example, between 1959 and 1988, 33 randomized trials with streptokinase for acute heart attack (myocardial infarction) involving over 35,000 patients were published. As each trial is published, it is combined with all previously published trials. A cumulative meta-analysis found “a consistent, statistically significant reduction in total mortality” $p < 0.001$ with streptokinase use by 1977, yet an additional 32,600 individuals

underwent randomization through 1988, with half receiving the inferior placebo. In contrast, for many years, physicians used a prophylactic drug called lidocaine to prevent life-threatening heart-rhythm disturbances from acute heart attacks, yet none of the randomized trials of lidocaine demonstrated any benefit, and finally, the cumulative meta-analysis found a trend toward harm. When the results of the meta-analysis were compared with comments in textbooks and review articles,

discrepancies were detected between the meta-analytic patterns of effectiveness in the randomized trials and the recommendations of reviewers [the review article authors]. Review articles often failed to mention important advances or exhibited delays in recommending effective preventive measures. In some cases, treatments that have no effect on mortality or are potentially harmful continued to be recommended by several clinical experts.¹⁷⁵

Guidelines

Clinical-practice guidelines are “systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances.”¹⁷⁶ Such guidelines have been widely developed and issued by medical-specialty associations, professional societies, government agencies, and healthcare organizations.¹⁷⁷ To avoid biases inherent in review articles (particularly single-authored ones) and to encourage transparency and acceptance, the IOM recommended best practices for the development of clinical-practice guidelines, including process transparency, management of conflict of interest, guideline group composition (multidisciplinary and balanced), systematic reviews that meet IOM standards, evidence foundation for rating the strength of the recommendations, recommendation articulation, external review, and updating.¹⁷⁸

The number, length, and diversity of guidelines developed by various professional organizations challenge practicing physicians.¹⁷⁹ Different professional organizations may issue guidelines on the same topic but with competing or similar recommendations. The composition of the panel and the processes for developing guideline recommendations may differ. For example, the United States Preventive Services Task Force (USPSTF) is “an independent panel of non-Federal experts in prevention and evidence-based medicine and is composed of primary care providers (such as internists, pediatricians, family physicians, gynecologists/obstetricians, nurses, and health behavior specialists).”¹⁸⁰ In their 2016 evaluation of mammography, the USPSTF “recommends biennial screening mammography for women aged 50 to 74 years” but “[t]he decision to start screening mammography in women prior to age 50 years should be an individual one.”¹⁸¹ In contrast, based on a writing group composed of radiologists, the American College of Radiology and Society of Breast Imaging recommend “annual mammography screening beginning at age 40” for all women at average risk.¹⁸²

For prostate cancer screening, however, the USPSTF’s 2018 update stated, “For men aged 55 to 69 years, the decision to undergo periodic PSA-based screening for prostate cancer should be an individual one and should include discussion of the potential benefits and harms of screening with their clinician.”¹⁸³ In the 2013 American Urological Association update, a statement panel composed of urologists, primary care physicians, radiation and medical oncologists, and epidemiologists “recommended shared decision-making for men age 55 to 69 years considering PSA-based screening, a target age group for whom benefits may outweigh harms”—essentially identical recommendations.

Practice guidelines provide recommendations on how to evaluate and treat patients, but because they apply to the general case, their recommendations may not apply to a particular individual patient—or some extrapolation may be required, particularly when multiple diseases exist, as in the elderly,¹⁸⁴ or when

treatment entails competing risks of harm. For example, anticoagulation is generally recommended for patients with atrial fibrillation (an abnormal heart rhythm disturbance) to prevent blood clots in the heart that could flow to the brain and cause a stroke, yet anticoagulation can also lead to life-threatening bleeding; therefore, for individual patients, physicians must weigh the risk of developing clots versus the risk of bleeding. Consequently, guidelines typically include statements such as “clinical or policy decisions involve more considerations than this body of evidence alone. Clinicians and policymakers should understand the evidence but individualize decision-making to the specific patient or situation.”¹⁸⁵

Some physicians who rely on personal style, review articles, and colleagues to influence their clinical practice have been concerned with how guidelines affect clinical autonomy and healthcare costs.¹⁸⁶ But just as clinicians have been reluctant to apply guidelines in practice, courts have generally been slow to apply them in deciding cases.¹⁸⁷ Political and legal issues have arisen with the development of guidelines.¹⁸⁸ In 2006, the Connecticut attorney general launched an antitrust suit against the Infectious Disease Society of America (IDSA) after IDSA promulgated a guideline recommending against the use of long-term antibiotics for the treatment of chronic Lyme disease.¹⁸⁹ Although the findings of the Centers for Disease Control and Prevention and the Food and Drug Administration (FDA) seemed to concur with IDSA’s guidelines, an advocacy group representing patients afflicted with chronic Lyme disease and the physicians who treated them protested; the attorney general’s decision to investigate followed shortly afterwards.¹⁹⁰ Organizations can violate antitrust laws if their guideline-setting process is an unreasonable attempt to advance their members’ economic interests by suppressing competition. After legal expenses that exceeded \$250,000, IDSA settled without admitting any fault, providing an example of

“the politicization of health policy, with elected officials advocating for health policies against the weight of scientific evidence.”¹⁹¹

Besides clinical practice guidelines, the IOM defined other types of statements: (1) medical review criteria are systematically developed statements that can be used to assess the appropriateness of specific healthcare decisions, services, and outcomes; (2) standards of quality are authoritative statements of minimum levels of acceptable performance or results, excellent levels of performance or results, or the range of acceptable performance or results; and (3) performance measures are methods or instruments to estimate or monitor the extent to which the actions of a healthcare practitioner or provider conform to practice guidelines, medical review criteria, or standards of quality.¹⁹²

Uncertainty and Tradeoffs in Therapeutic Decision-Making Evidence

Medical decision-making often involves complexity, uncertainty, and tradeoffs¹⁹³ because of unique genetic factors, lifestyle habits, known conditions, medication histories, and ambiguity about possible diagnoses, test results, treatment benefits, and therapeutic harms. Given inherent diagnostic and therapeutic uncertainty, clinicians often make treatment decisions in the face of uncertainty.

Well-performed randomized trials provide the least biased estimates of treatment benefit and harm by comparing groups with equivalent prognoses. Sticking strictly to the scientific evidence, some physicians may limit their use of medications to the specific drug at the specific doses found to be beneficial in such trials. Others may assume class effects (drugs with similar structure, mechanism of action, or pharmacologic effects, e.g., lowering blood pressure) until proven otherwise. Others may consider additional factors such as out-of-pocket costs for patients or patient preferences. When physicians evaluate patients who might benefit from a treatment but who would have been excluded from the study in which the benefit was demonstrated, they must weigh the risks of harm and benefits through extrapolation in the absence of definitive evidence of benefit or of harm. Indeed, because few medical recommendations are based on randomized trials (the least biased level of evidence), physicians frequently and necessarily face uncertainty in making testing and treatment decisions. For example, in an academic pediatric cardiology hospital, only 3% of clinically

significant decisions are related to a specific study.¹⁹⁴ In most disciplines, clear evidence of efficacy and risks of treatment are lacking. In cardiology (one of the best-studied areas of medical care), nearly one-half of guideline recommendations are based on expert opinion, case studies, or standards of care.¹⁹⁵

Applying well-designed studies to populations of patients represents another problem. The Randomized Aldactone Evaluation Study demonstrated that spironolactone reduced mortality and hospitalizations for heart failure and improved quality of life with minimal risk of seriously high levels of potassium (hyperkalemia).¹⁹⁶ Published in a prominent medical journal, prescriptions for spironolactone rose quickly because of familiarity with the medication and the poor prognosis of patients with heart failure. In Ontario, hospitalizations per 1,000 patients for high potassium, however, rose from 2.4 in 1994 to 11.0 in 2001, resulting in an estimated 560 additional hospitalizations for high potassium and 73 additional hospital deaths in older patients with heart failure.¹⁹⁷ As opposed to the study population, community individuals were older, and more frequently women, and more often had absolute or relative contraindications to treatment with only 25% characterized as ideal candidates for spironolactone.¹⁹⁸ These factors increased the risk that spironolactone therapy would lead to high potassium levels that could be life-threatening. Criteria for entry into randomized trials of drugs typically exclude individuals with concomitant medication use, with medical comorbidities, who are female, and who have disadvantaged socioeconomic status, thereby limiting the ability to generalize the results of a trial to the clinical population being treated.¹⁹⁹ Clinicians refer to randomized controlled studies as assessments of drug efficacy in restricted patient populations, whereas studies of treatment in general clinical populations are often referred to as effectiveness studies.

To be sufficiently powered (i.e., to have enough patients enrolled to avoid Type II error) to demonstrate statistical significance,²⁰⁰ randomized controlled trials

usually require high event rates, prolonged follow-up, or large numbers of patients. Because of impracticality, expense, and the time period needed to obtain long-term outcomes, these trials may often choose a surrogate marker that is associated with a clinically important event or with survival. For example, statins were approved on the basis of their safety and efficacy in lowering cholesterol but were only demonstrated to improve survival in patients with known coronary heart disease years later.²⁰¹ Fast-track approval of new drugs for HIV infection was based on safety and efficacy in reducing viral levels (as a surrogate or substitute outcome measure felt to be related to survival) as opposed to a demonstration of improved survival.

On the other hand, in the late 1970s, patients with frequent extra heartbeats (ventricular premature contractions) following a heart attack had an increased risk of sudden death. On that basis, those in the then-emerging field of cardiac electrophysiology believed that reducing ventricular premature beats (as a surrogate outcome measure) would decrease subsequent sudden cardiac death. In early randomized controlled trials, oral antiarrhythmic drugs such as encainide and flecainide were approved by the FDA on the basis of their ability to suppress these extra heartbeats in patients who had had a myocardial infarction. Years after approval of these drugs, however, a randomized controlled trial designed to demonstrate the survival benefit of these drugs was discontinued after only ten months because of a statistically significant higher rate of mortality in patients receiving the drugs. Although these drugs effectively suppressed the extra heartbeats, the study found that they actually increased the likelihood of fatal heart rhythm disturbances.²⁰²

Prior to approval by the FDA, drugs and devices must undergo Phase 1, 2, and 3 clinical trials to demonstrate safety and efficacy. Following preliminary chemical discovery, toxicology, and animal studies, Phase 1 studies examine the safety of new drugs in healthy individuals. Phase 2 studies involve varying drug doses in individuals with the disease to explore efficacy and responses and adverse effects. Based on the dose or doses identified in Phase 2, a Phase 3 study examines drug response in a larger number of patients to again determine safety and efficacy in the hope of getting a new drug approved for sale by regulatory authorities. However, because fewer than 10,000 individuals have usually received the drug during most trials, uncommon adverse outcomes may not become apparent until usage is broadened and extended. For example, about 1 in 24,200, or

40,500, patients who received the antibiotic chloramphenicol²⁰³ developed fatal aplastic anemia (in which the bone marrow no longer produces any blood cells). This adverse effect was discovered only in the 1960s after chloramphenicol was initially considered safe and had been widely used during the 1950s.²⁰⁴

For all approved drug and therapeutic biological products, the FDA managed postmarketing safety surveillance beginning in 1969 through the Adverse Event Reporting System, a voluntary reporting system with many limitations. For example, in 1999, rofecoxib (Vioxx), a Cox-2 selective nonsteroidal anti-inflammatory drug (NSAID), was approved for pain relief in part on the basis of studies that suggested that it induced less gastrointestinal bleeding than other NSAIDs. In 2004, the manufacturer announced a voluntary worldwide withdrawal of rofecoxib when a prospective study confirmed that the drug increased the risk of myocardial infarctions (heart attacks) and stroke with chronic use.²⁰⁵ Beginning in 2014 and officially in 2016, the FDA began Active Postmarket Risk Identification and Analysis (ARIA) with the development of the Sentinel Initiative to analyze real-world safety data through “the largest multisite distributed database in the world dedicated to medical product safety” that involves big data from twenty-five academic, health-system, and health-insurer collaborators with experience and expertise in epidemiology, clinical medicine, pharmacy, statistics, health informatics, and data science (natural language processing and machine learning).²⁰⁶

Even in a randomized trial in which a drug is found to be beneficial, some patients who received the drug may have been harmed, emphasizing the need to individualize the balancing of risks of harm and benefits and explaining in part why some clinicians may not adhere to guideline recommendations. The fundamental dilemma was articulated by Bernard in 1865: The response of the “average” patient to therapy is not necessarily the response of the patient being treated.²⁰⁷ Indeed, the average results of clinical trials do not apply to all patients in the trial; this is called heterogeneity of treatment effects²⁰⁸ wherein even with well-defined inclusion and exclusion criteria, variation in outcome risk, and therefore treatment benefit, exists so that even “typical” patients included in the trial may not get the average observed trial benefits.

The Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries Trial is a case in point. The trial suggested that accelerated tissue

plasminogen accelerator (tPA), a potent anticoagulant, reduced mortality from acute heart attacks (myocardial infarction) by dissolving blood clots, with the tradeoff being an increased risk of bleeding in the brain from tPA.²⁰⁹ In a reanalysis of this study, most (85%) of the survival benefit of tPA accrued to half of the patients (those at highest risk of dying from their heart attack). Some patients with very low risk of dying from their heart attack who received tPA were likely harmed because their risk of bleeding in their brain exceeded the benefit.²¹⁰ Therefore, to optimize treatment decisions in practice, clinicians may attempt to individualize treatment decisions based on their assessment of the patient's risk of harm versus benefit. Even then, clinicians may be reluctant to administer a medication such as tPA that can cause severe harm, such as bleeding into the brain (intracranial hemorrhage). A single clinical experience with a patient who bled when given tPA might well color a clinician's judgment about the benefits of the treatment going forward (the availability heuristic).

A fundamental principle of evidence-based medicine is that “[e]vidence alone is never sufficient to make a clinical decision.”²¹¹ Nearly all medical decisions involve some tradeoff between a benefit and a harm. Besides the options and the likelihood of the outcomes, patient preferences about the resulting outcomes should affect care choices, especially when there are tradeoffs, such as a risk of complications or dying from a procedure or treatment versus some benefit such as living longer (provided the patient survives the short-term risk of the procedure) or improving their quality of life (relieving symptoms). Besides individualizing risk of harm and benefit assessments, clinicians may also deviate from guideline recommendations (warranted variation) because of a particular patient's higher risk of adverse events or lower likelihood of benefit or because of patient preferences for the alternative outcomes, such as when risks occur at different times. For example, given a hypothetical choice between living 12.5 years for certain or a 50:50 chance of living 25 years or dying immediately, most individuals would choose 12.5 years. Although both options yield, on average, 12.5 years, individuals tend to be risk averse and prefer to avoid the near-term risk of dying. When interviewed, some patients with operable lung cancer were quite averse to possible immediate death from surgery, and so, based on their

preferences, these patients probably should opt for radiation therapy despite its poorer long-term survival.²¹²

Besides risk aversion, some treatments may improve quality of life but place patients at risk for shortened life expectancy, and some patients may be willing to trade off quality of life for length of life. When presented with laryngeal cancer scenarios, some volunteer research subjects chose radiation therapy over surgery to preserve their voices despite a reduced likelihood of future survival. “These results suggest that treatment choices should be made on the basis of patients’ attitudes toward the quality as well as the quantity of survival.”²¹³

To illustrate this principle, a National Institutes of Health Consensus Conference recommended breast-conserving surgery when possible for women with Stage I and II breast cancer, because well-designed studies with long-term follow-up on thousands of women demonstrated equivalence of lumpectomy and radiation therapy or mastectomy for survival and disease-free survival (being alive without breast cancer recurrence).²¹⁴ In one study, lumpectomy and radiation appeared to have a lower risk of breast cancer recurrence, with five women reported to have had breast cancer recurrences following lumpectomy and radiation versus ten women after mastectomy.²¹⁵ However, breast cancer that recurred in the breast that had been operated on was censored (i.e., deliberately not considered in the statistical analysis, likely because the breast would have been removed with the alternative intervention mastectomy).²¹⁶ When including these censored cancer recurrences, 20 breast cancer recurrences occurred after lumpectomy versus ten after mastectomy, and so lumpectomy actually had a higher overall risk of recurrence.²¹⁷ As expressed by one woman, “The decision about treatment for breast cancer remains an intensely personal one. The mastectomy I chose . . . felt a lot less invasive than the prospect of six weeks of daily radiation, not to mention the 14% risk of local recurrence.”²¹⁸ In such a case,

patient preferences²¹⁹ about tradeoffs involving breast preservation and increased risk of breast cancer recurrence or the need for radiation therapy associated with lumpectomy may play an important role in determining the optimal decision for any particular patient.²²⁰

Biases

Cognitive psychology

In *Predictably Irrational: The Hidden Forces That Shape Our Decisions*, Dan Ariely refers to

the simple and compelling idea that we are capable of making the right decision for ourselves. . . . In fact, this book is about human *irrationality*—about our distance from perfection. . . . Understanding irrationality is important for our everyday actions and decisions, and for understanding how we design our environment and the choices it presents to us.²²¹

Beyond the cognitive biases associated with heuristics (representativeness, availability, and anchoring, mentioned earlier) and patient- and hospital-related factors leading to medical errors, medical decision-making is susceptible to pitfalls related to other cognitive biases, including framing effects (being influenced by wording and context, e.g., choosing riskier options when described in negative terms such as mortality), blind obedience (deference to authority or technology), number of alternatives (choosing one treatment more often when presented with additional options), premature closure (focusing narrowly on a single opinion), and personality traits such as tolerance of ambiguity or overconfidence.²²² A systematic review of cognitive biases in medical decisions made by physicians found that at least one cognitive factor or bias was present in every study, with five of seven studies showing an association with medical errors.²²³ Lastly, an

emerging area concerns noise, that is, variability in judgments that should be identical. Specifically, different physicians do not make identical decisions for the same patient; this noise was especially high in psychiatry but found even in radiology (with, among other examples, forensic science and bail decisions): “Whenever you look at human judgments, you are likely to find noise [random scatter]. To improve the quality of our judgments, we need to overcome noise as well as bias [systematic deviation].”²²⁴

Race and ethnicity

Beyond the biases associated with the types and severity of the diseases that physicians may see, the 2003 IOM report *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care* found that “[r]acial and ethnic minorities tend to receive a lower quality of healthcare than non-minorities, even when access-related factors, such as patients’ insurance status and income, are controlled. The sources of these disparities are complex, are rooted in historic and contemporary inequities, and involve many participants at several levels, including health systems, their administrative and bureaucratic processes, utilization managers, healthcare professionals, and patients.”²²⁵ Evidence of barriers leading to unequal treatment included access (even when equally insured), language, geography, cultural familiarity, health-system financial and institutional arrangements, and legal, regulatory, and policy environments.²²⁶ These health inequities arose from a “historic context in which healthcare has been differentially allocated on the basis of social class, race, and ethnicity.”²²⁷ Although this report is more than 20 years old, a 2021 study examining screening colonoscopy found consistent evidence of inequities including access to screening, the quality of screening, delay from diagnosis to initiation of treatment, and quality of treatment.²²⁸ Thus, criticism of the inclusion of race in prediction models (referred to as clinical algorithms) arose in major journals because “medicine is not a stand-alone institution immune to racial inequities, but rather is an institution of structural racism. A pervasive example of this participation is race-based medicine, the system by which research characterizing race as an

essential biological variable, translates into clinical practice, leading to inequitable care”;²²⁹ “[t]hese algorithms propagate race-based medicine”;²³⁰ and “[r]ace is a historically derived social construct that has no place as a biological proxy.”²³¹

Estimating kidney function with race and without

One area of focus became the estimation of kidney function and reconsidering whether the equation for estimating the glomerular filtration rate (GFR) should include race. The inclusion of race historically led to higher values of kidney function for people who are black. Those higher values could avoid overdiagnosis and overtreatment but could also delay referral to specialty care and transplantation and result in poorer health outcomes, particularly in a population at higher risk for end-stage kidney disease and related mortality than the general population.²³² Others have raised performance and data issues including validation, overall and within-group accuracy, availability of assays, and equation parameters in patients who are black.²³³

In response, the National Kidney Foundation and American Society of Nephrology created the NKF-ASN Task Force on Reassessing the Inclusion of Race in Diagnosing Kidney Disease. The task force, including ninety-seven experts with input from the community at large (students, trainees, clinicians, scientists, other health professionals, patients, family members and other public stakeholders), clarified the problem and evidence, narrowed the list of twenty-six approaches that did or did not consider race for estimating GFR to five, and evaluated those on “assay availability and standardization; implementation; population diversity in equation development; performance compared to measured GFR; consequences to clinical care, population tracking and research; and patient centeredness.”²³⁴ They ultimately recommended immediate implementation of a CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) creatinine equation that was revised by excluding the race variable in calculation and reporting based on “acceptable performance characteristics

and potential consequences that do not disproportionately affect any one group of individuals.”²³⁵

Algorithms as standards

Beyond estimating kidney function, prediction algorithms and risk scores have become embedded in some guidelines to help clinicians to individualize treatment decisions—for example, for recommending a statin based on estimating a 10-year risk of having a stroke or heart attack with the American College of Cardiology/American Heart Association (ACC/AHA) Pooled Cohort Equations.²³⁶ However, studies suggest that these equations overpredict (higher estimates than those observed) in broad populations and underpredict (lower estimates than those observed) in disadvantaged communities. Moreover, the ACC/AHA, the U.S. Preventive Services Task Force, and the U.S. Department of Veterans Affairs each have different ten-year thresholds of heart attack or stroke for initiating a statin ranging from 7.5% to 12% or greater.²³⁷

A 2023 publication promoted using an algorithm to provide individualized risk for lung cancer. The editorial to that publication, however, points out that the use of that algorithm would have implications on safety (improved effectiveness of patient selection but worse safety profile, i.e., unnecessary invasive procedures and treatment of overdiagnosed cancers), patient-centeredness (the unmet need for clarity about patient values, preferences, and goals), timeliness (delays due to incorporating the algorithm into the electronic health record and an altered workflow), and equity (if minority-serving institutions have fewer resources to implement).²³⁸ On this topic the U.S. Preventive Services Task Force identifies the need for research “on the benefits and harms of using risk prediction models to select patients for lung cancer screening, including whether use of risk prediction models represents a barrier to wider implementation of lung cancer screening in primary care.” The task force recommended annual lung cancer screening for those aged 50 to 80 years old with a measure of smoking exposure (at least 20 pack-years, e.g., one pack of cigarettes smoked daily for 20 years), and with less than 15 years elapsed since stopping smoking.²³⁹

Thus, although a few clinical prediction or risk scores are recommended or mentioned in some guidelines and in use to assist with risk prediction and treatment decisions, implementation, external validity, and other issues as described above remain.

Algorithmic fairness and clinical prediction

In a perspective titled *Predictably Unequal: Understanding and Addressing Concerns That Algorithmic Clinical Prediction May Increase Health Disparities*, Paulus and Kent discuss concepts of algorithmic fairness versus algorithmic bias in healthcare in the context of increasing use of predictive algorithms (e.g., machine learning, artificial intelligence, or prediction models) to support decision-making.²⁴⁰ They acknowledge that fairness concerns apply when these predictive model algorithms lead to polar decisions, that is, where the predictions lead to decisions that benefit some groups but not others, such as in the allocation of healthcare resources, particularly scarce ones.²⁴¹ They examine different fairness criteria and demonstrate that “[e]ven when models are used to balance benefits–harms to make optimal decisions for individuals (i.e., for non-polar decisions)—and fairness concerns are not germane—model, data or sampling issues can lead to biased predictions that support decisions that are differentially harmful/beneficial across groups.”²⁴² Although they review potential sources of bias and methods for diagnosing and remedying bias, the core problematic issue may be that we lack agreed-upon definitions of fairness.

For example, they cite a commercial software used to predict reoffense after release based on data from 7,000 arrests.²⁴³ It found a higher risk of reoffense in defendants who were black, leading to potentially longer sentences, than those who were white, even though the algorithm was “race-unaware.” This was even the case among those who did not recidivate, that is, truly zero risk, resulting in unequal error rates consistent with “unfairness” and perhaps also “legal definitions of discrimination through ‘disparate impact.’” The software developers, however, argued that the model had good calibration—that is, good agreement between the observed and the predicted reoffense. However, when examining two fairness criteria that equalized either (1) type I/II error rates (sensitivity and specificity) or (2) test fairness with consistent calibration (strata-specific outcome

rates), Paulus and Kent found both criteria cannot simultaneously be satisfied when the outcome rates differ across two groups (except in the case of perfect prediction), “leading to the conclusion that unfairness is inevitable” (Figure 6).²⁴⁴

Figure 6. Mutual incompatibility of fairness criteria.

Source: From Jessica K. Paulus & David M. Kent, *Predictably Unequal: Understanding and Addressing Concerns That Algorithmic Clinical Prediction May Increase Health Disparities*, 3(99) NPJ Digit. Med. 2 (2020), <https://doi.org/10.1038/s41746-020-0304-9>. Reproduced with permission.

A multitude of fairness criteria exist with likely mutual incompatibility, so satisfying all of them becomes impossible because of inevitable unfairness by at least one criteria, thereby suggesting the impossibility of a fair and unbiased decision because there will be at least one unequal outcome.

To satisfy [a] more stringent, narrow, and rigorous definition of unfairness, it is not enough to observe differences in outcomes—one must understand the causes for these outcome differences. Such a causal concept of fairness is closely aligned to the legal concept of disparate treatment. According to causal definitions of fairness, similar individuals should not be treated differently due to having certain protected attributes that qualify for special

244. Paulus & Kent, *supra* note 240, at 2. D+ = disease present, D- = disease absent, T+ = test positive, T- = test negative.

protection from discrimination, such as a certain race/ethnicity or gender. However, causality is fundamentally unidentifiable in observational data, except with unverifiable assumptions. Thus, we are more typically stuck with deeply imperfect but ascertainable criteria serving as (often poor) proxies for causal fairness.²⁴⁵

Given the emerging healthcare applications of machine artificial-intelligence research despite the lack of consensus on application and evaluation, it is important to recognize that current literature provides some frameworks for guidance about the evaluation of artificial intelligence in medicine as well as stages of development, reporting, evaluation, implementation, and surveillance.²⁴⁶

Informed Consent

Principles

Medical informed consent is an ethical, moral, and legal responsibility of physicians.²⁴⁷ It is guided by four ethical principles: autonomy, beneficence, non-maleficence, and justice.²⁴⁸ Autonomy refers to informed, rational decision-making after “unbiased and thoughtful deliberation.”²⁴⁹ Beneficence represents the “moral obligation of physicians to act for the benefit of patients.”²⁵⁰ These two principles place physicians in conflict because they wish to provide the care they believe is best for the patient, but because that care usually involves some risk or cost, physicians also recognize that patient autonomy and preferences may affect their recommendation.²⁵¹ In a study examining the incidence of erectile dysfunction with use of a beta-blocker medication known to be beneficial, heart disease patients were (1) blinded to the drug, (2) informed of the drug name only, or (3) informed about its erectile dysfunction adverse effect. Among those blinded, 3.1% developed erectile dysfunction compared with 15.6% of those

given the drug name and 31.2% of those informed about adverse effects, showing that being informed increased the risk for adverse effects and might deprive patients of benefit from a drug because they stop taking it.²⁵² Physicians must balance the desire to provide beneficial care with the obligation to promote autonomous decisions by informing patients of potential adverse effects or tradeoffs.

Standards

State jurisdictions differ in their standards for disclosure, with half adopting the physician or professional standard (the information that other local physicians with similar skill levels would provide) and the other half adopting the patient or materiality standard (the information that a reasonable patient would deem important in decision-making).²⁵³ The informed-consent process involves the disclosure of alternative treatment options, including no treatment, and the risks and benefits associated with each alternative. Discussion should include severe risks and frequent risks, but the courts have not provided explicit guidance about what constitutes sufficient severity or frequency. Patients should be considered by the court to be competent and should have the capacity to make decisions (understanding choices, risks, and benefits). The decision should be voluntary—of free mind and free will, without coercion or manipulation. The language used should be understandable to the patient, and treatment should not proceed unless the physician believes the patient understands the options and their risks and benefits.

Patients may withdraw consent or refuse treatment. Such an action should engender additional discussion, and documentation may include the completion of a withdrawal-of-consent form. In certain situations, exceptions to medical consent may arise in emergencies, when the treatment is recognized by prudent physicians to involve no material risk to patients and when the procedure is unanticipated and not known to be necessary at the time of consent.²⁵⁴

In 2024, the American Law Institute recognized that patients have choices among alternative treatments, so plaintiffs no longer need to prove that patients in similar situations would not have chosen treatment if they had received complete disclosure of risks, and now only need to prove that they would have chosen an alternative treatment that would have been reasonable for them.²⁵⁵

Patient care

The *Merenstein* case described an unpublished trial in which, during his residency, Dr. Merenstein examined a highly educated man.²⁵⁶ The examination included a discussion of the relevant risks and benefits regarding prostate cancer screening using the prostate-specific antigen (PSA) test based on recommendations from the U.S. Preventive Services Task Force, the American College of Physicians–American Society of Internal Medicine, the American Medical Association, the American Urological Association, the American Cancer Association, and the American Academy of Family Physicians. Dr. Merenstein testified that the patient declined the test because of the high false-positive rate, the risk of treatment-related adverse effects, and the low risk of dying from prostate cancer. Another physician seeing the same patient subsequently ordered a PSA without any patient discussion. The PSA was high, and the patient was diagnosed with incurable advanced prostate cancer. The plaintiff’s attorney argued that despite the guidelines above, the standard of care in Virginia was to order the blood test without discussion, based on four physician witnesses who supported the plaintiff’s attorney “that the standard of care in Virginia was to order the test without discussing it with the patient,” so the jury ruled in favor of the plaintiff.²⁵⁷ It is important to note that the standard of care varies from state to state with about half having physician-based standards requiring “physicians to inform a patient of the risks, benefits and alternatives to a treatment in the same manner that a ‘reasonably prudent practitioner’ in the field would,” and the other half having patient-based standards requiring physicians to provide “all information on the risks, benefits and alternatives to a treatment that a ‘reasonable patient’ would attach significance to in making a treatment decision.”²⁵⁸

In 2024, the American Law Institute shifted its historic focus on local habitual practice to more patient-centered reasonable care, defined as that from competent and qualified clinicians that could override customary community practices, e.g., through evidence-based medicine.²⁵⁹

Patient preferences

To illustrate the importance of patient preferences, a woman with breast cancer described her experience:

256. Daniel Merenstein, *A Piece of My Mind: Winners and Losers*, 291 JAMA 15, 15–16 (2004), <https://doi.org/10.1001/jama.291.1.15>.

257. King & Moulton, *supra* note 248, at 434.

258. *Id.* at 432–34.

259. Aaron et al., *supra* note 255.

[A]s the surgeon diagramed the incision points on my chest with a felt-tip pen, my husband asked a question: Is it really necessary to transfer this back muscle? The doctor's answer shocked us. No, he said, he could simply operate on my chest. That would cut surgery and recovery time in half. He had planned the more complicated procedure because he thought it would have the best cosmetic result. "I assumed that's what you wanted."²⁶⁰

Instead the woman preferred the less invasive approach that shortened her recovery time.

Randomized trials

In the research setting, a randomized trial with and without informed consent demonstrated that the process of getting informed consent altered the effect of a placebo when given to patients with insomnia. The first patient of each pair was randomized to no informed consent and the second to informed consent. Out of 56 patients randomized to informed consent, 26 declined to participate in the study (the patients without informed consent had no choice and were unaware of their participation in a study). The informed consent process created a "biased" group because the age and gender for those who declined participation differed significantly from those who did agree to be included in the study. The hypnotic activity of placebo was significantly higher without informed consent, and adverse events were found more commonly in the group receiving informed consent. The study suggests that the process of getting informed consent introduced biases in the patient population and affected the efficacy and adverse effects observed in this clinical trial, thereby potentially affecting the general applicability of any findings involving informed consent.²⁶¹

Health information sources

Besides physicians, patients may get health information from the internet, family, friends, and the media (newspapers, magazines, television). Of internet users, 80% had searched for information on at least 1 of 15 major health topics, but use varied from 62% to 89% by age, sex, education, and race/ethnicity groups.²⁶² The

percent of all adults who look online for health information varied from 72% for those 18–29 to 30% for those 65 and older.²⁶³ Over the past decade, smartphone use has grown dramatically across all age groups, but especially those 65 and older (13% in 2012 to 61% in 2021).²⁶⁴ A cross-sectional November 2006 and May 2007 national survey of U.S. adults who had made a medical decision found that internet use averaged 28%, but varied from 17% for breast cancer screening to 48% for hip/knee replacement, among those 40 years of age and older.²⁶⁵ However, even among internet users, healthcare providers were felt to be the most influential source of information for medical decisions, followed by the internet, family and friends, and then media. In this digital age, clinicians remain the most influential information source for now.

Risk Communication

Multiple health outcomes may result from alternative treatment choices, and how patients feel about the relative importance of those outcomes varies.²⁶⁶ When patients with recently diagnosed, curable prostate cancer were presented with 93 possible questions that might be important to patients like themselves, 91 of the questions were cited as relevant to at least one patient, demonstrating that personal health goals and concerns vary substantially.²⁶⁷ Communication skills should include patient problem assessment (appropriate questioning techniques, seeking patient's beliefs, checking patient's understanding of the problem); patient education and counseling (eliciting patient's perspective, providing clear instructions and explanations, assessing understanding); negotiation and shared decision-making (surveying problems and delineating options, arriving at mutually acceptable solutions); and relationship development and maintenance (encouraging patient expression, communicating a supportive attitude, explaining any jargon, and using nonverbal behavior to enhance communication).²⁶⁸

268. Michael J. Yedidia et al., *Effect of Communications Training on Medical Student Performance*, 290 *JAMA* 1157, 1159 (2003), <https://doi.org/10.1001/jama.290.9.1157>.

Types of risk-communication estimates

Certain forms of risk communication, however, may be confusing and should be avoided: “single event probabilities, conditional probabilities (such as sensitivity and specificity), and relative risks.”²⁶⁹ Single-event probabilities are a “source of miscommunication” because the events remain unspecified, for example, a statement that a medication results in a 30% to 50% chance of developing erectile dysfunction could be misconstrued by patients to mean an erectile dysfunction problem in 30% to 50% of each their sexual encounters instead of a more specific statement such as out of 10 people like you taking this medication, three to five of them experience erectile dysfunction.²⁷⁰ This natural frequency statement specifies a reference class (e.g., out of 10 people and not each encounter), thereby reducing misunderstanding.²⁷¹

For communicating benefit by citing relative risk (ratio of the risk of dying in a group taking a medication divided by the risk of dying in a group not taking a medication), consider an advertising statement that taking a cholesterol-lowering medication reduces the risk of dying by 22%.²⁷² This may be misinterpreted as saying that out of 1,000 patients with high cholesterol, 220 of them can avoid dying by taking cholesterol-lowering medications. The actual data show that 32 deaths occur among 1,000 patients taking the medication, and 41 deaths occur among 1,000 patients taking the placebo, so the relative risk is 0.78 (32/41). The relative risk reduction equals one minus the relative risk or 0.22 (22%). A preferred way to express the benefit would be the absolute risk reduction (the difference between 41 and 32 deaths in 1,000 patients), or to say that in a group of 1,000 people like you with high cholesterol, taking a cholesterol medication for five years helps nine of them avoid dying.²⁷³

To illustrate potential misinterpretation of risk further, a relative risk reduction of 22% has very different absolute risk reductions depending on the event rates without treatment. If the mortality rate is 20% without treatment, then the absolute risk reduction is 4.4% or saving 44 of 1,000 treated patients (22% times 20%), but for an event rate of 2% without treatment, then the same 22% risk reduction results in an absolute reduction of 0.44% or saving 4.4 of 1,000 treated patients. The number needed to treat is an alternative form of risk communication to account for the risk without treatment. It is the reciprocal of the absolute risk difference or one divided

by the quantity nine lives saved per 1,000 ($1 \div (9/1000)$) treated with cholesterol medications in the prior paragraph. Therefore 111 patients need to be treated with a cholesterol medication for five years to save one of them, or in the illustrative example above with a relative risk reduction of 22% and a mortality rate of 20% or 2%, either 23 or 227, respectively, would need to be treated to save one patient.

Breast-cancer screening communication

In the analysis of randomized trials of mammography for the U.S. Preventive Services Task Force, the number needed to screen (NNS) to avoid one breast-cancer death over 10 years was 3,448 (10,000/2.9) for 39- to 49-year-olds, 1,299 (10,000/7.7) for 50- to 59-year-olds, and 469 (10,000/21.3) for 60- to 69-year-olds.²⁷⁴ The numbers needed to harm (NNH) with annual or biennial mammography over 10 years were: screening every 1.6 (1/0.61) to 2.4 (1/0.42) 40-year-old women yields one false positive result and screening 14 (1/0.07) to 20 (1/0.05) 40-year-old women yields one breast biopsy.²⁷⁵ Screening for breast cancer and treating those found to have breast cancer saves lives. From epidemiologic population-based incidence and mortality data and from screening trials with long-term follow-up, it becomes clear that some patients experience over-diagnosis, i.e., some women have screen-detected cancer that would never have developed clinical signs or symptoms or caused their mortality in their lifetime. Estimates of overdiagnosis from trials ranged from 11% to 22%, and so, out of 100 women diagnosed with breast cancer from screening, five to nine of them undergo treatment for a cancer that may have never caused any mortality.²⁷⁶ Importantly, no one can tell if any particular woman has been overdiagnosed because this is unobservable.²⁷⁷

To summarize the evidence,

Mammography does save lives, more effectively among older women, but does cause some harm. Do the benefits justify the risks? The misplaced propaganda battle seems to now rest on the ratio of the risks of saving a life compared with the risk of overdiagnosis, two very low percentages that are imprecisely estimated and depend on age and length of follow-up.²⁷⁸

Technologies

Stephen Hawking said, “Our future is a race between the growing power of technology and the wisdom with which we use it.”²⁷⁹ Rapidly growing sources of data fuel technology growth, particularly artificial intelligence (AI) with the potential to improve diagnosis, clinical care, health research, drug development, and public health (surveillance, outbreak response, and health system monitoring).²⁸⁰ However, the World Health Organization (WHO) identifies six key ethical principles for the use of AI in health:

- Protecting human autonomy: Providers must have the necessary information to make safe and effective use of AI systems. Patients must understand what part those systems play in their care. The AI systems must protect privacy and confidentiality with informed consent and appropriate legal protection of data;²⁸¹
- Promoting human well-being and safety and the public interest: The AI systems should meet regulatory requirements and be safe, accurate and efficient. The systems should practice quality control and quality improvement and, importantly, do no harm;²⁸²
- Ensuring transparency, explainability, and intelligibility: The design or deployment of an AI technology should be published or documented with sufficient information to facilitate public deliberation and consultation;²⁸³
- Fostering responsibility and accountability: Establishing predefined points of human supervision through regulatory principles upstream and downstream of any AI algorithm would provide a “human warranty”;²⁸⁴
- Ensuring inclusiveness and equity: Design features should promote the “widest possible appropriate, equitable use and access, irrespective of age, sex, gender, income, race, ethnicity, sexual orientation, ability or other characteristics protected under human rights codes” and should seek to “minimize inevitable disparities in power that arise between providers and patients, between policy-makers and people, and between companies and governments”;²⁸⁵ and
- Promoting AI that is responsive and sustainable: Designers, developers, and users should “continuously, systematically and transparently assess AI

applications during actual use” and governments and companies should address anticipated disruptions in the workplace to ensure sustainability.²⁸⁶

Data collection and use

Personal health data has grown massively to include “genomic data, radiological images, medical records^[287] and nonhealth data converted into health data . . . from standard sources (e.g. health services, public health, research) and further sources (environmental, lifestyle, socioeconomic, behavioural and social).” Concerns include (1) the quality of the data and inherent biases in the training data (e.g., underrepresentation and their effect on algorithms); (2) safeguarding individual privacy (e.g., discrimination due to health status; cyber theft and accidental or intentional disclosure); (3) collected health data may exceed what is required—of particular concern is a “behavioral data surplus” that is “repurposed for uses that raise serious ethical, legal and human rights” questions;²⁸⁸ and (4) data colonialism “may foster a divide between those who accumulate, acquire, analyze and control such data and those who provide the data but have little control over their use.” As noted by the WHO, “true informed consent is increasingly infeasible in an era of biomedical big data, especially in an environment driven mainly by companies seeking to generate profits from the use of data” because of the “scale and complexity” of such data and because “all of the potential uses may not be known,” such as for “population-level data analytics or predictive-risk modeling.”²⁸⁹

286. *Id.* at vi.

287. Malpractice litigation includes the prominent use of electronic medical records with metadata (often referred to as “audit trails”) that allow someone to determine exactly when an entry was made into a record, what work station it was entered from, and whether any edits were made and when. An area of uncertainty remains as to the scope of a patient’s official or “legal” medical record under HIPAA and whether it includes text messages between clinicians, e.g., does the hospital have a duty to preserve such data and disclose it to the patient?

288. Ethics and Governance of Artificial Intelligence for Health: WHO Guidance, *supra* note 280, at 37. See, e.g., *Dinerstein v. Google, LLC*, 484 F. Supp. 3d 561 (2020), in which the University of Chicago was accused of sharing identifiable patient data with Google for the purposes of developing medical diagnostic tools. The health records shared with Google “were de-identified, except that dates of service were maintained” in the dataset, and the dataset also included “de-identified, free-text medical notes.” Marcelo Corrales Compagnucci et al., Box 3: *Dinerstein v. Google*, in Ethics and Governance of Artificial Intelligence for Health: WHO Guidance, *supra* note 280, at 38 (citing Alvin Rajkomar et al., *Scalable and Accurate Deep Learning with Electronic Health Records*, 1(18) NPJ Digit. Med. 6 (2018), <https://doi.org/10.1038/s41746-018-0029-1>). Another example is hospitals that gain consent to retain discarded biological samples from patients for research purposes when consenting to treatment at a facility.

289. Ethics and Governance of Artificial Intelligence for Health: WHO Guidance, *supra* note 280, at 40.

Shared Decision-Making

The “professional values of competence, expertise, empathy, honesty, and commitment are all relevant to communicating risk: Getting the facts right and conveying them in an understandable way are not enough.”²⁹⁰ Shared and informed decision-making has emerged as one part of patient care. It distinguishes problem solving that identifies one “right” course that leaves little room for patient involvement from decision-making in which several courses of action may be reasonable and in which patient involvement should determine the optimal choice. In such cases, healthcare choices depend not only on the likelihood of alternative outcomes resulting from each strategy but also on the patient preferences for possible outcomes and their attitudes about risk taking to improve future survival or quality of life and the timing of that risk (whether the risk occurs now or in the future).²⁹¹

Informed decision-making is

when an individual understands the nature of the disease or condition being addressed; understands the clinical service and its likely consequences, including risks, limitations, benefits, alternatives, and uncertainties; has considered his or her preferences as appropriate; has participated in decision making at a personally desirable level; and either makes a decision consistent with his or her preferences and values or elects to defer a decision to a later time.²⁹²

Shared decision-making is “when a patient and his or her healthcare provider(s), in the clinical setting, both express preferences and participate in making treatment decisions.”²⁹³ To assist with shared decision-making, health decision aids have been developed to help patients and their physicians choose among reasonable clinical options together by describing the “benefits, harms, probabilities, and scientific uncertainties.”²⁹⁴ In 2007, the legislature in the state of Washington became the first to establish and recognize in law a role for shared decision-making in informed consent.²⁹⁵ The bill goes on to encourage the development, certification, use, and evaluation of decision aids. The consent form

295. Bridget M. Kuehn, *States Explore Shared Decision Making*, 301 *JAMA* 2539, 2539 (2009), <https://doi.org/10.1001/jama.2009.867>.

provides written documentation that the consent process occurred, but the crux of the medical consent process is the discussion that occurs between a physician and a patient. Physicians share their medical knowledge and expertise, and patients share their values (health goals) and preferences. It is an opportunity to strengthen the patient–physician relationship through shared decision-making, respect, and trust. Incorporating patient health goals into shared decision-making is supported by the core principles of medical decision analysis: the concept of utility-maximizing decisions, in which the probabilities of possible health outcomes from alternative choices is multiplied by the patient’s utility (a quantitative measure of preference) for those outcomes and summed over all possible probability–outcome pairs for each treatment choice (including no treatment). The intervention with the highest expected utility should be the preferred option.

In six mock trials of malpractice alleging failure to perform a prostate-specific antigen in response to the *Merenstein* case, a study found that 47 jurors were not willing to accept verbal testimony that a discussion occurred, but when documentation occurred, most (72%) felt that the defendant fulfilled the standard of care—although 28% still felt that screening should be done even if documentation had occurred. When a decision aid was included, 94% felt that the standard of care had been met.²⁹⁶ With regard to variation in care, a decision aid for surgery for a benign enlargement of the prostate decreased the likelihood of surgery versus control in one study but increased it in the other, the difference being the extent of surgery in the control group. In the United States, surgery decreased from 13% in the control group to 8% with a decision aid, and in the United Kingdom, surgery increased from 2% in the control group to 11% with a decision aid.²⁹⁷

Summary and Future Directions

Having sequenced the human genome, medical research is poised for exponential growth as the code for human biology (genomics) is translated into proteins (proteomics) and chemicals (metabolomics) to identify molecular pathways that lead to disease or that promote health. With advances in medical technologies in diagnosis and preventive and symptomatic treatment, the practice of medicine will be profoundly altered and redefined. For example, consider lymphoma, a blood cancer that used to be classified simply by appearance under the microscope as either

Hodgkin's or non-Hodgkin's lymphoma. As science has evolved, it is now further classified by cellular markers that identify the underlying cancer cells as one of two cells that help with immunity (protecting the body from infection and cancer): T cells or B cells. Current research has characterized those cells further by identifying underlying genetic and cellular markers and pathways that distinguish these lymphomas and provide potential therapeutic targets. The growth in the research enterprise, both basic science and clinical translational—the translation of bench research to the bedside or the identification of a clinical need leading to basic science research to further elucidate molecular pathways and develop novel treatments or diagnostics—has greatly expanded research capacity to generate scientific medical research of all types.

With greatly expanded knowledge, research, and specialization, judgments about admissibility and about what constitutes expertise become increasingly difficult and complex. The sifting of this research into sufficiently substantiated, competent, and reliable evidence, however, relies on the traditional scientific foundation: first, biological plausibility and prior evidence; and second, consistent repeated findings. The practice of medicine at its core will continue to be a physician and patient interaction with professional judgment and communication as central elements of the relationship. Judgment is essential because of uncertainties in the underlying professional knowledge or because even if the evidence is credible and substantiated, there may be tradeoffs in risks of harms and benefits for testing and for treatment. Communication is critical because most decisions involve tradeoffs, in which case individual patient preferences for the outcomes that may be unique to a patient and that may affect decision-making should be considered.

In summary, medical terms shared by the legal and medical professions have differing meanings, for example, differential diagnosis, differential etiology, and general and specific causation. The basic concepts of diagnostic reasoning and clinical decision-making and the types of evidence used to make judgments as treating physicians or experts involve the same overarching theoretical issues: (1) alternative reasoning processes; (2) weighing risks, benefits, and evidence; and (3) communicating those risks.

Glossary of Terms

adequacy. In diagnostic verification, testing a hypothesized diagnosis for its adequacy in explaining the course of the disease.

atrial fibrillation. An abnormal heart rhythm where the heart muscles do not contract together so that blood swirls, leading to blood clots usually in the upper left part of the heart (left atrium). Those clots can then leave the heart and cause strokes or other symptoms.

attending physician. The physician primarily responsible for the patient's care at the hospital in which the patient is being treated.

Bayes' theorem (rule). In medicine, it is a method to calculate a post-test probability after a test result in a patient with a pretest probability of disease (suspicion) with additional information such as from a test result by using test characteristics: sensitivity for how well it performs in individuals with disease and specificity for how well it performs in those without disease.

causal reasoning. For physicians, causal reasoning typically involves understanding how abnormalities in physiology, anatomy, genetics, or biochemistry led to the clinical manifestations of disease. Through such reasoning, physicians develop a "causal cascade" or "chain or web of causation" linking a sequence of plausible cause-and-effect mechanisms to arrive at the pathogenesis or pathophysiology of a disease.

chief complaint. The primary or main symptom that caused the patient to seek medical attention.

coherency. In diagnostic verification, testing a particular diagnosis for its coherency involves determining the consistency of that particular diagnosis with predisposing risk factors, physiological mechanisms, and resulting manifestations.

conditional probability. The probability or likelihood of something, given that something else occurred or is present, for example, the likelihood of disease if a test is positive (post-test probability) or the likelihood of a positive test if disease is present (sensitivity). See Bayes' theorem (rule).

consulting physician. A physician, usually a specialist, who is asked by the patient's attending physician to provide an opinion regarding diagnosis, testing, or treatment or to perform a procedure or intervention, for example, surgery.

deductive reasoning. The process of having a specific diagnosis in mind and identifying the symptoms, signs, and lab tests that may occur with that diagnosis with the conclusion being certain. See differential diagnosis.

diagnostic test. A test ordered to confirm or exclude possible causes of a patient's symptoms or signs (distinct from screening test).

diagnostic verification. The last stage of narrowing the differential diagnosis to a final diagnosis by testing the validity of the diagnosis for its coherency, adequacy, and parsimony.

differential diagnosis. A set of diseases that clinicians consider as possible causes of the patient's complaint until the diagnosis is nearly final (diagnostic verification).

differential etiology. Term used by the court or witnesses to establish or refute external causation for a plaintiff's condition. For physicians, etiology refers to cause.

external causation. External causation is established by demonstrating that the cause of harm or disease originates from outside the plaintiff's body, for example, a defendant's action or product.

general causation. General causation is established by demonstrating, usually through scientific evidence, that a defendant's action or product causes (or is capable of causing) disease.

heuristics. Quick automatic rules of thumb or cognitive shortcuts often involving pattern recognition that facilitate rapid diagnostic and treatment decision-making. Use of heuristics or "thinking fast" may predispose to known cognitive errors, even among experts. See hypothetico-deductive.

hypothesis generation. A limited list of potential diagnostic hypotheses in response to symptoms, signs, and lab test results. See differential diagnosis.

hypothesis modification. A change in the list of diagnostic hypotheses (differential diagnosis) in response to additional information, for example, symptoms, signs, and lab test results. See differential diagnosis.

hypothesis refinement. A change in the likelihood of the potential diagnostic hypotheses (differential diagnosis) in response to additional information, for example, symptoms, signs, and lab test results. As additional information emerges, physicians evaluate those data for their consistency with the possibilities on the list and whether those data would increase or decrease the likelihood of each possibility. See differential diagnosis.

hypothetico-deductive. Deliberative and analytical reasoning involving hypothesis generation, hypothesis modification, hypothesis refinement, and diagnostic verification. Thinking "slow" is typically applied for problems outside an individual's expertise or difficult problems with atypical issues, as it may avoid known cognitive errors. See heuristics.

individual causation. See specific causation.

inductive reasoning. The process of arriving at a diagnosis based on symptoms, signs, and lab tests with the conclusion being probable rather than certain. See differential diagnosis.

intracranial hemorrhage. Bleeding that occurs within the substance of the brain.

myocardial infarction. The technical term for a heart attack.

osteopaths. Doctors of osteopathy (D.O.s), who receive similar training, licensure, and credentialing as medical doctors (M.D.s).

overdiagnosis. Screening and diagnostic testing can lead to the detection of apparent disease that may never cause harm, for example, the identification of slow-growing cancers that, even if untreated, would never cause symptoms or reduce survival because the screening test cannot distinguish the cancerous-appearing cells that would become symptomatic or cause mortality from those that would never do so. See overtreatment.

overtreatment. The treatment of patients with pseudo disease whose disease would never cause symptoms or reduce survival. The treatment may place patients at risk for treatment-related morbidity and possibly mortality without any potential for benefit. See overdiagnosis.

parsimony. In diagnostic verification, testing a particular diagnosis for its parsimony involves choosing the simplest single explanation as opposed to requiring the simultaneous occurrence of two diseases to explain the findings.

pathogenesis. See causal reasoning.

pathology test. Microscopic examination of body tissue typically obtained by a biopsy or during surgery to determine if the tissue appears to be abnormal (different than would be expected for the source of the tissue). The visual components of the abnormality are typically described (e.g., types of cells, appearance of cells, scarring, effect of stains or molecular markers that help facilitate identification of the components) and on the basis of visual pattern, the abnormality may be classified, for example, malignancy (cancer) or dysplasia (precancerous).

post-test probability. The suspicion or probability of a disease after additional information (such as from a test) has been obtained. The predictive value positive (or positive predictive value) is the probability of disease in those known to have a positive test result. The predictive value negative (or negative predictive value) is the probability of disease in those known to have a negative test result.

predictive value. The predictive value of a test when applied to a specific population of patients with a specific prevalence of disease.

pretest probability. The suspicion or probability of a disease before additional information (such as from a test) is obtained. Also referred to as prior probability.

prior probability. See pretest probability.

sarcoidosis. A collection of inflammatory cells called granulomas causing scar tissue that collect most often in the lungs or skin but can involve multiple other parts of the body.

screening test. A test performed in the absence of symptoms or signs to detect disease earlier—for example, cancer screening (distinct from diagnostic test).

sensitivity. Likelihood of a positive finding (usually referring to a test result but could also be a symptom or a sign) among individuals known to have a disease (distinct from specificity).

sign. An abnormal physical finding identified at the time of physical examination (distinct from symptoms).

specific causation. Established by demonstrating that a defendant's action or product is the cause of a particular plaintiff's disease. Also referred to as individual causation.

specificity. Likelihood of a negative finding (usually referring to a test result but could also be a symptom or a sign) among individuals who do not have a particular disease (distinct from sensitivity).

symptoms. The patient's description of a change in function, sensation, or appearance (distinct from sign).

syndrome. A collection of symptoms and signs that together characterize a specific disease or a specific group of diseases.

Introduction

Science's understanding of the human brain is increasing exponentially. We know almost infinitely more than we did thirty years ago; however, we know almost nothing compared with what we are likely to know thirty years from now. The development of machine learning algorithms and artificial intelligence (AI) has allowed us to pull much more information out of existing methods of observing and recording brain activity, including greatly boosting the value of the old technology of electroencephalography (EEG).¹ The electrodes and electrode arrays that serve as tools for recording and stimulating small numbers of neurons inside living brains have improved greatly.² The development of human neural organoids and the increase in human/nonhuman brain chimeras have given us new ways to watch how brain tissues develop and function.³ And, less excitingly but equally importantly, increased use has given us better understanding of the limitations of some of our existing tools.⁴

We still remain very far from a deep and broad understanding of how human brains work, but some advances in understanding the human brain and its attendant mental states have resulted in neuroscience evidence already appearing in courtrooms. If, as neuroscience indicates, our mental states correspond to, and result from, physical states of our brain, our increased ability to discern those physical states will have huge implications for the law. Since 2008, lawyers in steadily increasing numbers have been trying to introduce neuropsychological and neuroimaging evidence as relevant to questions of individual criminal responsibility, such as claims of insanity or diminished responsibility, on issues of either criminal liability or sentencing. In May 2010, parties in two cases sought to introduce neuroimaging in court as evidence of honesty; we have begun to see efforts to use it to prove that a person is in pain. These and other uses of neuroscience are almost certain to increase with our growing knowledge of the human brain as well as continued technological advances in accurately and precisely measuring the brain. This reference guide strives to give judges some background knowledge about neuroscience and the strengths and weaknesses of its

possible applications in litigation in order to help them become better prepared for these cases.⁵

Evidence about the brain has been used in the courtroom for decades, by psychologists, psychiatrists, neurologists, and other professionals. That evidence has been used to help courts decide issues such as the existence or extent of injuries, criminal defenses of insanity or reduced capacity, questions of competency in widely varying contexts, and more. Most, if not all, of the tools and techniques discussed in this reference guide could be used in court to provide evidence relevant to these efforts to answer more traditional legal questions about human brains and minds. We have chosen to focus this guide on some of the new ways in which—and different professionals through which—neuroscience evidence may enter the court, either for new questions, such as lie detection, or through new methods, like neuroimaging to provide evidence of *mens rea*, because judges and lawyers will be less familiar with them. This reference guide's descriptions of the techniques, and of their strengths and weaknesses, should apply even when more customary issues are presented.

This reference guide begins with a brief overview of the structure and function of the human brain. It then describes some of the tools neuroscientists use to understand the brain—tools likely to produce findings that parties will seek to introduce in court. Next, it discusses a number of fundamental issues that must be considered when interpreting neuroscientific findings. Finally, after discussing, in general, the evidentiary issues raised by neuroscience-based evidence, this guide concludes by analyzing a few illustrative situations in which neuroscientific evidence is likely to appear in court—now and, to an increasing extent, in the future.

The Human Brain

This abbreviated and simplified discussion of the human brain describes the cellular basis of the nervous system, the structure of the brain, and finally our current understandings of how the brain works. More detailed, but still accessible,

5. The *Reference Guide on Neuroscience* in the third edition of this manual, upon which this chapter is based, was published in 2011 with that aim. *A Primer on Criminal Law and Neuroscience* (Stephen J. Morse & Adina L. Roskies eds., 2013) is another useful source, commissioned by the Law and Neuroscience Project, funded by the John D. and Catherine T. MacArthur Foundation. That project had already published a pamphlet written by neuroscientists for judges, with brief discussions of issues relevant to law and neuroscience: *A Judge's Guide to Neuroscience: A Concise Introduction* (Michael S. Gazzaniga & Jed. S. Rakoff eds., 2010). More recently, a textbook on law and neuroscience has been published in a second edition: *Law and Neuroscience* (Owen D. Jones, Jeffrey D. Schall & Francis X. Shen eds., 2d ed. 2020). One early book on a broad range of issues in law and neuroscience also deserves mention: *Neuroscience and the Law: Brain, Mind, and the Scales of Justice* (Brent Garland ed., 2004).

information about the human brain can be found in academic textbooks and in popular books for general audiences.⁶

Cells

Like most of the human body, the nervous system is made up of cells. Adult humans contain somewhere between 30 trillion and 40 trillion human cells. Each of those cells is both individually alive and part of a larger living organism.

For all people, each human cell in the body (except for a few unusual cell types, like red blood cells) contains each person's entire complement of human genes—their genome. The genes, found on very long molecules of deoxyribonucleic acid (DNA) that make up a human's forty-six chromosomes, work by leading the cells to make other molecules, notably proteins and ribonucleic acid (RNA). Cells are different from each other not because they *contain* different genes, but because they turn on and off different sets of genes. All human cells seem to use the same group of several thousand “housekeeping” genes that run the cell's basic machinery, but skin cells, kidney cells, and brain cells differ in which other genes they use. Scientists count different numbers of types of human cells, with estimates ranging from a few hundred to a few thousand (depending largely on how narrowly or broadly one defines a cell type).

The most important cells in the nervous system are called neurons. Neurons pass messages from one to another in a complex way that appears to be responsible for brain function, conscious or otherwise.

Neurons come in many sizes, shapes, and subtypes (with their own names), but they generally have three features: a cell body, short extensions called dendrites, and a longer extension called an axon (see Figure 1). The cell body contains the nucleus of the cell, which in turn contains the forty-six chromosomes

6. The Society for Neuroscience, the very large scholarly society that covers a wide range of brain science, has published a brief and useful primer about the human brain called *Brain Facts*. The most recent edition, the eighth, published in 2018, is available free at <https://perma.cc/TEL6-6YNG>. Widely used academic textbooks include Eric R. Kandel et al., *Principles of Neural Science* (6th ed. 2021); Michael S. Gazzaniga, Richard B. Ivry & George R. Mangun, *Cognitive Neuroscience: The Biology of the Mind* (6th ed. 2025); and Larry Squire et al., *Fundamental Neuroscience* (4th ed. 2012). Some particularly interesting books about various aspects of the brain written for a popular audience include Oliver Sacks, *The Man Who Mistook His Wife for a Hat and Other Clinical Tales* (1985); Antonio R. Damasio, *Descartes' Error: Emotion, Reason, and the Human Brain* (1994); Daniel L. Schacter, *Searching for Memory: The Brain, the Mind, and the Past* (1996); Joseph E. LeDoux, *The Emotional Brain: The Mysterious Underpinnings of Emotional Life* (1996); Christopher D. Frith, *Making up the Mind: How the Brain Creates Our Mental World* (2007); Sandra Aamodt & Sam Wang, *Welcome to Your Brain: Why You Lose Your Car Keys but Never Forget How to Drive and Other Puzzles of Everyday Life* (2008). Matthew Cobb, *The Idea of the Brain: The Past and Future of Neuroscience* (2020), provides a good history of neuroscience.

with the cell's DNA. The dendrites and axons both reach out to make connections with other neurons. The dendrites generally receive information from other neurons; the axons send information.

Communication between neurons occurs at areas called synapses (Figure 2), where two neurons almost meet. At a synapse, the two neurons will come within less than a micrometer (a millionth of a meter) of each other, with the presynaptic side, on the axon, separated from the postsynaptic side, on the dendrite, by a gap called the synaptic cleft. At synapses, when the axon (on the presynaptic side) “fires” (becomes active), it releases molecules, known as neurotransmitters, into the synaptic cleft. Some of those molecules are picked up by special receptors on the dendrite that is on the postsynaptic side of the cleft. More than 100 different neurotransmitters have been identified; among the best known are dopamine, serotonin, glutamate, and acetylcholine.

At the postsynaptic side of the cleft, neurotransmitters binding to the receptors can have a wide range of effects. Sometimes they cause the receiving (postsynaptic) neuron to fire, sometimes they suppress (inhibit) the postsynaptic neuron from firing, and sometimes they seem to do neither. The response of the receiving neuron is a complicated summation of the various messages it receives from multiple neurons that converge, through synapses, on its dendrites.

A neuron that does fire does so by generating an electrical current that flows down the length of its axon (away from the cell body). We normally think of electrical current as flowing in things like copper wiring. In that case, free

electrons move down the wire. The electrical currents of neurons are more complicated. Molecules with a positive or negative electrical charge (ions) move through the neuron's membrane and create differences in the electrical charge between the inside and outside of the neuron, with the current traveling along the axon, rather like a fire brigade passing buckets of water in only one direction down the line. Firing occurs in milliseconds. This process of moving ions in and out of the cell membrane requires that the cell use large amounts of energy. When the current reaches the end of the axon, it may or may not lead to the axon releasing neurotransmitters into the synaptic cleft. This complicated part-electrical, part-chemical system is how information passes from one neuron to another.

The axons of human neurons are all microscopically narrow, but they vary enormously in length. Some are micrometers long; others, such as the axons of neurons running from the base of the spinal cord to the toes, are several feet long.

Longer axons tend to be coated with a fatty substance called myelin. Myelin helps insulate the axon and thus increases the strength and efficiency of the electrical signal, much like the insulation wrapped around a copper wire. (The destruction of this myelin sheathing is the cause of multiple sclerosis.) Axons coated with myelin appear white; thus, areas of the nervous system that have many myelin-coated axons are referred to as “white matter.” Cell bodies, by contrast, look gray; areas with many cell bodies and relatively few axons make up our “gray matter.” White matter can roughly be thought of as the wiring that connects gray matter to the rest of the body or to other areas of gray matter.

What we call nerves are really bundles of neurons. For example, we all have nerves that run down our arms to our fingers. Some of those nerves consist of neurons that pass messages from the fingers, up the arm, to other neurons in the spinal cord that then pass the messages on to the brain, where they are analyzed and experienced. This is how we feel things with our fingers. Other nerves are bundles of neurons that pass messages from the brain through the spinal cord to nerves that run down the arms to the fingers, telling them when and how to move.

Neurons can connect with other neurons or with other kinds of cells. Neurons that control body movements ultimately connect to muscle cells—these are called motor neurons. Neurons that feed information into the brain start with specialized sensory cells (i.e., cells specialized for detecting different types of stimuli—light, touch, heat, pain, and more) that fire in response to the appropriate stimulus. Their firings ultimately lead, directly or through other neurons, into the brain. These are sensory neurons. These neurons send information only in one direction—motor neurons ultimately from the brain, sensory neurons to the brain. The paralysis caused by, for example, severe damage to the spinal cord both prevents the legs from receiving messages to move that would come from the brain through the motor neurons and keeps the brain from receiving messages from sensory neurons in the legs about what the legs are experiencing. The break in the spinal column prevents the messages from getting through, just as a break in a local telephone line will keep two parties from connecting. (There are, unfortunately, not yet any human equivalents to wireless service.)

Estimates of the number of cells in a human brain vary widely, from a few hundred billion to several trillion. These cells include those that make up blood vessels and various connective tissues in the brain, but most of them are specialized brain cells. About 80 to 100 billion of these brain cells are neurons; the other cells (and the source of most of the uncertainty about the number of cells) are principally another class of cells referred to generally as glial cells.

Glial cells play many important roles in the brain, including, for example, producing and maintaining the myelin sheaths that insulate axons and serving as a special immune system for the brain. Traditionally, glial cells were often dismissed as “mere support staff”—their name comes from the Greek word for “glue,” which indicates the early understanding of their role. But emerging

evidence suggests that they may play a much larger role in mental processes than previously believed. Work pioneered by the late Ben Barres has shown that glial cells not only are crucial for holding neurons together, but are essential for forming, editing, and pruning neuronal connections (synapses). They also produce factors that, themselves, affect neurotransmitter concentrations and the firings of neurons. The full importance of glial cells is still being discovered, and another edition of this manual may devote more space to them. At this point, however, glial cells have not been used significantly in the kinds of neuroscience evidence that has been working its way into courts. So we will concentrate on neurons, the brain structures they form, and how those structures work.

Brain Structure

Anatomists refer to the brain, the spinal cord, and a few other nerves directly connecting to the brain as the central nervous system. All the other nerves are part of the peripheral nervous system. This reference guide will not discuss the peripheral nervous system in any detail, despite its importance in, for example, assessing some aspects of personal injuries. We will also, less fairly, ignore parts of the central nervous system other than the brain, even though the spinal cord, in particular, plays an important role not just in passing messages going into and coming out from the brain, but in changing their strength and meanings.

The average adult human brain weighs about three pounds and fills a volume of about 1,300 cubic centimeters. Two standard wine bottles hold 750 cubic centimeters each, so, if liquid, a human brain would not quite fill up a double bottle (a magnum); it would fill a measuring bowl to about 5.4 cups. Living brains have a consistency similar to that of Jell-O. Despite their softness, brains are made up of regular shapes and structures that are generally consistent from person to person. Just as every nondamaged or nondeformed human face has two eyes, two ears, one nose, and one mouth with standard numbers of various kinds of teeth, every normal brain has the same set of identifiable structures, both large and small. And, like noses or eyes, these brain structures are not exactly identical from person to person.

Neuroscientists have long worked to describe and define particular regions of the brain. In some ways this is like describing parcels of land in property documents, and, like property descriptions, several different methods are used. At the largest scale, the brain is often divided into three parts: the brain stem, the cerebellum, and the cerebrum (Figure 3).⁷

7. The brain also is sometimes divided into the forebrain, midbrain, and hindbrain. This classification is useful for some purposes, particularly in describing the history and development of the

Figure 3. Lateral (left) and mid-sagittal (right) views of the human brain.

Source: Courtesy of Anthony Wagner, Stanford University.

The brain stem is found near the bottom of the brain and is, in some ways, effectively an extension of the spinal cord. Its various parts play crucial roles in controlling the body's autonomic (involuntary or unconscious) functions, such as heart rate and digestion. The brain stem also contains important regions that regulate processing in the cerebrum, one example of the strong pattern of interconnections in brain regions. For instance, the substantia nigra and ventral tegmental area in the brain stem consist of critical neurons that generate the neurotransmitter dopamine. While the substantia nigra is crucial for motor control, the ventral tegmental area is important for learning about rewards. The loss of neurons in the substantia nigra is associated with the movement problems of Parkinson's disease.

The cerebellum, which is about the size and shape of a squashed tennis ball, is tucked away in the back of the skull. It plays a major role in fine motor control and seems to keep a library of learned motor skills, such as riding a bicycle. Although it is relatively small by volume, it is the region of the brain with the largest number of neurons. It was long thought that damage to the cerebellum had little to no effect on a person's personality or cognitive abilities, but resulted primarily in unsteady gait, difficulty in making precise movements, and problems in learning movements. However, more recent studies of patients with cerebellar damage and functional brain imaging studies of healthy individuals indicate that

vertebrate brain, but it does not entirely correspond with the categorization of cerebrum, brain stem, and cerebellum, and it is not used in this reference guide.

the cerebellum also plays a role in more cognitive functions, including supporting aspects of working memory, attention, and language.

The cerebrum is the largest part of the human brain, making up about 85% of its volume. The cerebrum is found at the front, top, and much of the back of the human brain. The human brain differs from the brains of other mammals mainly in that it has a vastly enlarged cerebrum.

There are several different ways to identify parts of, or locations in, the cerebrum. First, the cerebrum is divided into two hemispheres—the famous left and right brain. These two hemispheres are connected by tracts of white matter—of axons—most notably the large connection called the corpus callosum. Oddly, in humans and most other vertebrates, the right hemisphere of the brain generally receives messages from and controls the movements of the left side of the body, while the left hemisphere receives messages from and controls the movements of the right side of the body.

Each hemisphere of the cerebrum is divided into four lobes (Figure 4): the frontal lobe in the front of the cerebrum (behind the forehead), the parietal lobe at the top and toward the back, the temporal lobe on the side (just behind and above the ears), and the occipital lobe at the back. Thus, one could describe a particular region as lying in the left frontal lobe—the frontal lobe of the left hemisphere.

Figure 4. Lobes of a hemisphere. Each hemisphere of the brain consists of four lobes: the frontal, parietal, temporal, and occipital lobes.

Source: Adapted from https://commons.wikimedia.org/wiki/File:Lobes_of_the_brain_NL.svg.

The surface of the cerebrum consists of the cortex, which is a sheet of gray matter a few millimeters thick. The cortex is not a smooth sheet in humans, but rather is heavily folded with valleys, called sulci (“sulcus” in the singular), and bulges, called gyri (“gyrus”). The sulci and gyri have their own names, so a location can be described as in the inferior frontal gyrus in the left frontal lobe. These folds allow the surface area of the cortex, as well as the total volume of the cortex, to be much greater than in other mammals, while still allowing it to fit inside our skulls, similar to the way the many folds of a car’s radiator give it a very large surface area (for radiating away heat) in a relatively small space.

The cerebral cortex is extraordinarily large in humans compared with other species and is clearly centrally involved in much of what makes our brains special, but the cerebrum contains many other important subcortical structures that we share with other vertebrates. Some of the more important of these structures include the thalamus, the hypothalamus, the basal ganglia, and the amygdala. These areas all connect widely, with the cortex, with each other, and with other parts of the brain, to form complex networks.

The functions of all these areas are many, complex, and not fully understood, but some facts are known. The thalamus seems to act as a main relay that carries information to and from the cerebral cortex, particularly for vision, hearing, touch, and proprioception (one’s sense of the position of the parts of one’s body). It also is, importantly, involved in sleep, wakefulness, and consciousness. The hypothalamus has a wide range of functions, including the regulation of body temperature, hunger, thirst, and fatigue. The basal ganglia are a group of regions in the brain that are involved in motor control and learning, among other things. They seem to be strongly involved in selecting movements, as well as in learning through reinforcement (as a result of rewards). The amygdala appears to be important in emotional processing, including how we attach emotional significance to particular stimuli.

In addition, many other parts of the brain, in the cortex or elsewhere, have their own special names, usually with Latin or Greek roots that may or may not seem descriptive today. The hippocampus, for example, is named for the Greek word for seahorse. For most of us, these names will have no obvious rhyme or reason, but merely must be learned as particular structures in the brain—the superior colliculus, the tegmentum, the globus pallidus, the substantia nigra, the cingulate cortex, and more. All of these structures come in pairs, with one in the left hemisphere and one in the right hemisphere; only the pineal gland is unpaired. Brain atlases include scores of names for particular structures or regions in the brain and detailed information about those structures or regions.

Some of these smaller structures may have special importance to human behavior. The nucleus accumbens, for example, is a small subcortical region in each hemisphere of the cerebrum that appears important for reward processing and motivation. In experiments with rats that received stimulation of this region

in return for pressing a lever, the rats would press the lever almost to the exclusion of any other behavior, including eating. The nucleus accumbens in humans appears linked to appetitive motivation, responding in anticipation of primary rewards (such as pleasure from food or sex) and secondary rewards (such as money). Through interactions with the orbital frontal cortex and dopamine-generating neurons in the midbrain (including the ventral tegmental area), the nucleus accumbens is considered part of a “reward network.” With a hypothesized role in addictive behavior and in reward computations, more broadly, this putative reward network is a topic of considerable ongoing research.

All of these various locations, whether defined broadly by area or by the names of specific structures, can be further subdivided using directions: front and back, up and down, toward the middle or toward the sides. Unfortunately, the directions often are not expressed in a straightforward manner, and several different terminological conventions exist. Locations toward the front or back of the brain can be referred to as either anterior or posterior, or as rostral or caudal (literally, toward the nose, or beak, or toward the tail). Locations toward the bottom or top of the brain are termed inferior or superior or, alternatively, as ventral or dorsal (toward the stomach or toward the back). A location toward the middle of the brain is called medial; one toward the side is called lateral. Thus, different locations could be described, for example, as in the left anterior cingulate cortex, in the dorsal medial (or sometimes dorsomedial) prefrontal cortex, or in the posterior hypothalamus.

Finally, one other method often is used, a method created by Korbinian Brodmann in 1909. Brodmann, a neuroanatomist, divided the brain into about forty-five different areas or regions. Each region was defined based on the kinds of neurons found there and how those neurons are organized. A location described by a Brodmann area (Figure 5) may or may not correspond closely with a structural location. Other organizational schemes exist, but Brodmann’s remains the most widely used to describe the approximate locations of findings in modern human brain imaging studies.

If these varied ways of naming different brain regions seem confusing, it is because they are. But think of them as being like U.S. Supreme Court decisions being cited to *U.S. Reports*, the *Supreme Court Reporter*, and *Supreme Court Reports: Lawyers’ Edition*. They are different methods of pointing to particular parts of the brain.

Some Aspects of How the Brain Works

Most of neuroscience is dedicated to finding out how the brain works, but although much has been learned, considerably more remains unknown. We could use many different ways to describe what is known about how the brain

Figure 5. Brodmann's areas.

Source: Professor Mark Dubin, University of Colorado.

works. This section will discuss a few important aspects of brain function and will make several general points about the localization and distribution of functions, as well as brain plasticity, before commenting on the effects of hormones and other chemical influences on the brain.

Some brain functions are localized in, or especially dependent on, particular regions of the brain. This has been known for many years as a result of studies of people who, through traumatic injury, stroke, or cancer, have lost, or lost the use

of, particular regions of their brains. For example, in the 1860s, French anatomist Paul Broca discovered through autopsies of patients that damage to a region in the left inferior frontal lobe (now known as Broca's area) caused an inability to speak. It is now known that some functions cannot normally be performed when particular brain areas are damaged or missing. The visual cortex, located at the back of the brain in the occipital lobes, is as necessary for vision as the eyes are; the hippocampus is necessary for the creation of many kinds of memory; and the motor cortex is necessary for voluntary movements. The motor cortex and the parallel somatosensory cortex, which is essential for processing sensory information such as the sense of touch from the body, are further subdivided, with particular regions necessary for causing motion or sensing feelings from the legs, arms, fingers, face, and so on.

At the same time, the fact that a region is necessary to a particular class of sensations, behaviors, or cognition does not mean either that it is not involved in other brain functions or that other brain regions do not also contribute to these particular abilities. The amygdala, for example, is involved in our feelings of fear, but it is also involved broadly in emotional reactions, both positive and negative. It also modulates learning, memory, and even sensory perception. Although some functions are localized, others are widely distributed. For example, the visual cortex is essential to vision, but actual visual perception involves many parts of the brain in addition to the occipital lobes. Memories appear to be stored over much of the cortex. Networks of brain regions participate in many of these functions.

For example, if you touch something very hot with your left index finger, your spinal cord, through a reflex loop, will cause you to pull your finger back very quickly. Then the part of your right somatosensory cortex devoted to the index finger will be involved in receiving and initially interpreting the sensation. Other areas of your brain will recognize the stimulus as painful, your motor regions will be involved in waving your hand back and forth or bringing your finger to your mouth, widespread parts of your cortex may lead to you remembering other instances of burning yourself, and your hippocampus may play a role in making a new long-term memory of this incident. There is no single brain region dedicated to reacting when your finger burns; many regions, both specific and general, contribute to the brain's response.

In addition, brains are at least somewhat "plastic" or changeable on both small and large scales. Anyone who can see has a working visual cortex, and it is always located in the back of the brain (in the occipital lobe), but its exact borders will vary slightly from person to person. Even within individuals, the shape of the brain and the size and location of its parts can change over time. This is most evident before birth, during childhood, and for many people well into their twenties. It is not true that adults make no new neurons, but we do not make many of them, and they are localized to two regions: the olfactory bulb, which plays a huge role in our senses of smell and taste, and the hippocampus, which is

essential for making most kinds of memories. Unfortunately, though, adults can and do lose neurons through the shrinkage or even destruction of parts of the brain, as a result of traumatic injury, disease, or aging.

Another kind of plasticity is ubiquitous in our brains' lives. The shape or number of our neurons does not change much after childhood, but their connections and functions can change markedly. The brain can adjust and change in response to a person's behavior or changes in that person's anatomy. If a person loses an arm to amputation, the parts of the motor and somatosensory cortices that had dealt with that arm may be "taken over" by other body parts. In some cases, this brain plasticity can be extreme. Young children who have lost an entire hemisphere of their brains may grow up to have normal or nearly normal functionality as the remaining hemisphere takes on the tasks of the missing hemisphere. Unfortunately, the possibilities of this kind of extreme plasticity do diminish with age, but rehabilitation after stroke in adults sometimes shows changes in the brain functions undertaken by particular brain regions.

Both kinds of plasticity—physical changes in the brain and connective and functional changes in the brain—pose some important problems for neuroimaging evidence. A criminal defendant's brain might have unusual and possibly detrimental physical or functional anomalies at or shortly before the time of trial, but those issues may not have existed at the time of the relevant events. This "time machine" problem is discussed further at pages 1244 and 1249.

The picture of the brain as a set of interconnected neurons that fire in networks or patterns in response to stimuli is useful but not complete. In addition to neuron firings, other factors affect how the brain works, particularly chemical factors.

Some of these factors are hormones, generated by the body either inside or outside the brain. They can affect how the brain functions, as well as how it develops. Sex hormones such as estrogen and testosterone can have both short-term and long-term effects on the brain. So can other hormones, such as cortisol, associated with stress, and oxytocin, associated with, among other things, trust and bonding. Endorphins, chemicals secreted by the pituitary gland in the brain, are associated with pain relief and a sense of well-being. Still other chemicals, brought in from outside the body, can have major effects on the brain, both in the short term and the long term. Examples include alcohol, caffeine, nicotine, morphine, and cocaine. These can trigger very specific brain reactions or can have broad effects.

Some Common Neuroscience Techniques

Neuroscientists use many techniques to study the brain. Some of them have been used for centuries, such as autopsies and the observation of patients with

brain damage. Some, such as the intentional destruction of parts of the brain, can be used ethically only in research on nonhuman animals. Of course, research with nonhuman animals, while often helpful in understanding human brains, is of less value when examining behaviors that are uniquely developed among humans. The current revolution in neuroscience is largely the result of a revolution in the tools available to neuroscientists, as new methods have been developed to image and to intervene in living brains. These methods, particularly the imaging methods that allow more precise measurements of human brain structure and function in living people, are giving rise to increasing efforts to introduce neuroscientific evidence in court.

This section will focus on several kinds of neuroimaging—computerized axial tomography (CAT scans), positron emission tomography (PET scans), single photon emission computed tomography (SPECT scans), magnetic resonance imaging (MRI), diffusion tensor imaging (DTI), and functional near-infrared spectroscopy (fNIRS), as well as an older method, electroencephalography (EEG) and its close relative magnetoencephalography (MEG). Some of these methods show the structure of the brain, others show the brain's functioning, and some do both. These are not the only important neuroscience techniques; several others will be discussed briefly at the end of this section. Genetic analysis provides yet another technique for increasing our understanding of human brains and behaviors, but this reference guide will not deal with the possible applications of human genetics to understanding behavior.

We go into these techniques at some length and in some detail, but we think that is crucial. A judge may be confronted with neuroscience evidence that has been developed using any of these methods. Having at least some background in what they are and their strengths and weaknesses may be invaluable. In the context of any given case, a judge may well choose to look at only the parts of this section relevant to that case rather than read the whole section.

Before digging into the techniques, though, it may be useful to discuss briefly the experts who will be testifying about them. All scientific evidence is presented through experts. In court cases involving brain or mind evidence, judges and juries regularly hear testimony from clinical psychologists and psychiatrists, often specialized as forensic psychologists or psychiatrists. Other kinds of specialist or subspecialist physicians may also testify, such as neurologists, neurosurgeons, neurointensivists, neuroradiologists, or neuropathologists.

Those experts may also be involved in presenting neuroscience evidence, but they will likely be joined or replaced by nonclinical experts in neuroscience, usually from universities or medical schools. Some will be located in departments of neuroscience, neurobiology, or some other term their employer uses for its basic brain science research department; others will be in psychology, psychiatry, neurology, or neurosurgery departments. Although some of these experts will be trained physicians and may even see some patients, most will have doctoral degrees and will focus their work on research. Rather than testifying about the condition

or history of a particular person, they will usually testify about neuroscience techniques or research establishing connections between the findings of those techniques and relevant human behaviors or mental conditions, based on peer-reviewed literature, often that they have published. They may or may not have examined the individual in question.

The distinctions among the types of experts who might testify about neuroscience findings is well discussed in a 2018 law review article.⁸

Neuroimaging

Although X-ray imaging has been used for over a century, it has not been very helpful in studying the brain. X-ray images are the shadows cast by dense objects. Not only is the brain surrounded by our very dense skulls, but there are no dense objects inside the brain to cast these shadows. Although a few features of the brain or its blood vessels could be seen through methods that involved the injection of air into some of the spaces in the brain or of contrast media into the blood, these provided limited information. The opportunity to see inside a living brain itself only goes back to about the 1970s, with the development of CAT scans. This ability has since exploded with the development of several new techniques. This section will discuss five of them: CAT scans (sometimes also called computer-assisted tomography or computed tomography), PET and SPECT scans, MRI, DTI, and fNIRS.

CAT Scans

The CAT scan is a multidimensional, computer-assisted X-ray machine. Instead of taking one X-ray from a fixed location, in a CAT scan both the X-ray source and the X-ray detectors opposite the source rotate around the person being scanned. Traditional X-ray machines shine the radiation through an object to a photographic negative, producing an actual picture that shows where dense objects blocked the X-rays. In a CAT scan (Figure 6), the X-ray detectors produce data sufficient to reconstruct the scanned object in three dimensions. Computerized algorithms can then be used to produce an image of any particular slice through the object. The multiple angles and computer analysis make it possible to pick out the relatively small density differences within the brain that traditional X-ray technology could not distinguish and to use them to produce images of the soft tissue.

8. See Jane Campbell Moriarty & Daniel D. Langleben, *Who Speaks for Neuroscience? Neuroimaging Evidence and Courtroom Expertise*, 68 Case W. Rsrv. L. Rev. 783 (2018), <https://perma.cc/ECK8-D7WS>.

Figure 6. CAT scan depicting axial sections of the human brain.

Source: https://en.wikipedia.org/wiki/File:Computed_tomography_of_human_brain_-_large.png.

The CAT scan provides a structural image of the brain. It is useful for showing some kinds of structural abnormalities, but it provides no direct information about the brain's functioning. A CAT scan brain image is not as precise as the image produced from an MRI, but because the procedure is both quick and (relatively) inexpensive, CAT scanners are common in hospitals. Medically, brain CAT scans are used mainly to look for bleeding or swelling inside the brain, although they also will record sizable tumors or other large structural abnormalities. For neuroscience, the great advantage of the CAT scan was its ability, for the first time, to see some details inside the skull, an ability that has been largely superseded for research by MRI. CAT scans have been used for decades in litigation to provide evidence about the physical condition of the brain, often in cases about brain injuries or medical malpractice. But they have also been used to argue that structural changes in the brain, shown on the CAT scan, are evidence of insanity or other mental impairments. Perhaps their most notable use was in 1982 in the trial of John Hinckley Jr., for the attempted assassination of President Ronald Reagan. A CAT scan of Hinckley's brain that showed widened sulci (the "valleys" in the surface of the brain) was introduced

into evidence to show that Hinckley suffered from organic brain damage in the form of shrinkage of his brain.⁹

PET Scans and SPECT Scans

Traditional X-ray machines and their more sophisticated descendant, the CAT scanner, project X-rays through the skull and create images based on how much of the X-rays are blocked or absorbed. PET scans and SPECT scans operate very differently. In these methods, a substance that emits radiation is introduced into the body. That radiation then is detected from outside the body in a way that can determine the location of the radiation source. These scans generally are not used for determining the brain's structure, but are used for understanding how it is functioning. They are particularly good at measuring one aspect of brain structure—the density of particular receptors, such as those for dopamine, at synapses in some areas of the brain, such as the frontal lobes.

Radioactive decay of atoms can take several forms, producing alpha, beta, or gamma radiation. PET scanners take advantage of isotopes of atoms that decay by giving off positive beta radiation. Beta decay usually involves the emission of an electron; positive beta decay involves the emission of a positron, the positively charged antimatter equivalent of an electron. When positrons (antimatter) meet electrons (matter), the two particles are annihilated and converted into two photons of gamma radiation with a known energy (511,000 electron volts) that follow directly opposite paths from the site of the annihilation. Inside the body, the collision between the positron and electron and the consequent production of the gamma radiation photons take place within a short distance (a millimeter or two) of the site of the initial radioactive decay that produced the positron.

PET scans, therefore, start with the introduction into a person's body of a radioactive tracer that decays by giving off a positron. One common tracer is fluorodeoxyglucose (FDG), a molecule that is almost identical to the simple sugar glucose, except that one of the oxygen atoms in glucose is replaced by an atom of fluorine-18, an isotope of the element fluorine with nine protons and nine neutrons. Fluorine normally found in nature is fluorine-19, with nine protons and ten neutrons, and is stable. Fluorine-18 is very unstable and decays quickly, through positive beta decay, losing about half of its mass every 110 minutes (its half-life). The body treats FDG as though it were glucose, and so the FDG is concentrated where the body needs the energy supplied by glucose. A major clinical

9. The effects of this evidence on the verdict are unclear. See Lincoln Caplan, *The Insanity Defense and the Trial of John W. Hinckley, Jr.* (1984), for a discussion of the case and its consequences for the law.

use of PET scans derives from the fact that tumor cells use energy, and hence glucose, at much higher rates than normal cells.

After giving the FDG time to become concentrated in the body, which usually takes about an hour, the person is put inside the scanner itself. There, the person is entirely surrounded by a very sensitive radiation detector, tuned to respond to gamma radiation of the energy produced by annihilated positrons. When two “hits” are detected by two sensors at about the same time, the source is known to be located on a line connecting the two. Very small differences in the timing of when the radiation is detected can help determine where along that line the annihilation took place. In this way, as more gamma radiation from the decaying FDG is detected, the general location of the FDG within the body can be determined and, as a result, tissue that is using a lot of glucose, such as a tumor, can be located.

In neuroscience research, PET scans also can be taken using different molecules that bind more specifically to particular tissues or cells. Some of these more specific ligands use fluorine-18, but others use a different radioactive tracer that also decays by emitting a positron—oxygen-15. This can be used to determine what parts of the brain are using more or less oxygen. Oxygen-15, however, has a much shorter half-life (two minutes) and so is more difficult and expensive to use than FDG. Similarly, carbon-11, with a half-life of twenty minutes, also can be used. Carbon-11 atoms can be introduced into various molecules that bind to important receptors in the brain, such as receptors for dopamine, serotonin, or opioids. This allows the study of the distribution and function of these receptors, both in healthy people and in people with various mental illnesses or neurological diseases.

The result of a PET scan is a record of the locations of positron decay events in the brain. Computer visualization tools can then create cross-sectional images of the brain, showing higher and lower rates of decay, with differences in magnitude typically depicted through the use of different colors.

PET scans are excellent for showing the location of various receptors in normal and abnormal brains (Figure 7). PET scans are also very good for showing areas of different glucose use and, hence, of different levels of metabolism. This can be very useful, for example, in detecting some kinds of brain damage, such as the damage that occurs with Alzheimer’s disease, where certain regions of the brain become abnormally inactive, or in brain regions that have been damaged by a stroke.

In addition, the comparison (subtraction) of two PET scan measurements—one scan when a person is engaged in a task that is thought to require particular brain functions and a second control (or baseline) scan that is not thought to require these functions—allows researchers indirectly to measure brain function. PET scans were initially used in this way in research to show what areas of the brain were used when people experienced various stimuli or performed particular tasks. It has been substantially superseded for this purpose by functional

MRI, which is less expensive, does not involve radiation exposure, provides better spatial resolution, and allows a longer period of testing.

SPECT scans are similar to PET scans. Each can produce a three-dimensional model of the brain and display images of any cross section through the brain. Like PET scans, they require the injection of a radioactive tracer material; unlike PET scans, the radioactive tracer directly emits gamma radiation rather than emitting positrons. These kinds of tracers are more stable, more accessible, and much cheaper than the positron-emitting tracers needed for PET scans. With a PET scan, the gamma detector entirely surrounds the person; with a SPECT scan, one to three gamma detectors are rotated around the body for about fifteen to twenty minutes. As with PET scans, the SPECT tracers can be used to measure brain metabolism or to attach to specific molecular receptors in the brain. The spatial resolution of a SPECT scan, however, is poorer than with a PET scan, with an uncertainty of about one centimeter.

Both PET and SPECT scans are most useful if coupled with good structural images. Contemporary PET and SPECT scanners often include a simultaneous CAT scan; there is some experimental work aimed at providing simultaneous PET and MRI scans.

MRI—Structural and Functional

MRI was developed in the 1970s, first came into wide use in the 1980s, and is currently the dominant neuroimaging technology for producing detailed images of the brain's structure and for measuring aspects of brain function. MRI

operates on completely different principles than either CAT scans or PET or SPECT scans; it does not rely on X-rays passing through the brain or on the decay of radioactive tracer molecules inside the brain. Rather, MRI's workings involve more complicated physics. This section will discuss the general characteristics of magnetic resonance imaging and then will focus on structural MRI, diffusion tensor imaging, and finally functional MRI.

The power of an MRI scanner is measured by the strength of its magnetic field, measured in units called tesla (T). The magnetic field of a small bar magnet is about 0.01T. The strength of the Earth's magnetic field is about 0.00005T. The MRI machines used for clinical purposes use magnetic fields of between 0.2T and 3.0T, with 1.5T or 3.0T being the systems most commonly used today. MRI machines for human research purposes have reached 9.4T. In general, the stronger the magnetic field, the better the image, although higher fields also can create their own measurement difficulties, especially when imaging brain function. MRI machines achieve these high magnetic fields through use of superconducting magnets, made by cooling the electromagnet with liquid helium at a temperature four degrees Celsius above absolute zero. For this and other reasons, MRI systems are complicated, with higher initial and continuing maintenance costs compared to some other methods for functional imaging (e.g., electroencephalography; see below).

In most MRI systems, the individual, on an examination table, slides into a cylindrical opening in the machine so that the part of the body to be imaged is in the middle of the magnet (Figure 8). Depending on the kind of imaging performed, the examination or experiment can take from about thirty minutes to more than two hours; throughout the scanning process the individual being examined needs to stay as motionless as possible to avoid corrupting the images. The main sensations are the loud thumping and buzzing noises made by the machine, as well as the machine's vibration.

MRI examinations appear to involve minimal risk. Unlike the other neuroimaging technologies discussed above, MRI does not involve any high-energy radiation. The magnetic field seems to be harmless, at least as long as magnetizable objects are kept away from it. MRI participants need to remove most metal objects; people with some kinds of implanted metallic devices, with tattoos with metal in their ink, or with fragments of ferrous metal anywhere in their bodies cannot be scanned because of the dangerous effects of the field on those bits of metal.

When an individual is positioned in the MRI scanner, the powerful field of the magnet causes the nuclei of atoms (usually the hydrogen nuclei of the body's water molecules) to align with the direction of the main magnetic field of the magnet. Using a brief electromagnetic pulse, these aligned atoms are then "flipped" out of alignment from the main magnetic field, and, after the pulse stops, the nuclei then rapidly realign with the strong main magnetic field. Because the

nuclei spin (like a top), they create an oscillating magnetic field that is measured by a receiver coil. During structural imaging, the strength of the signal generated partially depends on the relative density of hydrogen nuclei, which varies from point to point in the body according to the density of water. In this manner, MRI scanners can generate images of the body's anatomy or of other scanned objects. Because an MRI scan can effectively distinguish between similar soft tissues, MRI can provide very high-resolution images of the brain's anatomy, which is, after all, made up of soft tissue.

Structural MRI scans produce very detailed images of the brain (Figure 9). They can be used to spot abnormalities, large and small, as well as to see normal

variation in the size and shape of brain features. Structural MRI can be used, for example, to see how brain features change as a person ages. Previously, getting that kind of detailed information about a brain required an autopsy or, at a minimum, extensive neurosurgery. This ability makes structural MRI both an important clinical tool and a very useful technique for research that tries to correlate human differences, normal and abnormal, to differences in brain structure, as well as for research that seeks to understand brain development.

Functional MRI (fMRI; Figure 10) harnesses the power of MRI in neuroscience for understanding brain function. While it is perhaps one of the most exciting technologies used in neuroscience, as discussed in the section titled “Replication” below, it has proven difficult to replicate many findings from fMRI research. The technique shows what regions of the brain are more or less active in response to the performance of particular tasks or the presentation of particular stimuli. It does not measure brain activity (the firing of neurons) directly but, instead, looks at how blood flow changes in response to brain activity and uses those changes, through the so-called BOLD response (the blood-oxygen-level-dependent response), to allow the researcher to infer patterns of brain activity.

Structural MRI generally creates its images through detecting the density of hydrogen atoms in the participant and flipping them with radio pulses. For fMRI, the scanner detects changes in the ratio of oxygenated hemoglobin (oxyhemoglobin) and deoxygenated hemoglobin (deoxyhemoglobin) in particular locations of the brain. Hemoglobin is the protein in red blood cells that carries oxygen from the lungs to the body. Based on metabolic demands, hemoglobin molecules supply oxygen for the body’s needs. Accordingly, “fresher” blood will have a higher ratio of oxyhemoglobin to deoxyhemoglobin than more “used” blood. Importantly, because deoxyhemoglobin (which is found at a higher level in “used” blood) causes the fMRI signal to decay, a higher ratio of oxyhemoglobin to deoxyhemoglobin will produce a stronger fMRI signal.

Neural activity is energy intensive for neurons, and neurons do not contain any significant reserves of oxygen or glucose. Therefore, the brain’s blood vessels respond quickly to increases in activity in any one region of the brain by sending more fresh blood to that area. This is the basis of the BOLD response, which measures changes in the ratio of oxyhemoglobin to deoxyhemoglobin in a brain region several seconds after activity in that region. In particular, when a brain region becomes more active, there is first, perhaps more intuitively, a decline in the ratio of oxyhemoglobin to deoxyhemoglobin immediately after activity in the region, apparently corresponding to the depletion of oxygen in the blood at the site of the activity. This decline, however, is very small and very hard to detect with fMRI. Immediately after this decrease, there is an infusion of fresh (oxyhemoglobin-rich) blood, which can take several seconds to reach maximum; it is this infusion that results in the increase in the oxy/deoxyhemoglobin ratio

that is measured in BOLD fMRI studies. Because even this subsequent increase is relatively small and variable, fMRI experiments typically involve many trials of the same task or class of stimuli in order to be able to see the signal amid the noise.

Thus, in a typical fMRI experiment, the participant will be placed in the scanner and the researchers will measure differences in the BOLD response throughout their brain under different conditions. A participant might, for example, be told to look at a video screen on which images of places alternate with images of faces. For purposes of the experiment, the computer will impose a spatial map on the participant's brain, dividing it into thousands of little cubes, each a few cubic millimeters in size, referred to as "voxels." Either while the data are being collected (so-called real-time fMRI¹⁰) or after an entire dataset has been gathered, a computerized program will compare the BOLD signal for each voxel when the screen was showing places to the signals when the screen contained faces. Regions that showed a statistically significant increase in the BOLD response several seconds after the face was on the video screen compared with the effects several seconds after a screen showing a face appeared. The researchers will infer that those regions were, in some way, involved in how the brain processes images of faces. The results will typically be shown as a structural brain image on which areas of more or less activation, as shown by a statistical test, will be represented by different colors.¹¹

fMRI was first proposed in 1990, and the first research results using BOLD-contrast fMRI in humans were published in 1992. The first decade of this century saw an explosive increase in the number of research articles based on fMRI, with nearly 2,500 articles published in 2008 alone—compared to about 450 in 1998.¹² The tide continued to rise; in 2015 alone, nearly 30,000 fMRI papers were published. MRI (functional and structural) is quite safe, and MRI machines are widespread in developed countries, largely for clinical use but increasingly for research use as well. Although fMRI research is subject to many questions and controversies (discussed below), this technique sparked a surge of

10. Use of this "real-time fMRI" has been increasing, but it is not yet clear whether the claims for it will stand up.

11. This example is actually a simplified version of experiments performed by Professor Nancy Kanwisher at MIT in the early 2000s that explored a region of the brain called the fusiform face area that is particularly involved in processing visions of faces. See Kathleen M. O'Craven & Nancy Kanwisher, *Mental Imagery of Faces and Places Activates Corresponding Stimulus-Specific Brain Regions*, 12 *J. Cognitive Neuroscience* 1013 (2000), <https://doi.org/10.1162/08989290051137549>.

DTI

DTI (diffusion tensor imaging) is a different application of MRI, one that uses the MRI data not to build a picture of the brain (structural MRI) or of changes in the ratio of oxygenated to deoxygenated hemoglobin over time in the brain (functional MRI) but to follow the ways water diffuses through brain tissue to map out the brain's white matter. As noted above, neuronal tissue in the brain can be divided roughly into gray matter (the bodies of neurons) and white matter (neuronal axons that transmit signals over distance). DTI uses MRI to see what direction water diffuses through brain tissue. Tracts of white matter are made up of bundles of axons coated with fatty myelin. Water will diffuse through that white matter along the direction of the axons and not, generally, across them. This method can be used, therefore, to trace the location of these bundles of white matter and hence the long-distance connections between different parts of the brain.

These kinds of “wiring diagrams” can be very important in brain research, but they also have clinical applications. Abnormal patterns of these connections may be associated with various conditions, from traumatic brain injury and stroke to brain tumors, Alzheimer's disease, and dyslexia, some of which may have legal implications.¹⁵

fNIRS

Like functional magnetic resonance imaging (fMRI), functional near-infrared spectroscopy can detect changes in hemoglobin within the brain, but it does so by measuring differences in the absorption of light that occurs through blood flow to different regions of the brain. fNIRS is effective because biological tissue is relatively transparent to infrared light in wavelengths ranging from 650 to 925 nanometers (nm). Light in this range is absorbed more strongly by oxygenated versus deoxygenated blood, and at different wavelengths. Deoxygenated blood is absorbed more strongly below 790 nm, and oxygenated blood more strongly above 790 nm.¹⁶ By detecting the changes in the relative concentrations of

different light-absorbing molecules, fNIRS can measure energy metabolism in the brain, including regional changes in brain activity.

fNIRS is portable, noninvasive, and cost-effective, and it allows real-time temporal tracking of brain activity. For these reasons, it is often used in clinical and research-based settings. For example, in the pediatric ICU, brain oxygenation levels are regularly monitored using fNIRS where long-term real-time monitoring of brain activity is necessary.¹⁷ Its disadvantages are that it cannot be used on parts of the brain more than four centimeters (a bit more than one and a half inches) below the skull and that its spatial resolution is low compared to fMRI, but higher than EEG, which we turn to next.

EEG and MEG

EEG (electroencephalography) is the measurement of the brain's electrical activity as exhibited on the scalp; MEG (magnetoencephalography) is the measurement of the small magnetic fields generated by the brain's electrical activity. The roots of EEG go back to the nineteenth century, but its use increased dramatically in the 1930s and 1940s.

The process for medical or research-grade EEG uses electrodes touching the participant's head, applied with an electrically conductive substance (a paste or a gel) to record electrical currents on the surface of the scalp. Multiple electrodes are used; for clinical purposes, 16 to 25 electrodes are commonly used, although arrays of more than 200 electrodes can be used. In MEG, superconducting "SQUIDS"¹⁸ are positioned over the scalp to detect the brain's tiny magnetic signals. The electrical currents are generated by the neurons throughout the brain, although EEG is more sensitive to currents emerging from neurons closer to the skull. It is therefore more challenging to use EEG to reveal the functioning of structures deep in the brain.

Because EEG and MEG directly measure neural activity, in contrast to the measures of blood flow in fMRI and fNIRS, the timing of the neural activity can be measured with great precision (the temporal resolution), down to milliseconds. On the other hand, in comparison to fMRI, EEG and MEG are poor at determining the location of the sources of the currents (the spatial resolution). Any one pattern of EEG or MEG signal at the scalp has an infinite number of possible source patterns, making the problem of determining the brain source of measured EEG/MEG signal particularly challenging and the results less precise.

17. *Id.*

18. SQUID stands for superconducting quantum interference device (and has nothing to do with the marine animal). This device can measure extremely small magnetic fields, including those generated by various processes in living organisms, and so is useful in biological studies.

Thus, EEG/MEG signal is a summation of the activity of thousands to millions of neurons at any one time.

The results of clinical EEG and MEG tests can be very useful for detecting some kinds of brain conditions, notably epilepsy, and are also part of the process of diagnosing brain death. EEG and MEG are also used for research, particularly in the form of event-related potentials, which correlate the size or pattern of the EEG or MEG signal with the performance of particular tasks or the presentation of particular stimuli. Thus, as with the hypothetical fMRI experiment described above, one could look for any consistent changes in the EEG or MEG signal when a participant sees faces rather than a blank screen. Apart from the determination of brain death, where EEG is already used, the most discussed possible legally relevant uses of EEG have been lie detection and memory detection.

EEG is safe, cheap, quiet, and portable. MEG is safe and quiet, but the technology is considerably more expensive than EEG and is not easily portable. EEG methods can tolerate much more head movement by the participant than PET or MRI techniques, although movement is often a challenge for MEG. EEG and MEG have good temporal resolution, distinguishing between milliseconds, which makes them very attractive for research, but their spatial resolution is inadequate for many research questions. As a result, some researchers use a combination of methods, integrating MRI and EEG or MEG data (acquired simultaneously or at different times) using sophisticated data analysis techniques.

Although EEG has most often been used in clinical and research-based settings, an increasing number of companies offer consumer-based devices with EEG electrodes. These devices have many fewer electrodes than clinical-grade EEG devices, and so offer much lower resolution and much noisier data. Large mainstream technology companies from Meta to Microsoft are developing consumer-based neural interface devices to enable consumers to meditate, play brain-controlled games, monitor their brain health, or even one day replace peripheral devices like keyboards and mice to interact with other technology. Widespread adoption of these consumer-based neural interface devices could significantly increase the amount of neural data being passively recorded in everyday life and potentially introduced into the legal system. The quality of the data and algorithms used to process the collected data will become increasingly at issue as these data are introduced into legal settings.

Other Techniques

Several other neuroscience techniques may also have legal applications. This section will briefly describe four other methods that may be discussed in court: lesion studies, transcranial magnetic stimulation, deep brain stimulation, and implanted microelectrode arrays.

Lesion Studies

One powerful way to test whether particular brain regions are associated with particular mental processes is to study mental processes after those brain regions have been destroyed or damaged. Observations of the consequences of such lesions, created by accidents or disease, were, in fact, the main way in which localization of brain function was originally understood.

For ethical reasons, the experimental destruction of brain tissue is limited to nonhuman animals. Nonetheless, in addition to accidental damage, on occasion, human brains will need to be intentionally damaged for clinical purposes. Tumors may have to be removed or, in some cases, epilepsy may have to be treated by removing the region of the brain where the seizures began. Valuable knowledge may be gained from following these individuals.

Our understanding of the role of the hippocampus in creating memories, as one example, was greatly aided by study of a patient known as H.M.¹⁹ When he was twenty-seven years old, H.M. was treated for intractable epilepsy, undergoing an experimental procedure that surgically removed his left and right medial temporal lobes, including most of his two hippocampi. The surgery was successful, but from that time until his death in 2008, H.M. could not form new long-term memories, either of events or of facts. His short-term memory, also known as working memory, was intact, and he could learn new motor, perceptual, and (some) cognitive skills (his “procedural memory” still functioned). He also could remember his life’s events from before his surgery, although his memories were weaker the closer the events were to the surgery. Those brain regions were clearly involved in making new long-term memories for facts or events, but not in storing old ones.

TMS

Transcranial magnetic stimulation (TMS) is a noninvasive method of creating a temporary, reversible, functional brain lesion. Using this technique, researchers disrupt the organized activity of the brain’s neurons by applying an electrical current. The current is formed by a rapidly changing magnetic field that is generated by a coil held next to the participant’s skull. The field penetrates the scalp and skull easily and causes a small current in a roughly conical portion of the

19. H.M.’s name, not publicly released until his death, was Henry Gustav Molaison. Details of his life can be found in several obituaries, including Benedict Carey, *H.M., An Unforgettable Amnesiac, Dies at 82*, N.Y. Times, Dec. 4, 2008, at A1, <https://www.nytimes.com/2008/12/05/us/05hm.html>, and H.M., *A Man Without Memories*, Economist, Dec. 18, 2008, <https://perma.cc/7CHX-UQNH>. The first scientific report of his case was William Beecher Scoville & Brenda Milner, *Loss of Recent Memory After Bilateral Hippocampal Lesions*, 20 J. Neurology Neurosurgery & Psychiatry 11 (1957), <https://doi.org/10.1136/jnnp.20.1.11>.

brain below the coil. This current induces a change in the typical responses of the neurons, which can block the normal functioning of that part of the brain.

TMS can be done in a number of ways. In some approaches, TMS happens while the participant performs the task to be studied. In these approaches, while the task is performed, TMS can be delivered as single pulses, paired pulses, or repetitive, rapid (more than once per second) pulses. Another method uses TMS for an extended period, often several minutes, before the task is performed. This sequential TMS uses slow (less than once per second) repetitive TMS.

The effects of single-pulse/paired-pulse and concurrent repetitive TMS are present while the coil is generating the magnetic field, and can extend for a few tens of milliseconds after the stimulation is turned off. By contrast, the effects of pretask repetitive TMS are thought to last for a few minutes (about half as long as the actual stimulation). When TMS is repeated regularly in nonhumans, long-term effects have been observed. Therefore, guidelines regarding how much stimulation can be applied in humans have been established.

The Food and Drug Administration (FDA) has approved TMS as a treatment for otherwise untreatable depression. The neuroscience research value of TMS stems more from its ability to create alteration of brain function in a relatively small area (about two centimeters) in an otherwise healthy brain, thus allowing for targeted testing of the role of a particular brain region for a particular class of cognitive abilities. By blocking normal functioning of the affected neurons, this can be equivalent, in effect, to a temporary lesion of that area of the brain. TMS appears to have minimal risks, but its long-term effects are not known.

DBS

Deep brain stimulation (DBS) is an FDA-approved treatment for several neurological conditions affecting movement, notably Parkinson's disease, essential tremor, and dystonia. The device used in DBS includes a lead that is implanted into a specific brain region, a pulse generator (generally implanted under the shoulder or in the abdomen), and a wire connecting the two. The pulse generator sends an electric current to the electrodes in the lead, which in turn affect the functioning of neurons in an area around the electrodes.

The precise manner by which DBS affects brain function remains unclear. Even for Parkinson's disease, for which it is widely used, individual patients sometimes benefit in unpredictable ways from placement of the lead in different locations and from different frequency or power of the stimulation.

Researchers are continuing to experiment with DBS for other conditions, such as depression, minimally conscious state, chronic pain, and overeating that leads to morbid obesity. The results are sometimes surprising. In a Canadian trial of DBS for appetite control, the obese patient did not ultimately lose weight but did suddenly develop a remarkable memory. That research group quickly started

a trial of DBS for dementia (although thus far without any obvious success).²⁰ Other surprises include some observed negative side effects from DBS, such as compulsive gambling, hypersexuality, and hallucinations. These kinds of unexpected consequences from DBS make it of continuing broader research interest.

Implanted Microelectrode Arrays

Ultimately, to understand the brain fully, one would like to know what each of its 100 billion neurons is doing at any given time, analyzed in terms of their collective patterns of activity.²¹ No current technology comes close to that kind of resolution. For example, although fMRI has a voxel size of a few cubic millimeters, it is looking at the blood flow responding to thousands or millions of neurons at each point in the brain. Conversely, while direct electrical recordings allow individual neurons to be examined and manipulated, it is not easy to record from many neurons at once. While still on a relatively small scale, recent developments now offer one method for recording from multiple neurons simultaneously by using an implanted microelectrode array.

A chip containing many tiny electrodes can be implanted directly into brain tissue. Some of those electrodes will make usable connections with neurons and can then be used either to record the activity of that neuron (when it is firing or not) or to stimulate the neuron to fire. These kinds of implants have been used in research on motor function, both in monkeys and occasionally in human patients. The research has been aimed at understanding better what neuronal activity leads to motion and hence, in the long run, perhaps to a method of treating quadriplegia or other motion disorders.

These arrays have several disadvantages as research tools. Arrays require neurosurgery for their implantation, with all of its consequent risks of infection or damage. They also have a limited lifespan, because the brain's defenses eventually prevent the electrical connection between the electrode and the neuron, usually over the span of a few months. Finally, the arrays can only reach a tiny number of the billions of neurons in the brain; current arrays have about one hundred microelectrodes. But the field and devices in use are changing rapidly. *Nature Electronics*

declared brain-computer interface technology the “Technology of the Year” in 2023, and dedicated a volume to its current state of development.²²

Issues in Interpreting Study Results

Lawyers trying to introduce neuroscience evidence will almost always be arguing that, when interpreted in the light of some preexisting research study, some kind of neuroscience-based test of the brain of a person in the case—usually a party, though sometimes a witness—is relevant to the case. It might be a claim that a PET scan shows that a criminal defendant was likely to have been legally insane at the time of the crime; it could be a claim that an fMRI of a witness demonstrates that they are lying. The judge will have to determine whether the scientific evidence is admissible at all under the Federal Rules of Evidence, and particularly under Rule 702. If the evidence is admissible, the finder of fact will need to consider the validity and strength of the underlying scientific finding, the accuracy of the particular test performed on the party or witness, and the application of the former to the latter.

Neuroscience-based evidence will commonly raise several scientific issues relevant to both the initial admissibility decision and the eventual determination of the weight to be given the evidence. This section will examine seven of these issues: replication, experimental design, participant selection and number, group averages, technical accuracy, statistical issues, and countermeasures. The discussion will focus on fMRI-based evidence, as that seems likely to be the method that will be used most frequently in the coming years, but most of the issues apply more broadly.

One general point is absolutely crucial. The various techniques discussed in the section titled “Some Common Neuroscience Techniques” above are generally accepted scientific procedures, for use both in research and, in most cases, in clinical care. Each one is a good scientific tool in general. The crucial issue is not likely to be whether the techniques meet the requirements for admissibility when used for *some* purposes, but whether the techniques—*when used for the purpose for which they are offered*—meet those requirements. Sometimes proponents of fMRI-based lie detection, for example, argue that the technique should be accepted because fMRI is the subject of tens of thousands of peer-reviewed publications. That is true, but irrelevant—the question is the application of fMRI to lie detection, which is the subject of far fewer, and much less definitive, publications.

Replication

A good general rule of thumb in science is never to rely on any experimental finding until it has been independently replicated. This may be particularly true with fMRI experiments, not because of fraud or negligence on the part of the experimenters, but because, for reasons discussed below, these experiments are very complicated. Replication builds confidence that those complications have not led to false results.

In many scientific fields, including much of fMRI research, replication is sometimes not as common as it should be. A scientist often is not rewarded for replicating (or failing to replicate) another's work. Grants, tenure, and awards tend to go to people doing original research. The rise of fMRI has meant that such original experiments are easy to conceive and to attempt—any researchers with experimental expertise, access to research participants (often undergraduates), and access to an MRI scanner (found at any major medical facility) can try their own experiments and, if the study design and logic are sound and the results are statistically significant, may well end up with published results. Experiments replicating, or failing to replicate, another's work are neither as exciting nor as publishable.

For example, as discussed in more detail below, more than fifteen different laboratories have collectively published twenty to thirty peer-reviewed articles finding some statistically significant relationship between fMRI-measured brain activity and deception. None of the studies is an independent replication of another laboratory's work. Each laboratory used its own experimental design, its own scanner, and its own method of analysis. Interestingly, the published results implicate many different areas of the brain as being activated when a participant lies. A few of the brain regions are found to be important in most of the studies, but many of the other brain regions showing a correlation with deception differ from publication to publication. Only a few of the laboratories have published replications of their own work; some of those laboratories have actually published findings with different results from those in their earlier publications.

That a finding has been replicated does not mean it is correct; different laboratories can make the same mistakes. Neither does failure of replication mean that a result is wrong. Nonetheless, the existence of independent replication is important support for a finding.

Problems in Experimental Design

The most important part of an fMRI experiment is not the MRI scanner, but the design of the underlying experiment being examined in the scanner. A poorly designed experiment may yield no useful information, and even a well-designed experiment may lead to information of uncertain relevance.

A well-designed experiment must focus on the particular mental state or brain process of interest while minimizing any systematic biases. This can be especially difficult with fMRI studies. After all, these studies are measuring blood flow in the brain associated with neuronal responses in particular regions. If, for example, in an experiment trying to assess how the brain reacts to pain, the experimental participants are consistently distracted at one point in the experiment by thinking about something else, the areas of brain activation will include the areas activated by the distraction. One of the earliest published lie-detection experiments was designed so that the experimental participants pushed a button for “yes” only when saying (honestly) that they held the card displayed; they pushed the “no” button both when they did not hold the card displayed and when they did hold it but were following instructions to lie. They were to say “yes” only twenty-four times out of 432 trials.²³ The resulting differences might have come from the differences in thinking about telling the truth or telling a lie—but they also may have come from the differences in thinking about pressing the “no” button (the most common action) and pressing the “yes” button (the less frequent response). The results themselves cannot distinguish between the two explanations.

Designing good experiments is difficult, but in some respects the better the experiment, the less relevant it may prove to a real situation. A laboratory experiment attempts to minimize distractions and differences among participants, but such factors will be common in real-world settings. Perhaps more importantly, for some kinds of experiments it will be difficult, if not impossible, to reproduce in the laboratory the conditions of interest in the real world. As an extreme example, if one is interested in how a murderer’s brain functions during a murder, one cannot conduct an experiment that involves having the participant commit a murder in the scanner. For ethical reasons, that condition of interest *cannot* be tested in the experiment.

The problem of trying to detect deception provides a different example. All published laboratory-based experiments involve people who know that they are taking part in a research project. Most of them are students and are being paid to participate in the project. They have received detailed information about the experiment and have signed a consent form. Typically, they are instructed to “lie” about a particular matter. Sometimes they are told what the lie should be (to deny that they see a particular playing card, such as the seven of clubs, on a screen in the scanner); sometimes they are told to make up a lie (about their most

23. Daniel D. Langleben et al., *Telling Truth from Lie in Individual Subjects with Fast Event-Related fMRI*, 26 Hum. Brain Mapping 262 (2005), <https://doi.org/10.1002/hbm.20191>. See discussion in Nancy Kanwisher, *The Use of fMRI in Lie Detection: What Has Been Shown and What Has Not*, in Emilio Bizzi et al., *Using Imaging to Identify Deceit: Scientific and Ethical Questions* 7, 10 (2009); see also discussion in Anthony Wagner, *Can Neuroscience Identify Lies?*, in *A Judge’s Guide to Neuroscience: A Concise Introduction* 13, *supra* note 5.

recent vacation, for example). In either case, they are following instructions—doing what they *should* be doing—when they tell the “lie.”

This situation is different from the realistic use of lie detection, when a guilty person needs to tell a convincing story to avoid a high-stakes outcome, such as arrest or conviction—and even an innocent person will be genuinely nervous about the possibility of an incorrect finding of deception. In an attempt to parallel these real-world characteristics, some laboratory-based studies have tried to give participants some incentive to lie successfully; for example, the participants may be told (falsely) that they will be paid more if they “fool” the experimenters. Although this may increase the perceived stakes, it seems unlikely that it creates a realistic level of stress. These differences between the laboratory and the real world do not mean that the experimental results of laboratory studies are unquestionably different from the results that would exist in a real-world situation, but they do raise serious questions about the extent to which the experimental data bear on detecting lies in the real world.

Few judges will be expert in the difficult task of designing valid experiments. Although judges may be able themselves to identify weaknesses in experimental design, more often they will need experts to address these questions. Judges will need to pay close attention to that expert testimony and the related argument, as details of experimental design may turn out to be absolutely crucial to the value of the experimental results.

The Number and Diversity of Participants

Doing fMRI scans is expensive. The total cost of performing an hour-long research scan of a participant ranges from about \$300 to \$1,000. Much fMRI research, particularly work without substantial medical implications, is not richly funded. As a result, studies tend to use only a small number of participants—many fMRI studies use ten to twenty participants, and some use even fewer. In the lie-detection literature, for example, the number of participants used ranges from four to about thirty.

It is unclear how representative such a small group would be of the general population. This is particularly true of the many studies that use university students as research participants. Students typically are from a restricted age range, are likely to be of above-average intelligence and socioeconomic background, may not accurately reflect the country’s ethnic diversity, and typically will underrepresent people with serious mental conditions. In order to limit possible confounding variables, it can make sense for a study design to select, for example, only healthy, right-handed, native-English-speaking male undergraduates who are not using drugs. But the very process of selecting such a restricted group raises questions about whether the findings will be relevant to other groups of

people. They may be directly relevant, or they may not be. At the early stages of any fMRI research, it may not be clear what kinds of differences among participants will or will not be important.

Applying Group Averages to Individuals

Most fMRI-based research looks for statistically significant associations between particular patterns of brain activation across a number of participants. It is highly unlikely that any fMRI pattern will be found always to occur under certain circumstances in *every* person tested, or even that it will always occur under those circumstances in any one person. Human brains and their responses are too complicated for that. Research is highly unlikely to show that brain pattern “A” follows stimulus “B” each and every time and in every single person, although it may show that A follows B most of the time.

Consider an experiment with ten participants that examines how brain activation varies with the sensation of pain. A typical approach to analyzing the data is to take the average brain activation patterns of all ten participants combined, looking for the regions that, across the group, have the greatest changes—the most statistically significant changes—when the painful stimulus is applied compared to when it is absent. Importantly, though, the most significant region showing increased activation on average may not be the region with the greatest increase in activation in any particular one of the ten participants. It may not even be the area with the greatest activation in *any* of the ten participants, but it may be the region that was most consistently active across the brains of the ten participants, even if the response was small in each person.

Although group averages are appropriate for many scientific questions, the problem is that the law, for the most part, is not concerned with “average” people, but with individuals. If these “averaged” brains show a particular pattern of brain activation in fMRI studies and a defendant’s brain does not, what, if anything, does that mean?

It may or may not mean anything—or, more accurately, the chances that it is meaningful will vary. The findings will need to be converted into an assessment of an individual’s likelihood of having a particular pattern of brain activation in response to a stimulus, and that likelihood can be measured in various ways.²⁴

Consider the following simplified example. Assume that 1,000 people have been tested to see how their brain responds to a particular painful stimulus. Each is scanned twice, once when touched by a painfully hot metal rod and once when the rod is at room temperature. Assume that all of them feel pain from the heated

24. Issues of sensitivity and specificity are discussed in more detail in David H. Kaye and Hal S. Stern, *Reference Guide on Statistics and Research Methods*, in this manual.

rod and that no one feels pain from the room-temperature rod. And, finally, assume that 900 of the 1,000 show a particular pattern of brain activation when touched with the hot rod, but only 50 of the 1,000 show the same pattern when touched with the room-temperature rod.

For these 1,000 people, using the fMRI activation pattern as a test for the perception of this pain would have a sensitivity of 90% (90% of the 1,000 who felt the pain would be correctly identified and only 10% would be false negatives). Using the activation as a test for the *lack* of the pattern would have a specificity of 95% (95% of those who did not feel pain were correctly identified and only 5% were false positives). Now ask, of all those who showed a positive test result, how many were actually positive? This percentage, the positive predictive value, would be 94.7%—900 out of 950. Depending on the planned use of the test, one might care more about one of these measures than another, and there are often trade-offs between them. Making a test more sensitive (so that it misses fewer people with the sought characteristic) often means making it less specific (so that it picks up more people who do not have the characteristic in question). In any event, when more people are tested, these estimates of sensitivity, specificity, and positive predictive value become more accurate.

There are other ways of measuring the accuracy of a test of an individual, but the important point is that some such conversion is essential. A research paper that reveals that the average participant's brain (more accurately, the "averaged participants' brain") showed a particular reaction to a stimulus does not, in itself, say anything useful about how likely any one person is to have the same reaction to that stimulus. Further analyses are required to provide that information. Researchers, who are often more interested in identifying possible mechanisms of brain action than in creating diagnostic tests, will not necessarily have analyzed their data in ways that make them usefully applied to individuals—or might not have even obtained enough data for that to be possible. At least in the near future, this is likely to be a major issue for applying fMRI studies to individuals, in the courtroom or elsewhere.

Technical Accuracy and Robustness of Imaging Results

MRI machines are variable, complicated, and finicky. The machines come in several different sizes, based on the strength of the magnet, with machines used for clinical purposes ranging from 0.2T to 3.0T and research scanners going as high as 9.4T, as noted earlier. Three companies dominate the market for MRI machines—General Electric, Siemens, and Philips—although several other companies also make the machines. Both the power and the manufacturer of an MRI system can make a substantial difference in the resulting data (and images).

These variations can be more important with functional MRI (though they also apply to structural MRI), so that a result seen on a 1.5T Siemens scanner might not appear on a 3.0T General Electric machine. Similarly, results from one 3.0T General Electric machine may be different from those on an identical model.

Even the exact same MRI machine may behave differently from day to day or month to month. The machines frequently need maintenance or adjustments and sometimes can be inoperable for days or even weeks at a time. Comparing results from even the same machine before and after maintenance—or a system upgrade—can be difficult. This can make it hard to compare results across different studies or between the group average of one study and results from an individual participant.

These issues concern not only the quality of the scans done in research, but, even more importantly, the credibility of the individual scan sought to be introduced at trial. If different machines were used, care must be taken to ensure that the results are comparable. The individual scans also can have other problems. Any one scan is subject not only to machine-derived artifacts and other problems noted above, but also to human-generated artifacts, such as those caused by the participant's movements during the scan.

Finally, another technical problem of a different kind comes from the nature of fMRI research itself. The scanner will record changes in the relative levels of oxyhemoglobin to deoxyhemoglobin for thousands of voxels throughout the brain. During data analysis, these signal changes will be tested to see if they show any change in the response between the experimental condition and the baseline (or control) condition. Importantly, with fMRI, there is no definitive way to quantify precisely how large a change there was in the neural response compared to baseline; hence, the researcher must set a somewhat arbitrary statistical cutoff value (a threshold) for saying that a voxel was activated or deactivated. A researcher who wants to look only at strong effects will require a large change from baseline; a researcher who wants to see a wide range of possible effects will allow smaller changes from baseline to count.

Neither way is “right”—we do not know whether there is some minimum change in the BOLD response that means an “important” amount of brain activation has taken place, and if such a true value exists, it is likely to differ across brain regions, across tasks, and across experimental contexts. What this means is that different choices of statistical cutoff values can produce enormous differences in the apparent results. And, of course, the cutoff values used in the studies and in the scan of the individual of interest must be consistent across repeated tests. This important fact often may not be known.

Statistical Issues

Interpreting fMRI results requires the application of complicated statistical methods. These methods are particularly difficult, and sometimes controversial,

for fMRI studies, partly because of the thousands of voxels being examined. Fundamentally, most fMRI experiments look at many thousands of voxels and try to determine whether any of them are, on average, activated or deactivated as a result of the task or stimulus being studied. A simple test for statistical significance asks whether a particular result might have arisen by chance more than one time in twenty (or 5%): Is it significant at the 0.05 level? If a researcher is looking at the results for thousands of different voxels, it is likely that a number of voxels will show an effect above the threshold just by chance. There are statistical ways to control the rate of these false positives, but they need to be applied carefully. At the same time, rigid control of false positives through statistical correction (or the use of a very conservative threshold) can create another problem—an increase in the false negative rate, which results in failing to detect true brain responses that are present in the data but that fall below the statistical threshold. The community of fMRI researchers recognizes that these issues of statistical significance are difficult to resolve.

Over the past decade, other statistical techniques are increasingly being used in neuroimaging research, including techniques that do not look at the statistical significance of changes in the BOLD response in individual voxels, but that instead examine changes in the distributed patterns of activation across many voxels in a region of the brain or across the whole brain. These techniques include methods known as principal component analysis, multivariate analysis, machine learning algorithms, and artificial intelligence. These methods, the details of which are not reviewed in this reference guide, are being used increasingly in neuroimaging research and are producing some of the most interesting results in the field. The techniques are complex, and determining how to interpret the results of these tests can be controversial. Thus, these methods alone may require substantial and potentially confusing expert testimony in addition to all the other expert testimony about the underlying neuroscience evidence.

Possible Countermeasures

When neuroimaging is being used to compare the brain of one individual—a defendant, plaintiff, or witness, for example—to others, the individual undergoing neuroimaging might be able to use countermeasures to make the results unusable or misleading. And at least some of those countermeasures may prove especially hard to detect.

Individuals can disrupt almost any kind of scanning, whether done for structural or functional purposes, by moving in the scanner. Unwilling participants could ruin scans by moving their bodies or heads, or possibly even by moving their tongues. Blatant movements to disrupt the scan would be apparent, both from watching the individual in the scanner and from seeing the results, leading

to a possible negative inference that the person was trying to interfere with the scan. Nonetheless, that scan itself would be useless.

More interesting are possible countermeasures for functional scans. Polygraphy may provide a useful comparison. Countermeasures have long been tried in polygraphy with some evidence of efficacy. Polygraphy typically looks at the differences in physiological measurements of the participant when asked anxiety-provoking questions or benign control questions. Individuals can use drugs or alcohol to try to dampen their body reactions when asked anxiety-provoking questions. They can try to use mental measures to control or affect their physiological reactions, calming themselves during anxiety-provoking questions and increasing their emotional reaction to control questions. And, when asked control questions, they can try to increase the physiological signs the polygraph measures through physical means. For example, individuals might bite their tongues, step on tacks hidden in their shoes, or tighten various muscles to try to increase their blood pressure, galvanic skin response, and so on.

Basic science and polygraph research give reason for concern that polygraph test accuracy may be degraded by countermeasures, particularly when used by major security threats who have a strong incentive and sufficient resources to use them effectively. If these measures are effective, they could seriously undermine any value of polygraph security screening.²⁵

Some of the countermeasures used by a polygraph participant can be detected by, for example, drug or alcohol tests or by carefully watching the individual's body. But purely mental actions cannot be detected. These kinds of countermeasures may be especially useful to individuals seeking to beat neuroscience-based lie detection. For example, some argue that deception produces different activation patterns than telling the truth because it is mentally harder to tell a lie—more of the brain needs to work to decide whether to lie and what lie to tell. If so, two mental countermeasures immediately suggest themselves: Make the lie easier to tell (through, perhaps, memorization or practice) or make the brain work harder when telling the truth (through, perhaps, counting backward from one hundred by sevens).

Countermeasures are not, of course, potentially useful only in the context of lie detection. A neuroimaging test to determine whether a person was having the subjective feeling of pain might be fooled by the participant remembering, in great detail, past experiences of pain. The possible uses of countermeasures in neuroimaging have yet to be extensively explored, but at this point they cast additional doubt on the reliability of neuroimaging in investigations or in litigation.

25. See Nat'l Rsch. Council, *The Polygraph and Lie Detection* 5 (2003), <https://doi.org/10.17226/10420>. This report is an invaluable resource for discussions of not just the scientific evidence about the reliability of the polygraph, but also for general background about the application of science to lie detection.

Questions About the Admissibility and the Creation of Neuroscience Evidence

The admissibility of neuroscience evidence will depend on many issues, some of them arising from rules of evidence, some from the U.S. Constitution, and some from other legal provisions. Another often-overlooked reality is that judges may have to decide whether to order the creation of this kind of evidence. Certainly, judges may be called to rule on the requests for criminal defendants (or convicts seeking postconviction relief) to be able to use neuroimaging. They may also have to decide motions in civil or criminal cases to compel neuroimaging. One could even imagine requests for warrants to “search the brains” of possible witnesses for evidence, or efforts to subpoena neural data collected by third parties who manufacture or supply consumer-based wearable EEG or MEG devices. This reference guide will not seek to resolve any of these questions, but will point out some of the problems that are likely to be raised regarding admitting neuroscience evidence in court.

Evidentiary Rules

This discussion looks at the main evidentiary issues that are likely to be raised in cases involving neuroscience evidence. Note, though, that judges will not always be governed by rules of evidence. In criminal sentencing or in probation hearings, among other things, the Federal Rules of Evidence do not apply²⁶ (although federal sentencing guidelines do require that evidence used in sentencing meet a lower bar that “has sufficient indicia of reliability to support its probable accuracy”²⁷). The Rules do apply, with limitations, in other contexts.²⁸ Nonetheless, even when the Rules do not directly apply, many of the principles behind them, discussed below, will be important.

Relevance

The starting point for all evidentiary questions must be relevance. If evidence is not relevant to the questions at hand, no other evidentiary concerns matter.

26. Fed. R. Evid. 1101(d).

27. U.S. Sentencing Guidelines Manual § 6A1.3(a).

28. Fed. R. Evid. 1101(e).

This basic reminder may be particularly useful with respect to neuroscience evidence. Evidence admitted, for example, to demonstrate that a criminal defendant had suffered brain damage sometime before the alleged crime is not, in itself, relevant. The proffered fact of the defendant's brain damage must be relevant. It may be relevant, for example, to whether the defendant could have formed the necessary criminal intent, to whether the defendant should be found not guilty by reason of insanity, to whether the defendant is currently competent to stand trial, or to mitigation in sentencing. It must, however, be relevant to *something* in order to be admissible at all, and specifying its relevance will help focus the evidentiary inquiry. The question, for example, would not be whether PET scans meet the evidentiary requirements to be admitted to demonstrate brain damage, but whether they have "any tendency to make a fact more or less probable than it would be without the evidence."²⁹ The brain damage may be relevant to a fact, but that fact must be "of consequence in determining the action."³⁰

Rule 702 and the Admissibility of Scientific Evidence

Neuroscience evidence will almost always be "scientific . . . knowledge" governed by Rule 702 of the Federal Rules of Evidence, as interpreted in *Daubert v. Merrell Dow Pharmaceuticals*³¹ and its progeny, both before and after the amendments to Rule 702 in 2023.³² Rule 702 allows the testimony of a qualified expert if:

A witness who is qualified as an expert by knowledge, skill, experience, training, or education may testify in the form of an opinion or otherwise if the proponent demonstrates to the court that it is more likely than not that:

- (a) the expert's scientific, technical, or other specialized knowledge will help the trier of fact to understand the evidence or to determine a fact in issue;
- (b) the testimony is based on sufficient facts or data;
- (c) the testimony is the product of reliable principles and methods; and
- (d) the expert's opinion reflects a reliable application of the principles and methods to the facts of the case.

29. Fed. R. Evid. 401(a).

30. Fed. R. Evid. 401(b).

31. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993).

32. Rule 702 is a subject covered by Liesa L. Richter and Daniel J. Capra in *The Admissibility of Scientific Evidence*, in this manual. That reference guide should be consulted for details about Rule 702 and its application. This reference guide merely briefly lays out the Rule and its application to neuroscience evidence.

In *Daubert*, the U.S. Supreme Court listed several nonexclusive guidelines for trial court judges considering testimony under Rule 702. The committee that proposed the 2000 amendments to Rule 702 summarized these factors as follows:

The specific factors explicated by the *Daubert* Court are (1) whether the expert's technique or theory can be or has been tested—that is, whether the expert's theory can be challenged in some objective sense, or whether it is instead simply a subjective, conclusory approach that cannot reasonably be assessed for reliability; (2) whether the technique or theory has been subject to peer review and publication; (3) the known or potential rate of error of the technique or theory when applied; (4) the existence and maintenance of standards and controls; and (5) whether the technique or theory has been generally accepted in the scientific community.³³

The 2023 amendments were similarly summarized by the advisory committee as follows:

First, the rule has been amended to clarify and emphasize that expert testimony may not be admitted unless the proponent demonstrates to the court that it is more likely than not that the proffered testimony meets the admissibility requirements set forth in the rule. . . . Rule 702(d) has also been amended to emphasize that each expert opinion must stay within the bounds of what can be concluded from a reliable application of the expert's basis and methodology.³⁴

The tests laid out in *Daubert* and in the evidentiary rules governing expert testimony have been the subjects of enormous discussion, both by commentators and by courts. And, to the extent that some neuroscience evidence has been admitted in federal courts (and the courts of states that follow Rule 702 or *Daubert*), it has passed those tests. We do not have the knowledge needed to analyze them in detail, but we will merely point out a few aspects that seem especially relevant to neuroscience evidence.

Neuroscience evidence should often be subject to tests, as long as the point of the neuroscience evidence is kept in mind. An fMRI scan might provide evidence that someone was having auditory hallucinations, but it could not prove that someone was not guilty by reason of insanity. The latter is a legal conclusion, not a scientific finding. The evidence might be relevant to the question of insanity, but one cannot plausibly conduct a scientific test of whether a particular pattern of brain activation is always associated with legal insanity. One might offer neuroimaging evidence about whether a person is likely to have unusual difficulty controlling his or her impulses, but that is not, in itself, proof that the person acted recklessly. The idea of testing helps separate the conclusions that

33. Fed. R. Evid. 702 advisory committee's notes.

34. *Id.*

neuroscience might be able to reach from the legal conclusions that will be beyond it.

Daubert's stress on the presence of peer review and publication corresponds nicely to scientists' perceptions. In many scientific fields, findings that are not published in a peer-reviewed journal are deeply discounted. In those fields, scientists usually begin to have confidence in findings only after peers, both those involved in the editorial process and, more importantly, those who read the publication, have had a chance to dissect them and to search intensively for errors either in theory or in practice. It is crucial, however, to recognize that publication and peer review are not in themselves enough. The publications need to be compared carefully to the evidence that is proffered.

First, the published, peer-reviewed articles must establish the specific scientific fact being offered. An (accurate) assertion that fMRI has been the basis of more than 12,000 peer-reviewed publications will help establish that fMRI can be used in ways that the scientific community finds reliable. By themselves, however, those publications do not establish any particular use of fMRI. If fMRI is being offered as proof of deception, the twenty or thirty peer-reviewed articles concerning its ability to detect deception are most important, not the 11,980 articles involving fMRI for other purposes.

Second, the existence of several peer-reviewed publications on the same general method does not support the accuracy of any one approach if those publications are mutually inconsistent. There are now about twenty to thirty peer-reviewed publications that, using fMRI, find statistically significant differences in patterns of brain activation depending on whether the participants were telling the truth or (typically) telling a lie when instructed to do so. Many of those publications find patterns that are different from, and often inconsistent with, the patterns described in the other publications. Multiple *inconsistent* publications do not add weight to a scientific method or theory; indeed, they may subtract from it.

Third, the peer-reviewed publication needs to describe in detail the method about which the expert plans to testify. A commercial firm might, for example, claim that its method is "based on" some peer-reviewed publications, but unless the details of the firm's methods were included in the publication, those details were neither published nor peer-reviewed. A proprietary algorithm used to generate a finding published in the peer-reviewed literature is not adequately supported by that literature.

The error rate is also crucial to most neuroscience evidence, in two different senses. One is the degree to which the machines used to produce the evidence make errors. While these kinds of errors may balance out in a large sample used in published literature, any scan of any one individual may well be affected by errors in the scanning process. Second, and more importantly, neuroscience evidence will almost never give an absolute answer, but will give a probabilistic one. For example, a certain brain structure or activation pattern will be found in some percentage of people with a particular mental condition or state. These

group averages will have error rates when they are applied to individuals. Those rates need to be known and presented.

The issue of standards and controls also is important in neuroscience. This area is new and has not undergone the kind of standardization seen, for example, in forensic DNA analysis. When trying to apply neuroscience findings to an individual, evidence from the individual needs to have been acquired in the same way, with the same standards and conditions, as the evidence from which the scientific conclusions were drawn—or, at least, in ways that can be made readily comparable. For example, there is no one standard in fMRI research for what statistical threshold should be used for a change in the BOLD signal to “count” as a meaningful activation or deactivation. An individual’s scan would need to be analyzed under the same definition for activation as was used in the research supporting the method, and the effects of the chosen threshold on finding a false positive or false negative must be considered.

The final consideration—general acceptance in the scientific community—also needs to be applied carefully. There is clearly general acceptance in the scientific community that fMRI can provide scientifically and sometimes clinically useful information about the workings of human brains, but that does not mean there is general acceptance of any particular fMRI application. Similarly, there may be general acceptance that fMRI can provide some general information about the physical correlates of a particular mental state, but without general acceptance that it can do so reliably in an individual case.

Rule 403

Rule 702 is not the only test that neuroscience evidence will need to pass to be admitted in court. Even evidence admissible under that rule must still escape the exclusion provided by Rule 403: Although relevant, evidence may be excluded “if its probative value is substantially outweighed by a danger of . . . unfair prejudice, confusing the issues, misleading the jury, undue delay, wasting time, or needlessly presenting cumulative evidence.”³⁵

As discussed in detail in one article,³⁶ Rule 403 may be particularly important with some attempted applications of neuroscience evidence because of the balance it requires between the value of evidence to the decision-maker and its costs.

The probative value of such evidence may often be questioned. Neuroscience evidence will rarely, if ever, be definitive. It is likely to have a range of

35. Fed. R. Evid. 403.

36. Teneille Brown & Emily Murphy, *Through a Scanner Darkly: Functional Neuroimaging as Evidence of a Criminal Defendant’s Past Mental States*, 62 Stan. L. Rev. 1119 (2010), <https://perma.cc/C2BL-VWHV>.

uncertainties, from the effectiveness of the method in general, to questions of its proper application in this case, to whether any given individual's reactions are the same as those previously tested.

The other side of Rule 403, however, is even more troublesome. The time necessary to introduce such evidence, and to educate the jury (and judge) about it, will usually be extensive. The possibilities for confusion are likely to be great. And there is at least some evidence that jurors (or, to be precise, “mock jurors”) are particularly likely to overestimate the power of neuroscience evidence.³⁷ A high-tech “picture” of a living brain, complete with brain regions shown in bright orange and deep purple (colors not seen in an actual brain), may have an unjustified appeal to a jury. In each case, judges will need to weigh possibilities of confusion or prejudice, along with the near certainty of lengthy testimony, against the claimed probative value of the evidence.

Other Potentially Relevant Evidentiary Issues

Neuroscience evidence will, of course, be subject in individual cases to all evidentiary rules (in the Federal Rules of Evidence or otherwise) and could be affected by many of them. Four examples follow where the application of several such rules to this kind of evidence may raise interesting issues; there are undoubtedly many others.

First, in June 2009 the U.S. Supreme Court decided *Melendez-Diaz v. Massachusetts*, where the five-justice majority held that the Confrontation Clause required the prosecution to present the testimony at trial of state laboratory analysts who had identified a substance as cocaine.³⁸ This would seem to apply to any use by the prosecution in criminal cases on neuropsychological or neuroimaging of a criminal defendant or witness, although it is unclear to whom it would apply. Would testimony be required from the person who observed the procedure, the person who analyzed the results of the procedure, an AI system that analyzed the results, or programmers of that AI? These are not questions unique to neuroscience evidence, but are provoked by *Melendez-Diaz*.

37. See Deena Skolnick Weisberg et al., *The Seductive Allure of Neuroscience Explanations*, 20 J. Cognitive Neuroscience 470 (2008), <https://doi.org/10.1162/jocn.2008.20040>; David P. McCabe & Alan D. Castel, *Seeing Is Believing: The Effect of Brain Images on Judgments of Scientific Reasoning*, 107 Cognition 343 (2008), <https://doi.org/10.1016/j.cognition.2007.07.017>. These articles are discussed in Brown & Murphy, *supra* note 36, at 1199–1202. *But see* Nicholas J. Schweitzer et al., *Neuroimages As Evidence in a Mens Rea Defense: No Impact*, 17 Psych. Pub. Pol’y & L. 357 (2011), <https://doi.org/10.1037/a0023581> (explaining that the experimental results seem to indicate that showing neuroimages to mock jurors does not affect their decisions).

38. 557 U.S. 305 (2009).

Second, the Federal Rules of Evidence put special limits on the admissibility of evidence of character and, in some cases, of predisposition.³⁹ In some cases, neuroscience evidence offered for the purpose of establishing a regular behavior of the person might be viewed as evidence of character⁴⁰ or predisposition (or lack of predisposition). Whether such evidence could be admitted might hinge on whether it was offered in a civil case or a criminal case, and, if in a criminal case, by the prosecution or the defendant.

Third, Federal Rule of Evidence 406 allows the admission of evidence about a habit or routine practice to prove that the relevant person's actions conformed to that habit or routine practice. It is conceivable that neuroscience evidence might be used to describe "habits of mind" and thus be offered under this rule.

The fourth example applies to neuroscience-based lie detection. Although New Mexico is the only U.S. jurisdiction that generally allows the introduction of polygraph evidence,⁴¹ several jurisdictions allow polygraph evidence in two specific situations. First, polygraph evidence is sometimes allowed when both parties have stipulated to its admission in advance of the performance of the test. (This does lead one to wonder whether a court would allow evidence from a psychic or from a fortune-telling toy, like the Magic 8 Ball, if both parties stipulated to it.) Second, polygraph evidence is sometimes allowed to impeach or to

39. Fed. R. Evid. 404, 405, 412–15, 608.

40. Evidence about lie detection has sometimes been viewed as "character evidence," introduced to bolster a witness's credibility. The Canadian Supreme Court has held that polygraph evidence is inadmissible in part because it violates the rule limiting character evidence:

What is the consequence of this rule in relation to polygraph evidence? Where such evidence is sought to be introduced, it is the operator who would be called as the witness, and it is clear, of course, that the purpose of his evidence would be to bolster the credibility of the accused and, in effect, to show him to be of good character by inviting the inference that he did not lie during the test. In other words, it is evidence not of general reputation but of a specific incident, and its admission would be precluded under the rule. It would follow, then, that the introduction of evidence of the polygraph test would violate the character evidence rule.

R. v. Béland, [1987] 2 S.C.R. 398, 414. The Canadian court also held that polygraph evidence violated another rule concerning character evidence, the rule against "oath-helping":

From the foregoing comments, it will be seen that the rule against oath-helping, that is, adducing evidence solely for the purpose of bolstering a witness's credibility, is well grounded in authority. It is apparent that, since the evidence of the polygraph examination has no other purpose, its admission would offend the well-established rule.

Id. at 408 (the court also ruled against polygraph evidence as violating the rule against prior consistent statements and, because the jury needs no help in assessing credibility, the rule on the use of expert witnesses.).

41. *Lee v. Martinez*, 96 P.3d 291 (N.M. 2004).

corroborate a witness's testimony.⁴² If a neuroscience-based lie-detection technique were found to be as reliable as the polygraph, presumably those jurisdictions would have to consider whether to extend these exceptions to such neuroscience evidence.

Constitutional and Other Substantive Rules

In many contexts, courts will be asked to admit neuroscience evidence or to order, allow, or punish its creation. Such actions may implicate a number of constitutional rights, international law, and international human rights, as well as other substantive legal and regulatory provisions. While this section will not seek to discuss all possible such claims or to resolve any of them, it raises some of the most interesting issues.

Possible Rights Against Neuroscience Evidence

Much of the discussion that follows presumes the compulsory creation of neuroscience data, or compulsory submission to neuroimaging or other testing that would generate neuroscience data. As brain sensors become more widely integrated into everyday headphones, earbuds, and even wrist-worn devices to detect motor neuron activity, neuroscience data may be increasingly created passively, without compulsion, which would reshape the legal analysis that would follow. Passively created data may be subject to discovery through subpoenas to third parties who operate the devices or consumer applications that collect the data generated by these devices.

The Fifth Amendment privilege against self-incrimination

Could a person be required to submit to neuroimaging to gather neuroscience data from their brains, or would that violate their privilege against self-incrimination? This has been discussed by legal scholars for more than a decade now because of the novel fact that neuroscience evidence could be seen as “real” physical evidence rather than “testimonial” evidence because it measures brain activity and blood flow rather than spoken words by an individual. The real-world use in the United States of such evidence has been quite limited, so the question remains a theoretical one. For what purpose might a person be asked to

42. See, e.g., *United States v. Piccinonna*, 885 F.2d 1529 (11th Cir. 1989) (en banc). See also *United States v. Allard*, 464 F.3d 529 (5th Cir. 2006); *Thornburg v. Mullin*, 422 F.3d 1113 (10th Cir. 2005).

submit to such examination? To gather identifying evidence, automatically processed memories, or silently uttered responses in their brain.⁴³

If neuroscience evidence were held to be “testimonial” and its creation compelled rather than “real” physical evidence passively created, it would be subject to the privilege, but if it were nontestimonial and not compelled, it would, under current law, not be. Examples of nontestimonial evidence for purposes of the privilege against self-incrimination include a blood alcohol test or medical X-rays. Examples of evidence created without compulsion include a private diary or other business documents created without government instruction to do so.

It is not the *type* of neuroimaging that addresses whether the privilege against self-incrimination is implicated but the nature of the evidence collected, the inferences that can be drawn from it, and whether a person is compelled to create it. How the evidence from the brain is generated (passively or in response to questions, for example) and the nature of the neuroscience evidence sought (evidence of brain damage, for example, versus silently uttered responses to questions or recalled memories that could infer unspoken thoughts) will be more relevant to deciding whether it runs afoul of the privilege against self-incrimination.

It is possible, however, that conscious answers may not be necessary but the brain could be queried for memories or other information nonetheless. Two EEG-based systems claim to be able to determine whether a person either recognizes or has “experiential knowledge” of an event (a memory derived from experience as opposed to being told about it).⁴⁴ Very substantial scientific questions exist about each system, but, assuming they were to be admitted as reliable, they would raise this question more starkly because they do not require the participant in the procedure to consciously create answers or respond to questions. The participant is shown photographs of relevant locations or read a description of the events while hooked up to an EEG. The brain waves, it is

43. See discussion of “spectrum of evidence” in Nita A. Farahany, *Incriminating Thoughts*, 64 Stan. L. Rev. 351 (2012), <https://perma.cc/2VX7-N6P7>.

44. The first system is the so-called Brain Fingerprinting, developed by Dr. Larry Farwell. This method was introduced successfully in evidence at the trial court level in a postconviction relief case in Iowa; the use of the method in that case is discussed briefly in the Iowa Supreme Court’s decision on appeal. *Harrington v. State*, 659 N.W.2d 509, 516 n.6 (Iowa 2003). The court expressed no view on whether that evidence was properly admitted. See *id.* at 516. The method is discussed on the website of Farwell’s company, Brain Fingerprinting Laboratories. It is discussed from a scientific perspective in J. Peter Rosenfeld, ‘Brain Fingerprinting’: A Critical Analysis, 4 Sci. Rev. Mental Health Prac. 20 (2005), <https://perma.cc/R4KF-92AS>. See also the brief discussion in Henry T. Greely & Judy Illes, *Neuroscience-Based Lie Detection: The Urgent Need for Regulation*, 33 Am. J.L. & Med. 377, 387–88 (2007), <https://doi.org/10.1177/009885880703300211>.

The second system is called Brain Electrical Oscillation Signature (BEOS) and was developed in India, where it has been introduced in trials and has been important in securing criminal convictions. See Anand Giridharadas, *India’s Novel Use of Brain Scans in Courts Is Debated*, N.Y. Times, Sep. 14, 2008, at A10, <https://www.nytimes.com/2008/09/15/world/asia/15brainscan.html>.

asserted, demonstrate whether the individual recognizes the photographs or has “experiential knowledge” of the events—no volitional communication is necessary. It might be harder to classify these automatically processed responses as “testimonial,” compared to unspoken silent utterances in response to questions.⁴⁵

Other possible legal protections against compulsory neuroscience procedures

Even if the privilege against self-incrimination applies to neuroscience methods of obtaining evidence, it only applies where someone invokes the privilege. The courts and other government bodies force people to answer questions all the time, often under penalty of criminal or civil sanctions or of the court’s contempt power. And the government can immunize a person from criminal prosecution and compel responses without running afoul of the privilege against self-incrimination. For example, a plaintiff in a civil case alleging damage to their health can be compelled to undergo medical testing at a defendant’s appropriate request. In that case, the plaintiff can refuse, but only at the risk of seeing their case dismissed. Presumably, a party could similarly demand that a party, or a witness, undergo a neuropsychological or neuroimaging examination, looking for either structural or functional aspects of the person’s brain or mental status relevant to the case or, for example, relevant to the accuracy of their memories.⁴⁶ If the privilege against self-incrimination is not available, or is available but not attractive, could the person asked have any other protection?

The answer is not clear. One might try to argue, along the lines of *Rochin v. California*,⁴⁷ that such a procedure violates the Due Process Clause of the Fifth and Fourteenth Amendments because it intrudes on the person in a manner that “shocks the conscience.” One might try to use the concept of “freedom of thought” referenced in some U.S. Supreme Court First Amendment cases to argue that the First Amendment’s freedoms of religion, speech, and the press encompass a broader protection of the contents of the mind through a right to cognitive liberty.⁴⁸ Until recently, governments could not directly access our thoughts⁴⁹—which is why freedom of thought as a fundamental right has largely been glossed over in history. Justices Murphy, Black, and Douglas, along with Chief Justice Stone, reflected this prevailing view in their 1942 dissenting and

45. Farahany, *supra* note 43; Farahany, *supra* note 2.

47. *Rochin v. California*, 342 U.S. 165 (1952).

48. See Paul Root Wolpe, *Is My Mind Mine? Neuroethics and Brain Imaging*, in *The Penn Center Guide to Bioethics* 86 (Arthur L. Caplan, Autumn Fiester & Vardit Ravitsky eds., 2009).

49. Simon McCarthy-Jones, *The Autonomous Mind: The Right to Freedom of Thought in the Twenty-First Century*, 2 *Frontiers A.I.* 1 (2019), <https://doi.org/10.3389/frai.2019.00019>.

concurring opinion in the U.S. Supreme Court case of *Jones v. City of Opelika*, when they argued that while freedom of thought is absolute, even “the most tyrannical government is powerless to control the inward workings of the mind.”⁵⁰ Now that there are ways to infer thought using neurotechnology, we find ourselves with very little history or theoretical work to help define its scope.

Scholars have advanced a theory of “cognitive liberty” as a human right that would include the right to mental privacy as part of the human right to privacy under the Universal Declaration of Human Rights (UDHR), the right to keep one’s thoughts private and not be punished for one’s thoughts under the right to freedom of thought in the UDHR, and a right to self-determination over one’s brain and mental experiences.⁵¹

That right, as one of this reference guide’s authors has argued, has been implicitly recognized in tort cases in the United States, which do not extend a duty to mitigate one’s injuries to measures that would tamper with memories or reduce one’s psychological injuries in the same manner that other physical injuries must be mitigated or one’s damages will be reduced in civil cases.⁵² And it is implicitly recognized in First Amendment cases, where freedom of thought is recognized as a precursor to freedom of speech.

But all of these rights and their applications and implications for neuroscience evidence remain speculative until courts grapple with new forms of neuroscience evidence and challenges to their creation or introduction in legal cases.

Other substantive rights against neuroscience evidence

At least one form of possible neuroscience evidence may already be covered by statutory provisions limiting its creation and use—lie detection. In 1988, Congress passed the federal Employee Polygraph Protection Act (EPPA).⁵³ Under this Act, almost all employers are forbidden to “directly or indirectly . . . require, request, suggest, or cause any employee or prospective employee to take or submit to any lie detector test” or to “use, accept, refer to, or inquire concerning the results of any lie detector test of any employee or prospective employee.”⁵⁴ The Act defines a “lie detector” broadly, as “a polygraph, deceptiongraph, voice stress

51. See, e.g., Farahany, *supra* note 2.

52. See, e.g., Nita A. Farahany, *The Costs of Changing Our Minds*, 69 Emory L.J. 75 (2019), <https://perma.cc/L488-XMBW>.

53. Federal Employee Policy Protection Act of 1988, Pub. L. No. 100–347, 102 Stat. 646 (codified at 29 U.S.C. §§ 2001–2009). See generally the discussion of federal and state laws in Greely & Illes, *supra* note 44, at 405–10, 421–31.

54. 29 U.S.C. § 2002 (1)–(2) (The section also prohibits employers from taking action against employees because of their refusal to take a test, because of the results of such a test, or for asserting their rights under the Act.); see *id.* § 2001 (3)–(4) (definitions).

analyzer, psychological stress evaluator, or any other similar device (whether mechanical or electrical) that is used, or the results of which are used, for the purpose of rendering a diagnostic opinion regarding the honesty or dishonesty of an individual.”⁵⁵ The Department of Labor can punish violators with civil fines, and those injured have a private right of action for damages.⁵⁶ The Act does provide narrow exceptions for polygraph tests in some circumstances.⁵⁷

In addition to federal statutes, many states passed their own versions of the EPPA, either before or after the federal act. The laws passed after the EPPA generally apply similar prohibitions to some employers not covered by the federal act (such as state and local governments), but with their own idiosyncratic set of exceptions. Many states have also passed laws regulating lie-detection services. Most of these seem clearly aimed at polygraphy, but, in some states, the language used is quite broad and may well encompass neuroscience-based lie detection.⁵⁸

States also may provide protection against neuroscience evidence that goes beyond lie detection and could prevent involuntary neuroscience procedures. Some states have constitutional or statutory rights of privacy that could be read to include a broad freedom for mental privacy. And in some states, such as California, such privacy rights apply not just to state action but to private actors as well.⁵⁹ Most employment cases would be covered by the EPPA and its state equivalents, but such state privacy protections might be used to help decide whether courts could compel neuroimaging scans or whether they could be required in nonemployment relationships, such as school/student or parent/child.

Neuroscience evidence and the Sixth and Seventh Amendment rights to trial by jury

One might also argue that some kinds of neuroscience evidence could be excluded from evidence as a result of the federal constitutional rights to trial by

55. *Id.* § 2001(3).

56. *Id.* § 2005.

57. *Id.* § 2006.

58. *See generally* Greely & Illes, *supra* note 44, at 409–10, 421–31 (for both state laws on employee protection and state laws more broadly regulating polygraphy).

59. “All people are by nature free and independent and have inalienable rights. Among these are enjoying and defending life and liberty, acquiring, possessing, and protecting property, and pursuing and obtaining safety, happiness, and privacy.” Calif. Const., art. I, § 1 (emphasis added). The words “and privacy” were added by constitutional amendment in 1972. The California Supreme Court had applied these privacy protections in suits against private actors: “In summary, the Privacy Initiative in article I, section 1 of the California Constitution creates a right of action against private as well as government entities.” *Hill v. Nat’l Collegiate Athletic Ass’n*, 865 P.2d 633, 644 (Cal. 1994).

jury in criminal and most civil cases. In *United States v. Scheffer*,⁶⁰ the U.S. Supreme Court upheld an express ban in the Military Rules of Evidence on the admission of any polygraph evidence against a criminal defendant's claimed Sixth Amendment right to introduce the evidence in their defense. Justice Thomas wrote the opinion of the Court, holding that the ban was justified by the questionable reliability of the polygraph. Justice Thomas continued, however, in a portion of the opinion joined only by Chief Justice Rehnquist and Justices Scalia and Souter, to hold that the Rule could also be justified by an interest in the role of the jury:

It is equally clear that Rule 707 serves a second legitimate governmental interest: Preserving the jury's core function of making credibility determinations in criminal trials. A fundamental premise of our criminal trial system is that "the jury is the lie detector." Determining the weight and credibility of witness testimony, therefore, has long been held to be the "part of every case [that] belongs to the jury, who are presumed to be fitted for it by their natural intelligence and their practical knowledge of men and the ways of men."⁶¹

The other four justices in the majority, and Justice Stevens in dissent, disagreed that the role of the jury justified this rule, but the question remains open. Justice Thomas's opinion did not argue that exclusion was *required* as part of the rights to jury trials in criminal and civil cases under the Sixth and Seventh Amendments, respectively, but one might try to extend his statements of the importance of the jury as "the lie detector" to such an argument.⁶²

Possible Rights to the Creation or Use of Neuroscience Evidence

The Eighth Amendment right to present evidence of mitigating circumstances in capital cases

In one of many ways in which "death is different," in *Lockett v. Ohio*,⁶³ the U.S. Supreme Court held that the Eighth Amendment guarantees a convicted defendant in a capital case a sentencing hearing in which the sentencing authority is able to consider any mitigating factors. In *Rupe v. Wood*,⁶⁴ the Ninth Circuit, in

60. 523 U.S. 303 (1998).

61. *Id.* at 312–13 (internal citation omitted).

62. The Federal Rules of Criminal Procedure effectively give the prosecution a right to a jury trial, by allowing a criminal defendant to waive such a trial only with the permission of both the prosecution and the court. Fed. R. Crim. P. 23(a). Many states allow a criminal defendant to waive a jury trial unilaterally, thus depriving the prosecution of an effective "right" to a jury.

63. 438 U.S. 586 (1978).

64. 93 F.3d 1434, 1439–41 (9th Cir. 1996). *But see* *United States v. Fulks*, 454 F.3d 410, 434 (4th Cir. 2006). *See generally* Christopher Domin, Comment, *Mitigating Evidence? The Admissibility of*

an appeal from the defendant's successful habeas corpus proceeding, applied that holding to find that a capital defendant had a constitutional right to have polygraph evidence admitted as mitigating evidence in his sentencing hearing. The court agreed that totally unreliable evidence, such as astrology, would not be admissible, but that the district court had properly ruled that polygraph evidence was not that unreliable. (The Washington Supreme Court had previously decided that polygraph evidence should be admitted in the penalty phase of capital cases under some circumstances.⁶⁵) Thus, capital defendants may argue that they have the right to present neuroscience evidence as mitigation even if it would not be admissible during the guilt phase.

The Sixth Amendment right to present a defense

The *Scheffer* case arose in the context of another right guaranteed by the Sixth Amendment, the right of a criminal defendant to present a defense. It seems likely that neuroimaging will first be offered by parties who have been its voluntary participants and who will argue that it strengthens their cases, just as other kinds of neuroscience evidence have. In fact, the main use of neuroimaging in the courts so far, at least in criminal cases, has been by defendants seeking to demonstrate a defense or mitigation of sentencing. If jurisdictions were to exclude such evidence categorically, they might face a similar Sixth Amendment challenge.

The U.S. Supreme Court has held that some prohibitions on evidence in criminal cases violate the right to present a defense. Thus, in *Rock v. Arkansas*,⁶⁶ the Court struck down a per se rule in Arkansas against the admission of hypnotically refreshed testimony, holding that it was “arbitrary or disproportionate to the purposes [it is] designed to serve.” The *Scheffer* case probably provides the model for how arguments about exclusions of neuroscience evidence would play out. Eight of the Justices in *Scheffer* agreed that the reliability of polygraphy was sufficiently questionable as to justify the per se ban on its use. Justice Stevens, however, dissented, finding polygraphy sufficiently reliable to invalidate its per se exclusion.

The Fourth Amendment

The Fourth Amendment raises some particularly interesting questions. It provides, of course, that, “The right of the people to be secure in their persons,

Polygraph Results in the Penalty Phase of a Capital Trial, 43 U.C. Davis L. Rev. 1461 (2010), <https://perma.cc/JA6C-DLGH> (arguing that the Supreme Court should resolve the resulting circuit split by adopting the Ninth Circuit's position).

65. *State v. Bartholomew*, 683 P.2d 1079, 1083–84 (Wash. 1984).

66. 483 U.S. 44, 56 (1987).

houses, papers, and effects, against unreasonable searches and seizures, shall not be violated, and no Warrants shall issue, but upon probable cause, supported by Oath or affirmation, and particularly describing the place to be searched, and the persons or things to be seized.” On the one hand, an involuntary neuroscience examination would seem to be a search or seizure and thus “unreasonable” neuroscience examinations are prohibited. To that extent, the Fourth Amendment would appear to be a protection against compulsory neuroscience testing.

On the other hand, neuroimaging may be considered noninvasive in that one does not have to physically invade a person’s body or effects to obtain information from the brain. A suspect can be compelled to undergo compulsory urine or blood tests, for example, and might similarly be compelled to undergo neuroimaging without it being considered an “unreasonable” search under the Fourth Amendment. Not all evidence obtained from the brain will be equally sensitive—one could obtain identifying information, automatic functioning information such as the processing of alcohol, memories from the brain, or silent utterances. Courts will be confronted with having to parse not just whether a search has occurred, but whether that search is unreasonable when neuroscience evidence is compelled. And the answers will likely turn on the nature of the neuroimaging used, whether it is compelled or passively collected neuroscience information from a wearable device, and the nature of the evidence being sought and the privacy interest implicated as a result.⁶⁷

Examples of the Possible Uses of Neuroscience in the Courts

Most of what follows deals with criminal cases. That is the area where the interest in neuroscience evidence has been strongest, and the scholarly literature, in both neuroscience and in law, has largely reflected that focus. But it is important to recognize that in U.S. civil cases, neuroscience evidence has been used to challenge or support the veracity of eyewitness memory, the reality and intensity of pain, and the mental capacity and competence of parties, witnesses, and testators.

For example, neuroscience has increasingly played an evidentiary role in civil cases involving allegations of brain injury, such as traumatic brain injury (TBI), stroke, or dementia.⁶⁸ In a product liability case involving a tractor

67. See, e.g., Nita A. Farahany, *Searching Secrets*, 160 U. Pa. L. Rev. 1239 (2012), <https://perma.cc/DU22-SDBU>.

68. See, e.g., *Dickson v. United Airlines*, No. 4:20-CV-5014-RMP, 2021 WL 4199954 (E.D. Wash. Aug. 3, 2021) (dispute between experts on neuroimaging findings and tier consistency with TBI).

accident that resulted in the plaintiff's facial and traumatic brain injury, neuroscience evidence played a central role. The plaintiff's expert testimony, partially based on magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI), was challenged by the defendant. However, the court upheld the admissibility of this evidence under Rule 702 of the Federal Rules of Evidence, recognizing DTI as a reliable methodology for identifying TBI.⁶⁹ Other decisions that have excluded DTI as scientifically unreliable have been challenged by scholars in the field.⁷⁰

Neuroscience has also been used in civil cases involving claims of chronic pain—such as fibromyalgia, complex regional pain syndrome (CRPS), or phantom limb pain—to challenge or corroborate the subjective reports of pain by the plaintiffs, including in claims and challenges for long-term disability payments.⁷¹ However, a consensus statement by neuroscientists, ethicists, and legal scholars in *Nature Reviews Neurology* opined that neuroscience evidence of chronic pain should be used to educate decision-makers about the underlying pathophysiology of the pain, but that “brain imaging is not yet sufficiently reliable to be used as a pain detector to either support or contradict an individual's self-report.”⁷²

Civil cases involving issues of memory, such as false or recovered memories, eyewitness identification, or consent, have also increasingly involved neuroscientific studies, often to explain or challenge the accuracy and reliability of witness or party testimony. However, this trend has raised scholarly concerns that neuroimaging can disproportionately influence juror assessments, particularly in determining awards in cases involving claims of pain and suffering.⁷³ All of these civil uses, and more, are likely to expand in coming years.

But we have some data about criminal cases. Over the past two decades, neuroscience evidence has increasingly been introduced by criminal defendants to challenge their competency and mental state, to put into question the voluntariness of their conduct, to support claims of insanity and mental diseases or defects, and to mitigate their punishment. Neuroscience evidence has been used to challenge the memory of eyewitnesses. And it could increasingly be used to challenge or interrogate the memory of witnesses, criminal suspects, or litigants

in civil and criminal cases. There are very few cases, civil or criminal, where the mental states of the parties are not at least theoretically relevant on issues of competency, intent, motive, recklessness, negligence, good or bad faith, memory, or other issues. And even if the parties' own mental states were not relevant, the mental states of witnesses almost always will be potentially relevant—are they telling the truth? Are they biased against one party or another? Is their memory as reliable as they claim it to be? The mental states and memory of jurors, and even of judges, occasionally may be called into question.⁷⁴

There are some important caveats on understanding the use of neuroscience in legal proceedings. First, while neuroscience evidence has been increasingly used, the evidence is usually based on neuropsychological testing and not neuroimaging. In criminal cases, neuroscience evidence has been most often introduced when the defendant is charged with a serious felony offense, rather than more minor misdemeanors, because it is expensive to investigate the neurological status of the defendant and thus impractical to introduce in misdemeanor cases. The garden-variety breach of contract or assault and battery is also not likely to provide a plausible context for convincing neuroscience evidence, especially if there is no evidence that the actor or the actions were odd or bizarre. And many cases will not provide, or justify, the resources necessary for a neurological evaluation or neuroimaging.

Second, even when neuroscience evidence is introduced, it often has a “time machine” problem. The neurological examination of a criminal defendant may be taking place months or years after the offense. Neuroscience-based testing after the crime is unlikely to discern a person's state of mind in the past. Unless the legally relevant action took place inside an MRI scanner or while a defendant was using wearable brain sensors, the best it may be able to do is to say that, based on the defendant's current mental condition or state, as shown by the current brain structure or functioning, the defendant is more or less likely than average to have had a particular mental state or condition at the time of the relevant event. If the time of the relevant event is the time of trial (or shortly before trial)—as would be the case with the truthfulness of testimony, the existence of bias, or the existence of a particular memory—that would not be a problem, but otherwise it would be.

The possibility of using real-time recordings of brain activity has reportedly already been attempted. An accused sought evidence of his brain activity recorded through electrodes implanted to address epileptic seizures as evidence he was suffering from an epileptic seizure at the time of an alleged attack.⁷⁵ Fitbit

data have similarly been used in several cases as circumstantial evidence to corroborate or disprove criminal case evidence.⁷⁶

Neuroscience evidence has been increasingly introduced into criminal cases and accepted in a number of such cases. More than 2,800 judicial opinions from 2005 to 2015 discuss the use of neuroscience evidence by a criminal defendant as part of their defense.⁷⁷ In general, this follows an evaluation of the defendant for specific neurological abnormalities that may at least in part explain, or partially excuse or mitigate, a defendant's behavior. This includes medical history, neuropsychological testing, brain scanning, or unsubstantiated claims of a past history of head trauma or brain injury. Since 2015, hundreds more cases per year have discussed similar claims.

In the majority of these criminal cases, the most serious charge against the criminal defendant is some degree of homicide, but in about 40% of the cases, the most serious charge is a felony other than homicide. In only about 10% of the cases do the judicial opinions discuss the use of neuroimaging as part of the neuroscience evidence introduced.⁷⁸

In some cases, rather than addressing the unique issues relevant to a specific person's brain, it has been used to inform broader policy choices about categories of individuals. This is particularly true for juvenile defendants and those under the age of twenty-six, who argue that their developing brain, as a class of individuals, warrants treating them differently than adults. Developmental neuroscience, which has shown that adolescents have developing brains that make conforming with the law more difficult than it is for adults, has been the empirical basis for recent constitutional prohibitions against the execution of—or punishment of life without the possibility of parole for—juveniles.⁷⁹ And an increasing number of criminal defendants have argued, albeit largely unsuccessfully, that the same logic ought to extend to them until at least twenty-six years of age, when the brain has by and large fully developed.⁸⁰ Three of the handful of published cases in which fMRI evidence was offered in court concerned challenges to state laws requiring warning labels on violent video games.⁸¹ The states

Supp. 2d 978 (E.D. Mich. 2005). Each of the three courts held that the state statutes violated the First Amendment.

sought, without success, to use fMRI studies of the effects of violent video games on the brains of children playing the games to support their statutes.⁸²

These “wholesale” uses of neuroscience may (or may not) end up affecting the law, but the courts would be more affected if various “retail” uses of neuroscience were to become common, where a party or a witness is subjected to neuroscience procedures to determine something relevant only to that particular case. An incomplete list of some of the most plausible categories for such retail uses includes the following:

- issues of responsibility, certainly criminal and likely also civil
- predicting future behavior for sentencing
- mitigating (or potentially aggravating) factors on sentencing
- competency, now or in the past, to take care of one’s affairs, to enter into agreements or make wills, to stand trial, to represent oneself, and to be executed
- credibility or deception in current statements
- bolstering or as evidence of a mental disease or defect in the insanity defense
- the existence or nonexistence of a memory of some event and, possibly, some information about the status of that memory (true, false; new, old, etc.)
- the presence of the subjective sensation of pain
- the presence of bias against a party

Many, but not all, of these issues have begun to be discussed in the literature. A few of them, such as criminal responsibility, mitigation, memory detection, and lie detection, are appearing in courtrooms; others, such as pain detection, have been introduced in a number of civil cases. This reference guide does not discuss all of these topics and does not discuss any of them in great depth, but it will discuss three of them substantially—criminal responsibility, detection of pain, and lie detection—in order to provide a flavor of the possibilities, as well as presenting a short discussion of a fourth: addiction.

82. The courts, sitting in equity and so without juries, all considered the scientific evidence and concluded that it was insufficient to sustain the statutes’ constitutionality. In *Blagojevich* the court heard testimony for the state directly from Dr. Kronenberger, the author of some of the fMRI-based articles on which the state relied, as well as from Dr. Howard Nusbaum, for the plaintiffs, who attacked Dr. Kronenberger’s studies. After a substantial discussion of the scientific arguments, the district court judge, Judge Matthew Kennelly, found that “Dr. Kronenberger’s studies cannot support the weight he attempts to put on them via his conclusions,” and did not provide a basis for the statute. *Blagojevich*, 404 F. Supp. at 1063–67. Judge Kennelly’s discussion of this point may be a good example of the kind of analysis neuroscience evidence may force upon judges.

Criminal Responsibility

Neuroscience may raise some deep questions about criminal responsibility. Assume we had excellent scientific evidence that a defendant could not help but commit the criminal acts because of a specific brain abnormality.⁸³ Should that affect the defendant's guilt and, if so, how? Should it affect their sentence or other subsequent treatment? The moral questions may prove daunting. Currently, the law assumes "legal" free will rather than engaging with the "philosophical" debates over free will.⁸⁴ The criminal law in all U.S. jurisdictions presumes that individuals are responsible agents capable of making choices and intending the natural consequence of their actions. While some commentators believe that neuroscience should change that assumption in criminal law, "[a]cts should be judged by their tendency under known circumstances, not by the actual intent which accompanies them."⁸⁵ The criminal defendant may nonetheless evade or receive a diminution in criminal responsibility through a successful presentation of a justification or excuse.

A finding of criminal liability requires the government to prove the actor voluntarily engaged in a harmful or threatening act proscribed by criminal law and did so with the requisite mental awareness of the circumstances of fact that made the conduct criminal. A conviction generally requires both an *actus reus* and a *mens rea*—a "guilty act" and a "guilty mind." An unconscious person cannot "act," but even a conscious act is often not enough. Specific crimes often require specific intents, such as acting with a particular purpose or in a knowing, reckless, or negligent way. Some crimes require even more defined mental states, such as a requirement for specific intent to not only commit a homicide, but to do so with knowledge of the special status of the victim, such as a police officer. And almost all crimes can be excused by legal insanity. In these and other ways, the mental state of the defendant may be relevant to a criminal case.

Neuroscience may provide evidence in some cases to support a defendant's claim of a justification or excuse by helping to establish that they suffer a mental disease or disorder. For example, a defendant who claims to have been insane at the time of the crime might try to support their claim by alleging that they are suffering from frontotemporal dementia, which prevented them from knowing the difference between right and wrong. Neuroimaging may be able to provide some evidence about whether the defendant is, in fact, suffering from frontotemporal dementia and how that affects the individual, at least at the time they

83. See Henry T. Greely, *Neuroscience and Criminal Responsibility Proving "Can't Help Himself" as a Narrow Bar to Criminal Liability*, in 13 *Law & Neuroscience*, Current Legal Issues 61 (Michael Freeman ed., 2011), <https://doi.org/10.1093/acprof:oso/9780199599844.003.0005>.

84. Nita A. Farahany & James E. Coleman, Jr., *Genetics, Neuroscience, and Criminal Responsibility*, in *The Impact of Behavioral Sciences on Criminal Law* 183 (Nita A. Farahany ed., 2009), <https://doi.org/10.1093/acprof:oso/9780195340525.003.0007>.

85. Oliver Wendell Holmes, Jr., *The Common Law* 66 (1881).

are undergoing the neurological evaluation.⁸⁶ Such neurological evaluation might even show that the defendant had a stroke or tumor in a particular part of the brain, which then could be used to argue in some way against the defendant's criminal responsibility.⁸⁷

Neuroimaging has been used more broadly in some criminal cases. For example, in the trial of John Hinckley Jr. for the attempted assassination of President Reagan, the defense used CAT scans of Hinckley's brain to support the argument, based largely on his bizarre behavior, that he suffered from schizophrenia. The scientific basis for that conclusion, offered early in the history of brain CAT scans, was questionable at the time and has become even weaker since, but Hinckley was found not guilty by reason of insanity. In November 2009, testimony about an fMRI scan was introduced in the penalty phase of a capital case as mitigating evidence that the defendant suffered from psychopathy. The defendant was sentenced to death, but after longer jury deliberations than defense counsel expected.⁸⁸ (This appears to have been the first time fMRI results were introduced in a criminal case.⁸⁹) To date, the most common types of neuroimaging that are introduced to support a defendant's claim about a brain abnormality or difference that at least in part explains their criminal conduct have been MRI or PET scans, rather than more advanced techniques like EEG, SPECT, or fMRI scanning.⁹⁰

Neuroscience evidence also may be relevant in wider arguments about criminal justice. Evidence about the development of adolescent brains has been referred to in appellate cases concerning the punishments appropriate for people who committed crimes while underage, including, as noted above, U.S. Supreme Court decisions. More broadly, some have urged that neuroscience will undercut much of the criminal justice system. The argument is that neuroscience

86. See, e.g., Nita A. Farahany, *Neuroscience and Behavioral Genetics in US Criminal Law: An Empirical Analysis*, 2 J.L. & Biosciences 485 (2015), <https://doi.org/10.1093/jlb/lsv059>.

87. In at least one fascinating case, a man who was convicted of sexual abuse of a child was found to have a large tumor pressing into his brain. When the tumor was removed, his criminal sexual impulses disappeared. When his impulses returned, so had his tumor. The tumor was removed a second time and, again, his impulses disappeared. Jeffrey M. Burns & Russell H. Swerdlow, *Right Orbitofrontal Tumor with Pedophilia Symptom and Constructional Apraxia Sign*, 60 Archives Neurology 437 (2003), <https://perma.cc/X2VU-VHWC>; *Doctors Say Pedophile Lost Urge After Tumor Removed*, USA Today, July 28, 2003, <https://perma.cc/NY89-2GQT>; see also Greely, *supra* note 83 (offering a longer discussion of this case).

88. The defendant in this Illinois case, Brian Dugan, confessed to the murder but sought to avoid the death penalty. See Virginia Hughes, *Science in Court: Head Case*, 464 Nature 340 (2010), <https://doi.org/10.1038/464340a> (providing an excellent discussion of this case).

89. It should be noted that other forms of neuroimaging, particularly PET and structural MRI scans, have been more widely used in criminal cases. Dr. Ruben Gur at the University of Pennsylvania estimates that he has used neuroimaging in testimony for criminal defendants about thirty times. *Id.*

90. Farahany, *supra* note 86.

ultimately will prove that no one—not even the sanest defendant—has free will and that this will fatally weaken the retributive aspect of criminal justice.⁹¹

The application of neuroscience evidence to individual claims of a lack of criminal responsibility has proven challenging.⁹² Such claims suffer from the time machine problem—the neuropsychological testing or imaging will almost always be from after, usually long after, the crime was committed and so cannot directly show a defendant’s brain state (and hence, by inference, his or her mental state) at or before the time of the crime. While this could change with more passively collected brain data if consumer neurotechnology becomes widespread, it remains to be seen how much we will be able to infer from that data, or how robust or reliable the data will be in an environment that is not well controlled, like a laboratory or clinical setting.

Careful neuroscience studies, either structural or functional, of the brains of criminals are rare. It seems highly unlikely that a “responsibility region” will ever be found, one that is universally activated in law-abiding people and that is deactivated in criminals (or vice versa). At most, the evidence is likely to show that people with particular brain structures or patterns of brain functioning commit crimes more frequently than people without such structures or patterns. Applying this group evidence to individual cases will be difficult, if not impossible. All of the problems of technical and statistical analysis of neuroimaging data, discussed above in the section titled “Issues in Interpreting Study Results,” apply. And it is possible that the to-be-scanned defendants will be able to implement countermeasures to “fool” the expert analyzing the scan.

The use of neuroscience to undermine criminal responsibility faces another problem: identifying a specific legal argument. It is not generally a defense to a criminal charge to assert that one has a predisposition to commit a crime, or even a very high statistical likelihood, as a result of social and demographic variables, of committing a crime. It is not clear whether neuroscience would, in any

91. See, e.g., Robert M. Sapolsky, *The Frontal Cortex and the Criminal Justice System*, in *Law and the Brain* 227 (Semir Zeki & Oliver Goodenough eds., 2006), <https://doi.org/10.1093/oso/9780198570103.003.0012>; Joshua Greene & Jonathan Cohen, *For the Law, Neuroscience Changes Nothing and Everything*, in *id.* at 207, <https://doi.org/10.1093/oso/9780198570103.003.0011>. These arguments have been forcefully made by Professor Stephen Morse. See, e.g., Stephen J. Morse, *Determinism and the Death of Folk Psychology: Two Challenges to Responsibility from Neuroscience*, 9 Minn. J.L. Sci. & Tech. 1 (2008), <https://perma.cc/985T-B4MR>; Stephen J. Morse, *The Non-Problem of Free Will in Forensic Psychiatry and Psychology*, 25 Behav. Sci. & L. 203 (2007), <https://doi.org/10.1002/bsl.744>; Stephen J. Morse, *Moral and Legal Responsibility and the New Neuroscience*, in *Neuroethics: Defining the Issues in Theory, Practice, and Policy* 33 (Judy Illes ed., 2d ed. 2006), <https://doi.org/10.1093/acprof:oso/9780198567219.003.0003>; Stephen J. Morse, *Brain Overclaim Syndrome and Criminal Responsibility: A Diagnostic Note*, 3 Ohio St. J. Crim. L. 397 (2006).

92. A good short discussion of these challenges can be found in A Judge’s Guide to Neuroscience: A Concise Introduction 37, *supra* note 5.

more than a very few cases,⁹³ provide evidence that was not equivalent to predisposition evidence. (And, of course, prudent defense counsel might think twice before presenting evidence to the jury that their client was strongly predisposed to commit crimes.)

We are at an early stage in our understanding of the brain and of the brain states related to the mental states involved in criminal responsibility. At this point, about all that can be said is that at least some criminal defense counsel, seeking to represent their clients zealously, will watch neuroscience carefully for arguments they could use to relieve their clients from criminal responsibility.

Lie Detection

In General

The use of neuroscience methods for lie detection probably has received more attention than any other issue raised in this reference guide.⁹⁴ This is due in part

93. See Greely, *supra* note 83 (arguing for a very narrow neuroscience-based defense).

94. For a technology whose results have yet to be admitted in court, the legal and ethical issues raised by fMRI-based lie detection have been discussed in an amazingly long list of scholarly publications from 2004 to the present. An undoubtedly incomplete list follows: Brown & Murphy, *supra* note 36; Anthony D. Wagner, *supra* note 23; Frederick Schauer, *Can Bad Science Be Good Evidence?: Neuroscience, Lie-Detection, Beyond*, 95 Cornell L. Rev. 1191 (2010); Frederick Schauer, *Neuroscience, Lie-Detection, and the Law: A Contrarian View*, 14 Trends Cognitive Scis. 101 (2010), <https://doi.org/10.1016/j.tics.2009.12.004>; Bizzi et al., *supra* note 23; Joëlle Anne Moreno, *The Future of Neuroimaged Lie Detection and the Law*, 42 Akron L. Rev. 717 (2009), <https://perma.cc/E58C-H7PQ>; Julie Seaman, *Black Boxes: fMRI Lie Detection and the Role of the Jury*, 42 Akron L. Rev. 931 (2009), <https://perma.cc/JHW9-RGP2>; Jane Campbell Moriarty, *Visions of Deception: Neuroimages and the Search for Truth*, 42 Akron L. Rev. 739 (2009), <https://perma.cc/SY9C-N24G>; Benjamin Holley, *It's All in Your Head: Neurotechnological Lie Detection and the Fourth and Fifth Amendments*, 28 Devs. Mental Health L. 1 (2009), <https://perma.cc/2GWS-WWPZ>; Brian Reese, Comment, *Using fMRI as a Lie Detector—Are We Lying to Ourselves?*, 19 Alb. L.J. Sci. & Tech. 205 (2009), <https://perma.cc/XJ2D-4QQF>; Cooper Ellenberg, *Lie Detection: A Changing of the Guard in the Quest for Truth in Court?*, 33 L. & Psych. Rev. 139 (2009), <https://perma.cc/R58K-58ZX>; Julie A. Seaman, *Black Boxes*, 58 Emory L.J. 427 (2008), <https://perma.cc/PAL6-B4BY>; Greely & Illes, *supra* note 44; Mark Pettit, *fMRI and BF Meet FRE: Brain Imaging and the Federal Rules of Evidence*, 33 Am. J.L. & Med. 319 (2007), <https://doi.org/10.1177/009885880703300208>; Jonathan H. Marks, *Interrogational Neuroimaging in Counterterrorism: A “No-Brainer” or a Human Rights Hazard?*, 33 Am. Rev. 1351, 1355 (2007), <https://perma.cc/33D7-86TA>; Jeffrey Bellin, *The Significance (If Any) for the Federal Criminal Justice System of Advances in Lie Detector Technology*, 80 Temp. L. Rev. 711 (2007), <https://perma.cc/XNV3-RE36>; Henry T. Greely, *The Social Consequences of Advances in Neuroscience: Legal Problems, Legal Perspectives*, in *Neuroethics: Defining the Issues in Theory, Practice, and Policy* 245, *supra* note 91, <https://doi.org/10.1093/acprof:oso/9780198567219.003.0017>; Charles N.W. Keckler, *Cross-Examining the Brain: A Legal Analysis of Neural Imaging for Credibility Impeachment*, 57 Hastings L.J. 509 (2006), <https://perma.cc/QVY5-7ZSR>; Archie Alexander, *Functional Magnetic Resonance Imaging Lie Detection: Is a “Brainstorm” Heading*

to the cultural interest in lie detection, dating back in its technological phase nearly a hundred years to the invention of the polygraph.⁹⁵ But it is also due to the fact that for several years two commercial firms offered fMRI-based lie-detection services for sale in the United States: Cephos and No Lie MRI.⁹⁶

Beyond the scientific validity of these techniques lies a host of legal questions. How accurate is accurate enough for admissibility in court or for other legal system uses? What are the implications of admissible and accurate lie detection for the Fourth, Fifth, Sixth, and Seventh Amendments? Would jurors be allowed to consider the failure, or refusal, of a party to take a lie-detector test? Would lie detection be available in discovery? Would each side get to do its own tests—and who would pay?

Accurate lie detection could make the justice system much more accurate. Incorrect convictions might become rare; so might incorrect acquittals. Accurate lie detection also could make the legal system much more efficient. It seems likely that far fewer cases would go to trial if the witnesses could expect to have their veracity accurately determined.

Inaccurate lie detection, on the other hand, holds the potential of ruining the innocent and immunizing the guilty. It is at least daunting to remember some of the failures of the polygraph, such as the case of Aldrich Ames, a Soviet (and then Russian) mole in the Central Intelligence Agency, who passed two Agency polygraph tests while serving as a paid spy.⁹⁷ The courts already have begun to decide whether and how to use these new methods of lie detection in

Toward the “Gatekeeper”?, 7 Hous. J. Health L. & Pol’y 1 (2007), <https://perma.cc/H4UR-HBR2>; Paul Root Wolpe, Kenneth R. Foster & David D. Langleben, *Emerging Neurotechnologies for Lie-Detection: Promises and Perils*, 5 Am. J. Bioethics 39, 42 (2005), <https://doi.org/10.1080/1526516059023367>; Henry T. Greely, *Premarket Approval Regulation for Lie Detection: An Idea Whose Time May Be Coming*, 5 Am. J. Bioethics, 50–52 (2006), <https://doi.org/10.1080/15265160590960988>; Sean Kevin Thompson, Note, *The Legality of the Use of Psychiatric Neuroimaging in Intelligence Interrogation*, 90 Cornell L. Rev. 1601 (2005), <https://perma.cc/DC5N-PFBK>; Henry T. Greely, *Prediction, Litigation, Privacy, and Property: Some Possible Legal and Social Implications of Advances in Neuroscience*, in *Neuroscience and the Law* 114–56, *supra* note 5, <https://perma.cc/9JXM-PVMV>; Judy Illes, *A Fish Story? Brain Maps, Lie Detection, and Personhood*, 6 Cerebrum 73 (2004), <https://perma.cc/8ZY4-V7X6>.

95. An interesting history of the polygraph can be found in Ken Alder, *The Lie Detectors: The History of an American Obsession* (2007). Perhaps the best overall discussion of the polygraph, including some discussion of its history, is found in the National Research Council report, commissioned in the wake of the Wen Ho Lee case, on the use of the technology for screening. Nat’l Rsch. Council, *supra* note 25.

96. Cephos stopped providing fMRI-based lie-detection services sometime after 2012; it seems to have some continuing existence with respect to DNA forensics. *See* Cephos, <https://perma.cc/F3JY-9D73>. No Lie MRI appears to have changed its name to Truthful Brain Corporation and to have created a nonprofit venture called Medicine for Law. It is not clear whether either of those is still active, although the second does have a website: <https://perma.cc/V78N-EB3F>.

97. *See* Senate Select Committee on Intelligence, *An Assessment of the Aldrich H. Ames Espionage Case and Its Implications for U.S. Intelligence* (1994), <https://perma.cc/26TT-55SK>.

the judicial process; the rest of society also will soon be forced to decide on their uses and limits.

But, of course, lie detection might have applications to litigation without ever being introduced in trials. As is the case today with the polygraph, the fact that it is not generally admissible in court might not stop the police or the prosecutors from using it to investigate alleged crimes. Similarly, defense counsel might well use it to attempt to persuade the authorities that their clients should not be charged or should be charged with lesser offenses. One could imagine the same kinds of pretrial uses of lie detection in civil cases, as the parties seek to affect each other's perceptions of the merits of the case.

Such lie-detection efforts could also affect society, and the law, outside of litigation. One could imagine prophylactic lie detection at the beginning of contractual relations, seeking to determine whether the other side honestly had the present intention of complying with the contract's terms. One can also imagine schools using lie detection as part of investigations of student misconduct, or parents seeking to use lie detection on their children. The law more broadly may have to decide whether and how private actors can use lie detection, determining whether, for example, to extend to other contexts—or to weaken or repeal—the Employee Polygraph Protection Act.⁹⁸

Efforts to use fMRI-based lie detection in the courts have faded in recent years, but another method of “recognition detection” may soon reach the courts. This section will discuss each approach, both to help judges if such evidence reaches their courts but also, at least for fMRI-based lie detection, as a case study of the legal system's response to such evidence.

fMRI-Based Lie Detection

Currently, as far as we know, evidence from fMRI-based lie detection has not been admitted into evidence in any court, but it was offered—and rejected—in at least three cases, *United States v. Semrau*,⁹⁹ *Wilson v. Corestaff Services L.P.*,¹⁰⁰ and a widely publicized murder trial, *Maryland v. Smith*,¹⁰¹ in the early 2010s.¹⁰²

100. 900 N.Y.S.2d 639 (N.Y. Sup. Ct. 2010).

101. Michael Laris, *Debate on Brain Scans as Lie Detectors Highlighted in Maryland Murder Trial*, Wash. Post, Aug. 26, 2012, <https://perma.cc/EG4Z-FZ84>.

102. In early 2009, a motion to admit fMRI-based lie-detection evidence, provided by No Lie MRI, was made, and then withdrawn, in a child custody case in San Diego. The case is discussed in a prematurely titled article by Alexis Madrigal, *fMRI Lie Detection to Get First Day in Court*, WIRED Sci., Mar. 16, 2009, <https://perma.cc/29SF-VKFH>. A somewhat similar method of using EEG to look for signs of “recognition” in the brain was admitted into one state court hearing for

Since then, efforts to introduce evidence from this technology have largely disappeared—we find no reported cases about such attempted uses since 2012—but the story of its rise and fall provides a good example of a path for new neuroscience evidence. And the underlying science still exists and could well end up in court again. This section will begin by analyzing the issues raised for courts by this technology and then will discuss these three cases, before ending with a quick look at possible uses for this kind of technology outside the courtroom.

Published research on fMRI and detecting deception dates back to about 2001.¹⁰³ As noted above, to date between twenty and thirty peer-reviewed articles from about fifteen laboratories have appeared claiming to find statistically significant correlations between patterns of brain activation and deception. Only a handful of the published studies have looked at the accuracy of determining deception in individual participants as opposed to group averages. Those studies generally claim accuracy rates of between about 75% and 90%. No Lie MRI has licensed the methods used by one laboratory, that of Dr. Daniel Langleben at the University of Pennsylvania; Cephos has licensed the method used by another laboratory, that of Dr. Frank A. Kozel, first at the Medical University of South Carolina and then at the University of Texas Southwestern Medical Center. (The method used by a British researcher, Dr. Sean Spence, has been used on a British reality television show.)

All of these studies rely on research participants, typically but not always college students, who are recruited for a study of deception. They are instructed to answer some questions truthfully in the scanner and to answer other questions inaccurately.¹⁰⁴ In the Langleben studies, for example, undergraduates were shown images of playing cards while in the scanner and asked to indicate whether they saw a particular card. They were instructed to answer truthfully except when they saw one particular card. Some of Kozel's studies used a different experimental paradigm, in which the participants were put in a room and told to take either a watch or a ring. When asked in the scanner separately whether they

postconviction relief at the trial court level in Iowa in 2001, and both it and another EEG-based method have been used in India. As far as we know, evidence from the use of EEG for lie detection has not been admitted in any other U.S. cases. *See supra* note 45.

103. The most recent reviews of the scientific literature on this subject are Wagner, *supra* note 23, and Shawn E. Christ et al., *The Contributions of Prefrontal Cortex and Executive Control to Deception: Evidence from Activation Likelihood Estimate Meta-Analyses*, 19 *Cerebral Cortex* 1557 (2009), <https://doi.org/10.1093/cercor/bhn189>. *See also* Greely & Illes, *supra* note 44 (for discussion of the articles through early 2007). The following discussion is based largely on those sources.

104. At least one fMRI study has attempted to investigate self-motivated lies, told by participants who were *not* instructed to lie, but who chose to lie for personal gain. Joshua D. Greene & Joseph M. Paxton, *Patterns of Neural Activity Associated with Honest and Dishonest Moral Decisions*, 106 *PNAS* 12506 (2009), <https://doi.org/10.1073/pnas.0900152106>. The experiment was designed to make it easy for participants to realize they would be given more money if they lied about how many times they correctly predicted a coin flip. Investigators could not, however, determine if a participant lied in any particular trial.

had taken the watch and then whether they had taken the ring, they were to reply “no” in both cases—truthfully once and falsely the other time. When analyzed in various ways, the fMRI results showed statistically different patterns of brain activation (small changes in BOLD response) when the participants were lying and when they were telling the truth.

In general, these studies are not guided by a consistent hypothesis about which brain regions should be activated or deactivated during truth or deception. The results are empirical; they see particular patterns that differ between the truth state and the lie state. Some have argued that the patterns show greater mental effort when deception is involved; others have argued that they show more impulse control when lying.

Are fMRI-based lie-detection methods accurate? As a class of experiments, these studies are subject to all the general problems discussed above in the section “Issues in Interpreting Study Results” regarding fMRI scans that might lead to neuroscience evidence. So far, there are only a few studies involving a limited number of participants. (The method used by No Lie MRI seems ultimately to have been based on the responses of four right-handed, healthy, male University of Pennsylvania undergraduates.¹⁰⁵) There have been, to date, no independent replications of any group’s findings.

The experience of the research participants in these fMRI studies of deception seems to be different from “lying” as the court system would perceive it. The participants knew they were involved in research, they were following orders to lie, and they knew that the most harm that could come to them from being detected in a lie might be lesser payment for taking part in the experiment. This seems hard to compare to a defendant lying about participating in a murder.¹⁰⁶ More fundamentally, it is not clear how one could conduct ethical but realistic experiments with lie detection. Research participants cannot credibly be threatened with jail if they do not convince the researcher of the truth of their lies.

Only a handful of researchers have published studies showing reported accuracy rates with individual participants and only with a small number of participants.¹⁰⁷ Some of the studies used complex and somewhat controversial

105. Langleben et al., *supra* note 23, at 267.

106. Michael Pardo has forcefully made this point by dissecting, philosophically, the meaning of the term *lie*. In 2018, in one of the latest scholarly discussions of fMRI lie detection, he argues that the studies are not detecting “lying” because they examine participants who are doing what they have been instructed to do. Michael S. Pardo, *Lying, Deception, and fMRI: A Critical Update*, in *Neurolaw and Responsibility for Action* 143 (Bebhinn Donnelly-Lazarov ed., 2018), <https://perma.cc/FLD9-PA5U>. Following earlier work from 2013, see Michael S. Pardo & Dennis Patterson, *Minds, Brains, and Law: The Conceptual Foundations of Law and Neuroscience* 105–06 (2013), where he discusses five subsequent studies, all of which he finds unhelpful.

107. See discussion in Wagner, *supra* note 23, at 29–35. Wagner analyzes eleven peer-reviewed, published papers. Seven come from Kozel’s laboratory; three come from Langleben’s. The only exception is a paper from John Cacioppo’s group, which concludes “[A]lthough fMRI may permit

statistical techniques. And although participants in at least one experiment were invited to try to use countermeasures against being detected, no specific countermeasures were tested.

United States v. Semrau is the most significant case involving fMRI lie detection. On June 1, 2010, U.S. Magistrate Judge Tu M. Pham of the Western District of Tennessee issued an amended thirty-nine-page report and recommendation on the prosecution's motion to exclude evidence from an fMRI-based lie-detection report by Cephos.¹⁰⁸ The report came after a hearing on May 13–14 featuring testimony from Steve Laken, CEO of Cephos, for admission, and from two experts arguing against admission. The district judge adopted the magistrate's report in its entirety during the trial and, in September 2012, the Sixth Circuit, in a lengthy opinion that relied heavily on the magistrate judge's report and recommendations, affirmed that the district court had not abused its discretion in excluding the evidence under either Rule 702 or Rule 403.¹⁰⁹

The defendant in this case, Dr. Semrau, a health professional accused of defrauding Medicare, offered as evidence a report from Cephos stating that he was being truthful when he answered a set of questions about his actions and knowledge concerning the alleged crimes.

Judge Pham first analyzed the motion under Rule 702, using the *Daubert* criteria. He concluded that the technique was testable and had been the subject of peer-reviewed publications. On the other hand, he concluded that the error rates for its use in realistic situations were unknown. Furthermore, he found there were no standards for its appropriate use. To the extent that the publications relied on by Cephos to establish its reliability constituted such standards, those standards had not actually been followed in the tests of the defendant. Cephos actually scanned Dr. Semrau two times on one day, asking questions about one aspect of the criminal charges during the first scan and then about another aspect in the second scan. The company's subsequent analysis of those scans indicated that the defendant had been truthful in the first scan but deceptive in the second scan. Cephos then scanned him a third time, several days later, on the second subject but with revised questions, and concluded that he was telling the truth that time. Nothing in the publications relied upon by Cephos indicated that the third scan

investigation of the neural correlates of lying, at the moment it does not appear to provide a very accurate marker of lying that can be generalized across individuals or even perhaps across types of lies by the same individuals." George T. Monteleone et al., *Detection of Deception Using fMRI: Better Than Chance, But Well Below Perfection*, 4 Soc. Neuroscience 528 (2009), <https://doi.org/10.1080/17470910801903530>. However, that study only looked at one brain region at a time, and it did not test combinations or patterns, which might have improved the predictive power.

108. *United States v. Semrau*, No. 07–10074, 2010 WL 6845092 (W.D. Tenn. June 1, 2010). The district court judge assigned to the case had a scheduling conflict on the date of the hearing on the prosecution's motion, so the hearing was held before a magistrate judge from that district.

109. 693 F.3d 510, 523–24 (6th Cir. 2012).

was appropriate. Finally, Judge Pham found that the method was not generally accepted in the relevant scientific community as sufficiently reliable for use in court, citing several publications, including some written by the authors whose methods Cephos used.

The magistrate judge then examined the motion under Rule 403 and found that the potential prejudicial effect of the evidence outweighed its probative value. He noted that the test had been conducted without the government's knowledge or participation, in a context where the defendant risked nothing by taking the test—a negative result would never be disclosed. He noted the jury's central role in determining credibility and considered the likelihood that the lie-detection evidence would be a lengthy and complicated distraction from the jury's central mission. Finally, he noted that the probative value of the evidence was greatly reduced because the report only gave a result concerning the defendant's general truthfulness when responding to more than ten questions about the events but did not even purport to say whether the defendant was telling the truth about any particular question.¹¹⁰

The Sixth Circuit panel affirmed unanimously, holding that the district court did not abuse its discretion in excluding the fMRI evidence pursuant to Rule 403 in light of (1) the questions surrounding the reliability of fMRI lie-detection tests in general and as performed on Dr. Semrau, (2) the failure to give the prosecution an opportunity to participate in the testing, and (3) the test result's inability to corroborate Dr. Semrau's answers as to the particular offenses for which he was charged.¹¹¹

In the same month as the magistrate judge's report in *Semrau*, a state trial court judge in Brooklyn excluded another Cephos lie-detection report in a civil case, *Wilson v. Corestaff Services L.P.*¹¹² This case involved a claim under state law by a former employee that she had been subject to retaliation for reporting sexual harassment. The plaintiff offered evidence from a Cephos report finding that

110. Interestingly, the Sixth Circuit panel stated, in a footnote, that “the prospect of introducing fMRI lie detection results into criminal trials is undoubtedly intriguing and, perhaps, a little scary.” *Id.* at 524 n.12. See Daniel S. Goldberg, *Against Reductionism in Law & Neuroscience*, 11 Hous. J. Health L. & Pol'y 321, 324 & n.6 (2011), <https://perma.cc/K4E4-6J4Q> (reviewing literature that “challenges the very idea that fMRI or other novel neuroimaging techniques either can or should be used as evidence in criminal proceedings”).

There may well come a time when the capabilities, reliability, and acceptance of fMRI lie detection—or even a technology not yet envisioned—advances to the point that a trial judge will conclude, as did Dr. Laken in this case: “I would subject myself to this over a jury any day.” Though we are not at that point today, we recognize that as science moves forward the balancing of Rule 403 may well lean toward finding that the probative value for some advancing technology is sufficient.

Semrau, 693 F.3d at 524 n.12.

111. *Id.* at 524.

112. 900 N.Y.S.2d 639 (N.Y. Sup. Ct. 2010).

her main witness was truthful when he described how the defendant's management said it would retaliate against the plaintiff.

That case did not involve an evidentiary hearing or, indeed, any expert testimony. The judge decided the lie-detection evidence was not appropriate under New York's version of the *Frye* test, noting that, in New York, "courts have advised that the threshold question under *Frye* in passing on the admissibility of expert's testimony is whether the testimony is 'within the ken of the typical juror.'" ¹¹³ Because credibility is a matter for the jury, the judge concluded that this kind of evidence was categorically excluded under New York's version of *Frye*. He also noted that "even a cursory review of the scientific literature demonstrates that the plaintiff is unable to establish that the use of the fMRI test to determine truthfulness or deceit is accepted as reliable in the relevant scientific community." ¹¹⁴

Finally, also in 2012, a Maryland trial court excluded a No Lie MRI fMRI-based lie-detection report in a well-publicized murder case. The judge held three days of pretrial hearings on the evidence before concluding there was no consensus among the experts: "These are brilliant people, and they don't agree." ¹¹⁵ No published opinion followed. ¹¹⁶

After 2012, fMRI-based lie detection continued to be discussed in the press and the academic literature for several years, ¹¹⁷ but without any other known efforts to introduce it. (*Semrau*, for example, has yet to be cited in any opinions involving lie detection.) Nonetheless, the science is still there and further attempts may be made.

The current fMRI-based methods of lie detection do provide one kind of protection for possible participants—they are obvious. No one is going to be put into an MRI for an hour and asked to respond, repeatedly, to questions without realizing something important is going on. Should researchers develop less obtrusive or obvious methods of neuroscience-based lie detection, we will have to deal with the possibilities of involuntary and, indeed, surreptitious lie detection.

Issues Involved in the Use of EEG-Based Brain “Recognition”

A different approach uses the unique neural signature in EEGs of suspects’ brains associated with the recognition, salience, or congruence of facts or events to interrogate the brain.¹¹⁸ While criminal suspects wear an EEG headset, they are shown images, words, or sounds during which their brainwave activity is recorded. Images from a crime scene such as a murder weapon, objects from crime scenes, the victim, or the victim’s clothing might all be triggering images. An analyst then interprets the brainwave activity to see if a characteristic EEG signal registers from the brain in response to any of the images.

The P300 wave was the first to be used for this purpose. It is an event-related potential (ERP) measurement of brain activity, where the amplitude of that waveform differs depending on whether a participant recognizes a prior fact.¹¹⁹ Whereas a traditional polygraph asks a person a series of yes or no questions and then looks at their physiological responses to infer if they are telling the truth or a lie, this approach is designed to reveal “recognition” of salient facts of a crime.¹²⁰

Although this EEG-based technique was initially heralded as an extraordinary scientific breakthrough, the broader scientific community raised serious doubts about the veracity of the approach.¹²¹ More recently, however, some scientists have started to independently test the technique and are encouraged that it could be applied more reliably.¹²² In particular, Dr. Peter Rosenfeld rigorously tested this approach, including looking for countermeasures—and countermeasures to countermeasures.¹²³

Another scientifically promising approach uses a different ERP brain response called the N400 signal, which seems to respond to congruence rather than salience. As an author of this reference guide explained:

You could show a suspect a series of faces that includes their suspected co-conspirators. Their N400 brain signals would be more negative for “incongruent” faces that didn’t belong than for “congruent” faces that did. Similarly, you could pair words together like “body” and “lake” versus “body” and “base-ment” to try to find out where a murder victim’s corpse is hidden.¹²⁴

Both the P300 and the N400 signals are detected with EEG, a cheap and easily used technology. Some of the earliest attempts in the United States to use the P300 technology, oddly referred to as “brain fingerprinting,” came from criminal defendants themselves, asking for the results of the test to be used to validate their claims of innocence.¹²⁵ More commonly, it is the police and not criminal suspects who have sought out the P300 technology.¹²⁶ But the practice has not become widespread in the United States, likely because criminal defendants will only rarely voluntarily submit to the test and cannot now be forced to do so. But it is finding some success overseas. P300 has been used in India since 2003. Singapore’s police services purchased the technology in 2013; and one source says police in Florida signed a contract in 2014 to use the approach.¹²⁷ A firm now named Brainwave Science has been marketing this approach, calling it “iCognitive,” with some success around the world. Australian counterterrorism authorities are currently looking into the potential use of brain fingerprinting to determine whether individuals returning from war zones have been illegally involved in conflict when they claim to have been participating in humanitarian work.¹²⁸

Detection of Pain

Detection of pain is likely to be another area for use of neuroscience evidence, although this will be mainly in civil cases or administrative appeals (often from denial of government disability payments). No matter where an injury occurs and no matter where it seems to hurt, pain is felt in the brain.¹²⁹ Without sensory nerves leading to the brain from a body region, there is usually no experience of pain. Without the brain machinery and functioning to process the signal, no pain is perceived.

Pain turns out to be complicated—even the common pain that is experienced from an acute injury to, say, an arm. Neurons near the site of the injury called nociceptors transmit the pain signal to the spinal cord, which relays it to the brain. But other neurons near the site of the injury will, over time, adapt to affect the pain signal. Cells in the spinal cord can also modulate the pain signal that is sent to the brain, making it stronger or weaker. The brain, in turn,

129. See Brain Facts, *supra* note 6, at 19–21, 49–50, which includes a useful brief description of the neuroscience of pain.

sends signals down to the spinal cord that cause, or at least affect, these modulations. And the actual sensation of pain—the “ouch”—takes place in the brain.

The immediate and localized sensation is processed in the somatosensory cortex, the brain region that takes sensory inputs from different body parts (with each body part getting its own portion of the somatosensory cortex) and processes them into a perceived sensation. The added knowledge that the sensation is painful seems to require the participation of other regions of the brain. Using fMRI and other techniques, some researchers have identified what they call the “pain matrix” in the brain, regions that are activated when experimental participants, in scanners, are exposed to painful stimuli. The brain regions identified as part of the so-called pain matrix vary from researcher to researcher, but generally include the thalamus, the insula, parts of the anterior cingulate cortex, and parts of the cerebellum.¹³⁰

Researchers have run experiments with participants in the scanner receiving painful or nonpainful stimuli and have attempted to find activation patterns that appear when pain is perceived and that do not appear when pain is absent. (The participants usually are given nonharmful painful stimuli such as having their skin touched with a hot metal rod or coated with a pepper-derived substance that causes a burning sensation.) Some have reported substantial success, detecting pain in more than 80% of the cases.¹³¹ Other studies have found a positive correlation between the degree of activation in the pain matrix and the degree of subjective pain, both as reported by the participants and as possibly indicated by the heat of the rod or the amount of the painful substance—the higher the temperature or the concentration of the painful substance, the greater the average activation in the pain matrix.¹³²

Other neuroscience studies of individual pain look not at brain function during painful episodes but at brain structure. Some researchers, for example, claim that different regions of the brain have different average size and neuron densities in patients who have had long-term chronic pain than in those who have not had such pain.¹³³

130. A good recent review of this work can be found in Maite M. van der Miesen, Martin A. Lindquist & Tor D. Wager, *Neuroimaging-based Biomarkers for Pain: State of the Field and Current Directions*, 4 PAIN Reps. e751 (2019), <https://doi.org/10.1097/PR.0000000000000751>.

Davis, *Recent Advances and Future Prospects in Neuroimaging of Acute and Chronic Pain*, 1 Future Neurology 203 (2006), <https://doi.org/10.2217/14796708.1.2.203>.

Pain is clearly complicated. Placebos, distractions, or great need can sometimes cause people not to sense, or perhaps not to notice, pain that could otherwise be overwhelming. Similarly, some people can become hypersensitive to pain, reporting severe pain when the stimulus normally would be benign. Amputees with phantom pain—the feeling of pain in a limb that has been gone for years—have been scanned while reporting this phantom pain. They show activation in the pain matrix. In some fMRI studies, people who have been hypnotized to feel pain, even when there is no painful stimulus, show activation in the pain matrix.¹³⁴ And in one fMRI study, participants who reported feeling emotional distress, as a result of apparently being excluded from a “game” being played among research participants, also showed, on average, statistically significant activation of the pain matrix.¹³⁵

Pain also plays an enormous role in the legal system.¹³⁶ The existence and extent of pain is a matter for trial in hundreds of thousands of injury cases each year. Perhaps more importantly, pain figures into uncounted workers’ compensation claims and Social Security disability claims. Pain is often difficult to prove, and the uncertainty of a jury’s response to claimed pain probably keeps much litigation alive. We know that the tests for pain currently presented to jurors, judges, and other legal decision-makers are not perfect. Anecdotes and the assessments of pain experts both are convincing that some nontrivial percentage of successful claimants are malingering and only pretending to feel pain; a much greater percentage may be exaggerating their pain.

A good test for whether a person is feeling pain, and, even better, a “scientific” way to measure the amount of that pain—at least compared to other pains felt by that individual, if not to pain as perceived by third parties—could help resolve a huge number of claims each year. If such pain detection were reliable, it would make justice both more accurate and more certain, leading to faster and cheaper resolution of many claims involving pain. The legal system, as well as the honest plaintiffs and defendants within it, would benefit.

Pustilnik, *Status and Surveillance in the Use of Brain-Based Pain Imaging in the Law*, in 1 *Developments in Neuroethics & Bioethics: Pain Neuroethics and Bioethics* 59, 61 (Daniel Z. Buchman & Karen D. Davis eds., 2018), <https://doi.org/10.1016/bs.dnb.2018.08.004>; Davis et al., *supra* note 72; Henry T. Greely, *Neuroscience, Mindreading, and the Courts: The Example of Pain*, 18 *J. Health Care L. & Pol’y* 171 (2015), <https://perma.cc/6KXM-PQQB>. The earliest, but still useful, discussion is found in Adam J. Kolber, *Pain Detection and the Privacy of Subjective Experience*, 33 *Am. J.L. & Med.* 433 (2007), <https://doi.org/10.1177/009885880703300212>. Kolber expands on that discussion in interesting ways in Adam J. Kolber, *The Experiential Future of the Law*, 60 *Emory L.J.* 585, 596–601 (2010), <https://perma.cc/P9QQ-AYWE>.

A greater understanding of pain also might lead to broader changes in the legal system. For example, emotional distress often is treated less favorably than direct physical pain. If neuroscience were to show that, in the brain, emotional distress seemed to be the same as physical pain, the law might change. Perhaps that would be more likely if neuroscience could provide assurance that sincere emotional pain could be detected and faked emotional distress would not be rewarded, the law again might change. Others have argued that even our system of criminal punishment might change if we could measure, more accurately, how much pain different punishments caused defendants, allowing judges to let the punishment fit the criminal, if not the crime.¹³⁷ A “pain detector” might even change the practice of medicine in legally relevant ways, by giving physicians a more certain way to check whether their patients are seeking controlled substances to relieve their own pain or are seeking them to abuse or to sell for someone else to abuse.

In at least one case, a researcher who studies the neuroscience of pain was retained as an expert witness to testify regarding whether neuroimaging could provide evidence that a claimant was, in fact, feeling pain. The case settled before the hearing.¹³⁸ In another case, a prominent neuroscientist was approached about being a witness against the admissibility of fMRI-based evidence of pain, but, before she had decided whether to take part, the party seeking to introduce the evidence changed its mind. This issue has not, as of the time of this writing, reached the courts yet, but lawyers clearly are thinking about these uses of neuroscience. (And note that in some administrative contexts, the evidentiary rules will not apply in their full rigor, possibly making the admission of such evidence more likely.)

Do either functional or structural methods of detecting pain work and, if so, how well? We do not know. These studies share many of the problems outlined above in the section titled “Issues in Interpreting Study Results.” The studies are few in number, with few participants (and usually sets of participants that are not very diverse). The experiments—usually involving giving college students a painful stimulus—are different from the experience of, for example, older people who claim to have lower back pain. Independent replication is rare, if it exists at all. The experiments almost always report that, on average, the group shows a statistically significant pattern of activation that differs depending on whether they are receiving the painful stimulus, but the group average does not in itself tell us about the sensitivity or specificity of such a test when applied to individuals. And the statistical and technical issues are daunting.

137. Adam J. Kolber, *How to Improve Empirical Desert*, 75 Brook. L. Rev. 433 (2009), <https://perma.cc/X56D-V8UR>.

138. Greg Miller, *Brain Scans of Pain Raise Questions for the Law*, 323 Sci. 195 (2009), <https://doi.org/10.1126/science.323.5911.195>.

In the area of pain, the issue of countermeasures may be the most interesting, particularly in light of the experiments conducted with hypnotized participants. Does remembered pain look the same in an fMRI scan as currently experienced pain? Does the detailed memory of kidney stone pain look any different from the present sensation of lower back pain? Can individuals effectively convince themselves that they are feeling pain and so appear to the scanner to be experiencing pain? The answer to these questions is clear: We do not yet know.

Pain detection also would raise legal questions. Could a plaintiff be forced to undergo a “pain scan”? If a plaintiff offered a pain scan in evidence, could the defendant compel the plaintiff to undergo such a scan with the defendant’s machine and expert? Would it matter if the scan were itself painful or even dangerous? Who would pay for these scans and for the experts to interpret them?

Detecting pain would be a form of neuroscience evidence with straightforward and far-reaching applications to the legal system. Whether it can be done, and, if so, how accurately, remain to be seen. So does the legal system’s reaction to this possibility.

Addiction

In addition to these three areas, we want to note another topic of great legal interest where neuroscience evidence may eventually play a major role: addiction. We are not giving it substantial discussion, because the research seems further from the courtroom at this point than with the other topics, but the extent of criminal cases involving addiction, in both federal and state courts, suggests its possible value.

In 1997, Alan Leshner, then director of the National Institute on Drug Abuse, published an influential article in *Science* titled “Addiction Is a Brain Disease, and It Matters.”¹³⁹ He argued that addiction is “a chronic, relapsing brain disorder,” and, therefore, a successful treatment would manage the illness but not be a “cure.” And he drew conclusions about both the criminal justice system (there should be less incarceration, more treatment) and society as a whole. “If the brain is the core of the problem, attending to the brain needs to be a core part of the solution.”¹⁴⁰

This vision of addiction as a brain disease is now over twenty-five years old and remains controversial.¹⁴¹ Not surprisingly, neuroscience research has probed

139. Alan I. Leshner, *Addiction Is a Brain Disease, and It Matters*, *Sci.*, Oct. 3, 1997, at 45, <https://doi.org/10.1126/science.278.5335.45>.

140. *Id.*

141. See, e.g., Neil Levy, *Addiction Is Not a Brain Disease (and It Matters)*, 4 *Frontiers Psychiatry* 24 (2013), <https://doi.org/10.3389/fpsy.2013.00024>; Markus Heilig et al., *Addiction as a Brain Disease Revised: Why It Still Matters, and the Need for Consilience*, 46 *Neuropsychopharmacology* 1715

many issues of addiction extensively, and much has been learned about pathways associated with addictive behavior, whether regarding illegal drugs, alcohol, or nicotine.¹⁴² Neuroscience has made progress in understanding how the brain acts during the three stages of addiction: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation. It has highlighted the important role of the neurotransmitter dopamine in many aspects of addiction. It has not, however, produced useful answers to predicting, preventing, or treating addiction, or to distinguishing between addiction and other kinds of uses of addictive substances. As is true with much of brain science, currently neuroscience can mainly tell us that “it is very complicated.”

That should change with increasing research, and, when it does, courts may be affected in at least two ways: “wholesale” and “retail.” The wholesale changes may be legal or policy shifts in dealing with addiction and addictive drugs, whether driven by legislatures, agencies, or the courts, similar to the changes in the constitutionality of punishment for some crimes committed by juveniles.

The U.S. Supreme Court long ago addressed some of the issues around addiction in two cases asking whether the Eighth Amendment’s prohibition on cruel and unusual punishment was violated by convictions for narcotics addiction (*Robinson v. California*, 370 U.S. 660 (1962)) or for being drunk in a public place (*Powell v. Texas*, 392 U.S. 514 (1968)). A 6–2 majority answered “yes” in *Robinson*; six years later, five justices answered “no” in *Powell*, although without being able to muster a majority opinion. As to crimes of addiction, *Robinson* has largely become a dead letter, but new neuroscience evidence might revive that doctrine.

For most judges, the issues of applying addiction neuroscience in cases will more likely be at the “retail” level. Strong neuroscience evidence that could distinguish “addiction” from lesser attachments might prove relevant in some cases, as could powerful evidence of a significant predisposition to addiction. New, well-proven treatments for addiction to various substances could spur changes in sentencing, parole, or probation conditions. Effective methods to block the effects of addictive substances, such as anti-drug vaccines that have been studied, might also affect individual cases. At this stage, these applications of

(2021), <https://doi.org/10.1038/s41386-020-00950-y>; John Davies, *Addiction Is Not a Brain Disease*, 26 *Addiction Res. & Theory* 1 (2017), <https://doi.org/10.1080/16066359.2017.1321741>.

142. See, e.g., George R. Uhl, George F. Koob & Jennifer Cable, *The Neurobiology of Addiction*, 1451 *Ann. N.Y. Acad. Scis.* 5 (2019), <https://doi.org/10.1111/nyas.13989>; Nora D. Volkow, Michael Michaelides & Ruben Baler, *The Neuroscience of Drug Reward and Addiction*, 99 *Physiological Rev.* 2115 (2019), <https://doi.org/10.1152/physrev.00014.2018>; Nora D. Volkow & Maureen Boyle, *Neuroscience of Addiction: Relevance to Prevention and Treatment*, 175 *Am. J. Psychiatry* 729 (2018), <https://doi.org/10.1176/appi.ajp.2018.17101174>. Koob has been director of the NIH’s National Institute on Alcohol Abuse and Alcoholism since 2014; Volkow (irrelevantly but interestingly a great-granddaughter of Leon Trotsky) has directed the NIH’s National Institute on Drug Abuse since 2003.

addiction neuroscience remain speculative; that might change before this manual reaches its fifth edition.

Conclusion

Atomic physicist Niels Bohr is often credited with having said, “It is always hard to predict things, especially the future.”¹⁴³ It seems highly likely that the massively increased understanding of the human brain that neuroscience is providing will have significant effects on the law and, more specifically, on the courts. Just what those effects will be cannot be accurately predicted, but we hope that this reference guide will provide some useful background to help judges cope with whatever neuroscience evidence comes their way.

143. This quotation has been attributed to many people, including Yogi Berra, but Bohr seems to be the most common nominee. Recently, one of us tracked down evidence that it actually was coined in the 1940s or perhaps 1930s by a Danish cartoonist, author, and inventor named Robert Storm Petersen. See *Robert Storm Petersen*, Wikipedia, <https://perma.cc/FR98-A6WA>. For a few more details, see Henry T. Greely, *The Death of Roe and the Future of Ex Vivo Embryos*, 9 J.L. & Biosciences 1, 2 & n.3 (2022), <https://doi.org/10.1093/jlb/lzac019>.

Glossary of Terms

axon. Portion of a neuron cell that transmits messages in the form of electrical impulses to dendrites of other neurons.

BOLD response (the blood-oxygen-level-dependent response). A measure used in functional MRI (fMRI) to allow an indirect measure of brain activity by examining how such activity affects blood flow.

brain stem. One of three major parts of the brain, joining the brain to the spinal cord and regulating autonomic functions such as heart rate and digestion, and, to an extent, the neural processing of the cerebellum.

central nervous system. The brain, the spinal cord, and other nerves directly connecting to the brain.

cerebellum. A brain structure at the top of the brain stem that keeps a library of learned motor skills.

cerebrum. Largest area of the brain (composed of two hemispheres) that controls cognitive functions.

computerized axial tomography (CAT scans). A multidimensional, computer-assisted X-ray machine that reveals the structural image of the brain in three dimensions.

corpus callosum. Axions that connect the two hemispheres of the brain.

cortex (cerebral cortex). Folded surface of the cerebrum that consists of gray matter and includes subcortical structures such as the thalamus, the hypothalamus, the basal ganglia, and the amygdala.

cortisol. A hormone produced by the adrenal glands that is released in response to stress.

deep brain stimulation (DBS). An electrical lead is implanted into a specific region of the brain and an electrical pulse is generated that affects the functioning of neurons in the nearby area.

dendrite. Portion of a neuron cell that receives messages from other neurons and relays them to the cell's nucleus.

diffusion tensor imaging (DTI). A technique that examines the way water diffuses through brain tissue to indicate the location of white matter.

electroencephalography (EEG). A technique that uses electrodes placed on the head to measure neural activity near the scalp.

endorphins. Hormones secreted by the pituitary gland in the brain that are associated with pain relief and a sense of well-being.

frontal lobe. Portion of the cerebrum near the forehead, associated with higher cognitive processes such as decision-making, reasoning, and planning.

functional near-infrared spectroscopy (fNIRS). A technique that detects changes in hemoglobin within the brain by measuring differences in the absorption of light that occurs through blood flow to different regions of the brain.

glial cells. Cells of the brain responsible for producing and maintaining the myelin sheaths that insulate axons and serve as a special immune system for the brain.

hippocampus. Area of the brain that is essential for making most kinds of memories and learning.

hypothalamus. A small structure at the base of the brain that regulates body temperature, hunger, thirst, and fatigue.

magnetic resonance imaging (MRI). The dominant neuroimaging technology, which uses a strong magnetic field to produce detailed images of the brain's structure and function.

myelin. Fatty substance encasing longer axons that helps insulate the axon and increases the strength and efficiency of the electrical signal.

neuron. Cells of the nervous system that transmit and receive nerve impulses from one such cell to another in a complex way that is responsible for brain function.

neurotransmitters. Chemical molecules that are released from the neuron into the synaptic cleft when a nerve impulse reaches the end of an axon. Some of the best-known neurotransmitters are dopamine, serotonin, glutamate, and acetylcholine.

nucleus accumbens. A small subcortical region in each hemisphere of the cerebrum that releases dopamine in response to rewarding experiences.

occipital lobe. Portion of the cerebrum at the back of the skull primarily concerned with vision.

olfactory bulb. Area of the brain that makes new neurons and plays a huge role in our senses of smell and taste.

oxytocin. A hormone that works as a neurotransmitter and has been linked with trust and bonding.

parietal lobe. Portion of the cerebrum at the top and toward the back of the skull that is concerned with reception and processing of sensory information from the body.

peripheral nervous system. Neural cells that are not part of the central nervous system.

positron emission tomography (PET scans). A brain imaging technique based on a radioactive tracer substance that measures the density of neural receptors.

single photon emission computed tomography (SPECT scans). A technique like PET scans using a different form of radioactive tracer.

substantia nigra. Area of the brain stem that generates the neurotransmitter dopamine as part of the brain's reward system.

synaptic cleft. The small space between two neurons where neurotransmitters are released.

temporal lobe. Portion at the sides of the cerebrum involved in hearing, language, memory storage, and emotion.

tesla (T). Measure of the strength of the magnetic field of an MRI scanner.

thalamus. A brain structure at the top of the brain stem that carries information to and from the cerebrum and other brain structures. This structure is especially important for transmission of sensory information such as vision, hearing, touch, and proprioception (one's sense of the position of the parts of one's body).

transcranial magnetic stimulation (TMS). A technique that generates a magnetic field near the skull that disrupts neural activity and alters brain function in a nearby region.

Overview of Mental Health Evidence

Range of Legal Cases in Which Mental Health Issues Arise

Evidence presented by mental health experts is common to a broad array of legal cases—criminal and civil.¹ In the criminal realm, these include assessments of defendants' mental states at the time of their alleged offenses (e.g., criminal responsibility, diminished capacity²) and subsequent to the offenses, but prior to the initiation of the adjudicatory process (e.g., competence to consent to a search, capacity to waive *Miranda* rights³).⁴ As cases move toward adjudication, defendants' competence to stand trial or to represent themselves at trial may need to be evaluated.⁵ Postconviction, mental health evidence may be introduced for sentencing, including suitability for probation and conditions of probation.⁶

1. See Eric Y. Drogin et al., *Handbook of Forensic Assessment: Psychological and Psychiatric Perspectives* (2011) (discussing role of mental health evidence in range of criminal and civil cases); Gary B. Melton et al., *Psychological Evaluations for the Courts: A Handbook for Mental Health Professionals and Lawyers* (4th ed. 2018) (discussing range of criminal and civil cases in which mental health evidence may be informative); Christopher Slobogin, Thomas L. Hafemeister & Douglas Mossman, *Law and the Mental Health System: Civil and Criminal Aspects* (7th ed. 2020) (discussing use of mental health evidence in criminal and civil contexts). This reference guide will focus on adult defendants and litigants and will not discuss matters pertaining to the evaluation of juveniles. For a review of relevant case law in this area, see Melton et al., *supra*. See also Kirk Heilbrun et al., *Evaluating Juvenile Transfer and Disposition: Law, Science, and Practice* (2017).

2. 18 U.S.C. § 17 (defining standard and burden of proof for insanity defense); *Clark v. Arizona*, 548 U.S. 735 (2006) (ruling on the use of testimony for diminished capacity).

3. See Thomas Grisso, *Evaluating Competencies: Forensic Assessments and Instruments* (2d ed. 2003); *Colorado v. Connelly*, 479 U.S. 157 (1986) (holding that a mental health condition alone will not make a confession involuntary under the Fourth Amendment, but may be used as a factor in assessing voluntariness of defendant's confession); *Miranda v. Arizona*, 384 U.S. 436 (1966) (holding confessions inadmissible unless suspect is made aware of rights and waives them); *United States v. Elrod*, 441 F.2d 353 (5th Cir. 1971) (holding that a person of below-average intelligence may be deemed incapable of giving consent). See also Wayne R. LaFare, *Search and Seizure: A Treatise on the Fourth Amendment* 92–93 (2004); Wayne R. LaFare, Jerold H. Israel & Nancy J. King, *Criminal Procedure* 363–65 (4th ed. 2004); Brian S. Love, *Beyond Police Conduct: Analyzing Voluntary Consent to Warrantless Searches by the Mentally Ill and Disabled*, 48 St. Louis U.L.J. 1469 (2004).

4. See generally Stephen J. Morse, *Mental Disorder and Criminal Law*, 101 J. Crim. L. & Criminology 885 (2011) (discussing use of mental health evidence in criminal-law contexts).

5. *Indiana v. Edwards*, 554 U.S. 164 (2008) (finding that the standards for competency to stand trial and to represent oneself need not be the same); *Farretta v. California*, 422 U.S. 806 (1975) (upholding defendant's right to refuse counsel and represent himself); *Pate v. Robinson*, 383 U.S. 375 (1966) (holding that the Due Process Clause of the Fourteenth Amendment does not allow a mentally incompetent criminal defendant to stand trial); *Dusky v. United States*, 362 U.S. 402 (1960) (establishing standard for competence to stand trial).

6. Roger W. Haines Jr., Frank O. Bowman & Jennifer C. Woll, *Federal Sentencing Guidelines Handbook: Text and Analysis* §§ 5B1.3(d)(5), 5D1.3(d)(5), 5H1.3 (2007–2008).

Capital cases may raise unique questions regarding a condemned prisoner's competence to waive appeals or to be executed.⁷ Postconfinement, mental health considerations may enter into parole determinations.

Mental health evidence in civil litigation is frequently introduced in personal-injury cases, where emotional harms may be alleged with or without concomitant physical injury.⁸ Issues of contract may turn on the competence of a party at the time that the contract was concluded or whether that person was subject to undue influence,⁹ and similar questions may be at the heart of litigation over wills and gifts.¹⁰ Broader questions of competence to conduct one's affairs are considered in guardianship cases,¹¹ and more esoteric ones may arise in litigation challenging a person's competence to enter into a marriage or to vote.¹²

7. See *Panetti v. Quarterman*, 551 U.S. 930 (2007) (holding that defendants sentenced to death must be competent at the time of execution); *Atkins v. Virginia*, 536 U.S. 304 (2002) (finding that executing intellectually disabled defendants constitutes cruel and unusual punishment under the Eighth Amendment); *Stewart v. Martinez-Villareal*, 523 U.S. 637 (1998) (holding that death row prisoners are not barred from filing incompetence-to-be-executed claims by dismissal of previous federal habeas petitions); *Ford v. Wainwright*, 477 U.S. 399 (1986) (upholding the common-law bar against executing incompetent inmates and holding that an inmate is entitled to a judicial hearing before being executed); *Rees v. Peyton*, 384 U.S. 312 (1966) (formulating the test for competency to waive further proceedings as requiring that the petitioner "appreciate his position and make a rational choice with respect to continuing or abandoning further litigation or on the other hand whether he is suffering from a mental disease, disorder, or defect which may substantially affect his capacity in the premises"). See also David DeMatteo et al., *Forensic Mental Health Assessments in Death Penalty Cases* (2011) (discussing role of mental health evidence in all phases of capital cases).

8. *Sheely v. MRI Radiology Network, P.A.*, 505 F.3d 1173 (11th Cir. 2007) (holding that damages are available under § 504 of the Rehabilitation Act when emotional distress was foreseeable); *Cooper v. FAA*, No. 07-1383 (N.D. Cal. Aug. 2008), *rev'd and remanded*, 596 F.3d 538 (9th Cir. 2010) (discussing mental distress as a result of disclosure of personal information); *Albright v. United States*, 732 F.2d 181 (C.A.D.C. 1984) (holding that alleging mental distress is sufficient to confer standing); *Molien v. Kaiser Found. Hosps.*, 616 P.2d 813 (Cal. 1980) (holding that plaintiff who is direct victim of negligent act need not be present when act occurs to recover for subsequent emotional distress); *Dillon v. Legg*, 441 P.2d 912 (Cal. 1968) (allowing recovery based on emotional distress not accompanied by physical injury); *Roes v. FHP, Inc.*, 985 P.2d 661 (Haw. 1999) (allowing assessment of damages for negligent infliction of emotional distress when plaintiff was in actual physical peril, even if no injury was suffered); *Rodriguez v. State*, 472 P.2d 509 (Haw. 1970) (permitting recovery where a reasonable person would suffer serious mental distress as a result of defendant's behavior).

9. See generally E. Allan Farnsworth, *Contracts* 228-33 (2004); John Parry & Eric Y. Drogin, *Mental Disability Law, Evidence, and Testimony* 151-52, 185-86 (2007).

10. See generally William M. McGovern Jr. & Sheldon F. Kurtz, *Wills, Trusts and Estates Including Taxation and Future Interests* 292-99 (6th ed. 2021); Parry & Drogin, *supra* note 9, at 149-51, 182-85.

11. Parry & Drogin, *supra* note 9, at 138-47, 177-81.

12. *Id.* at 54. See *Missouri Prot. & Advoc. Servs. v. Carnahan*, 499 F.3d 803 (8th Cir. 2007) (upholding a state law allowing disenfranchisement of persons under guardianship because it permits individualized determinations of capacity to vote); *Doe v. Rowe*, 156 F. Supp. 2d 35

Suits alleging infringement of the statutory and constitutional rights of persons with mental disorders (e.g., under the Americans with Disabilities Act (ADA) or the Civil Rights of Institutionalized Persons Act) often involve detailed consideration of psychiatric diagnosis and treatment and of institutional conditions.¹³ Allegations of professional malpractice by mental health professionals, including failure to protect foreseeable victims of a patient's violence,¹⁴ invariably call for mental health expert testimony, as do commitment proceedings for the hospitalization of persons with mental disorders¹⁵ or who are alleged to be dangerous sex offenders.¹⁶

Retrospective, Contemporaneous, and Prospective Assessments

Retrospective assessments are called for when criminal defendants assert insanity or diminished-capacity defenses, claiming that their state of mind at the time of

(D. Me. 2001) (finding a state law denying the vote to anyone under guardianship by reason of mental disability in violation of the Equal Protection Clause of the U.S. Constitution and Title II of the Americans with Disabilities Act (ADA)).

13. *Pennsylvania Dep't of Corr. v. Yeskey*, 524 U.S. 206 (1998) (holding that ADA coverage extended to prisoners); *McAlinden v. Cnty. of San Diego*, 192 F.3d 1226 (9th Cir. 1999), *cert. denied*, 120 S. Ct. 2689 (2000) (reversing summary judgment against plaintiff who alleged that anxiety and somatoform disorders impaired major life activities of sexual relations and sleep); *Gates v. Cook*, 376 F.3d 323 (5th Cir. 2004) (upholding district court's finding that prison conditions, including inadequate mental health provisions, violated the Eighth Amendment of the U.S. Constitution); *Steele v. Thiokol Corp.*, 241 F.3d 1248 (10th Cir. 2001) (finding that major life activity under the ADA, involving interacting with others, not substantially impaired by obsessive-compulsive disorder); *Anderson v. North Dakota State Hosp.*, 232 F.3d 634 (8th Cir. 2000) (finding that a plaintiff's fear of snakes did not limit ability to work); *Sinkler v. Midwest Prop. Mgmt.*, 209 F.3d 678 (7th Cir. 2000) (holding driving phobia did not substantially limit major life activity of working and hence was not an impairment under the ADA); *Clark v. State of Cal.*, 123 F.3d 1267 (9th Cir. 1997) (finding state not immune on Eleventh Amendment grounds to suit alleging discrimination under ADA by developmentally disabled inmates); *Gaul v. AT&T, Inc.*, 955 F. Supp. 346 (D.N.J. 1997) (finding that depression and anxiety disorders may constitute a mental disability under the ADA).

14. *Tarasoff v. Regents of the Univ. of Cal.*, 551 P.2d 334 (Cal. 1976).

15. *Addington v. Texas*, 441 U.S. 418 (1979) (holding that standard of proof for involuntary commitment is clear and convincing evidence); *O'Connor v. Donaldson*, 422 U.S. 563 (1975) (holding unconstitutional the confinement of a nondangerous mentally ill person capable of surviving safely in freedom alone or with assistance); *Lake v. Cameron*, 364 F.2d 657 (D.C. Cir. 1966) (discussing least restrictive alternative doctrine as applied to institutionalized individuals).

16. *United States v. Comstock*, 560 U.S. 126 (2010); *Kansas v. Crane*, 534 U.S. 407 (2002); *Kansas v. Hendricks*, 521 U.S. 346 (1997). See David DeMatteo et al., *A National Survey of United States Sexually Violent Predator Legislation: Policy, Procedures, and Practice*, 14 Int'l J. Forensic Mental Health 245 (2015), <https://doi.org/10.1080/14999013.2015.1110847> (discussing sexually violent predator legislation in all U.S. jurisdictions).

the crime should excuse or mitigate the consequences of their behaviors,¹⁷ or when questions are raised about competence at some point in the past to waive legal rights (e.g., waiver of *Miranda* rights).¹⁸ In civil contexts, challenges to the capacity of a now-deceased testator to write a will or of a party to enter into a contract, among other issues, will call for a similar look back at a person's functioning at some point in the past.¹⁹ A variety of sources of information are available for such assessments. In some cases (e.g., in criminal proceedings) the defendant is likely to be available for clinical examination, whereas in other cases the defendant will not be able to be assessed directly (e.g., challenges to a will). Although persons being evaluated will usually have an interest in portraying themselves in a particular light, direct assessments can still be valuable in determining the consistency of the reported symptoms with other aspects of a person's history and current status.²⁰ Whether or not a person can be assessed directly, information, including direct reports and contemporaneous records, from those who were in contact with the person before and during the time in question is usually an essential part of the evaluation. Sometimes the available data from all of these sources are so limited or contradictory that they will not allow an evaluator to reach an opinion on a person's state of mind at a point in the past. However, when evaluators are thorough, seeking information from multiple sources in relevant areas, they are usually able to provide the decision-maker with useful information.

Current-state evaluations are the most straightforward task for a mental health professional. In criminal-justice settings, concerns about a person's current competence to exercise or waive rights will call for such evaluations (e.g., competence to stand trial or competence to represent oneself at trial).²¹ Civil

Moran*, 509 U.S. 389 (1993) (holding that a defendant competent to stand trial is also sufficiently competent to plead guilty or waive the right to legal counsel).

issues calling for contemporaneous assessments include workers' compensation and other disability claims and litigation alleging emotional harms due to negligent or intentional torts, workplace discrimination, and other harm-inducing situations.²² Careful consideration needs to be given to the possibility that persons being assessed in these circumstances could deliberately exaggerate or minimize the severity of their experienced symptoms to secure a more favorable outcome in their case.²³

The evaluation of a person's future mental state and consequent behaviors, by contrast, is particularly difficult, especially when the outcome being predicted is relatively infrequent.²⁴ In criminal proceedings, predictive assessments like this may come into play when bail is set,²⁵ at sentencing,²⁶ or as part of probation and parole decisions.²⁷ Predictive assessments often involve estimating the probable effectiveness of treatment—especially in the juvenile justice system, where a key consideration in decisions whether to transfer a juvenile to adult courts is often whether the juvenile is amenable to mental health treatment.²⁸ Predictions of behavior related to mental health disorders are also seen in civil cases, for example, in the civil commitments of persons with mental disorders and in statutes authorizing the commitment of dangerous sex offenders.²⁹ Damage assessments in civil cases that allege emotional harms will usually call for some estimate on the duration of symptoms and response to treatment.³⁰ The

29. See *O'Connor v. Donaldson*, 422 U.S. 563 (1975) (finding that a state may not confine a citizen who is nondangerous and capable of living by herself or with aid). For an example of a sex-offender civil-commitment statute, see Minn. Stat. § 253B.185 (2008). The constitutionality of civil commitment for dangerous sex offenders was upheld in *Kansas v. Hendricks*, 521 U.S. 346 (1997) (setting forth the procedures for the commitment of convicted sex offenders deemed dangerous because of a mental abnormality).

30. See Melton et al., *supra* note 1.

uncertainties of the course of mental disorders and their responsiveness to interventions are relevant—but so are the unknowable contingencies of life (e.g., what occurs with family, job, and friends). At best, predictive assessments can provide general statements of the probability of particular outcomes, with an acknowledgment of the uncertainties involved.³¹

Diagnosis vs. Functional Impairment

A diagnosis of mental disorder per se will almost never settle the legal question in a case in which mental health evidence is presented. However, a diagnosis may play a role in determining whether a claim or proceeding can go forward. With the insanity defense, for example, the impairments of understanding, appreciation, and behavioral control that constitute the various legal standards must be based, in one popular formulation, on a “mental disease or defect.”³² In the absence of a diagnosis of mental disorder (including intellectual disability or consequences of injury to the brain), an affirmative defense of insanity will not prevail.³³ Comparable situations exist in civil commitment proceedings and work-disability determinations.³⁴

Notwithstanding the threshold role played by a mental disorder diagnosis in many cases, the ultimate legal issue usually will turn on the impact of the mental disorder on the person’s functional abilities.³⁵ Those abilities may refer to the person’s cognitive capacities, including capacities to make legally relevant decisions, or *decisional capacities* (e.g., granting consent for the police to conduct a warrantless search, altering a will), or *performative capacities*, that is, the capacity to behave in a particular way (e.g., conforming one’s conduct to the requirements of the law, cooperating with an attorney in one’s own defense, resisting undue influence), or both (e.g., skill as a parent, competence to proceed with criminal

31. For a more detailed discussion of predictive assessment regarding future dangerousness, see section titled “Prediction of Violence” below.

32. The American Law Institute’s standard for the insanity defense reads, “A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirements of the law.” Model Penal Code and Commentaries § 4.01(1) (Official Draft and Revised Comments 1985) (adopted by American Law Institute, May 24, 1962). The federal insanity defense was codified in the Insanity Defense Reform Act of 1984, 18 U.S.C. § 17. See also *Durham v. United States*, 214 F.2d 862 (D.C. Cir. 1954) (“[A]n accused is not criminally responsible if his unlawful act was the product of mental disease or defect.”); note *United States v. Brawner*, 471 F.2d 969 (1972) (which overturned the *Durham* Rule or “product test”).

35. Grisso, *supra* note 3.

adjudication). Many of the legal questions related to mental health evidence will involve a determination of the influence of a mental state or disorder on one or both of these sets of capacities. The mere presence of a mental disorder will almost always be insufficient for that purpose. Mental disorder in a criminal defendant, for example, if it does not interfere substantially with competence to stand trial, does not present a basis for postponing adjudication of the case.³⁶ Some degree of mental disorder, including neurocognitive impairment, without affecting relevant abilities, does not provide grounds for voiding a will.³⁷ This can be generalized to all criminal and civil competency determinations, most assessments of emotional harms, and probably to the majority of cases in which mental health testimony is offered: Unless a mental disorder can be shown to have affected a person's functional decisional or performative capacity, a diagnosis of mental disorder per se will not be determinative of the outcome.³⁸

Despite its importance to the adjudicative process, mental health evidence is often introduced in the context of a serious stigma that attaches to mental disorders³⁹ and considerable popular confusion regarding their nature, consequences, and susceptibility to treatment.⁴⁰ Diagnoses of mental disorders often are perceived to be less reliable and more subjective than diagnoses of other medical conditions.⁴¹ Symptoms of mental disorders may be seen as reflections of moral weakness or lack of will, and the impact of disorders on functional abilities may not be recognized or may occasionally be exaggerated.⁴² The potential impact and limits of current treatments are not widely understood. Even the various types of mental health professionals are frequently confused.⁴³ The first section of this reference guide clarifies these issues; subsequently, we address questions

43. The degree of popular confusion is underscored by the results of a web-based search for "psychiatrist vs. psychologist," which turns up a remarkably large number of websites attempting to explain the differences between the two professions.

specifically related to the introduction of evidence by mental health experts and provide a case example.

Mental Health Experts

Evidence related to mental state and mental health disorders may be presented by experts from a number of disciplines, but it is most commonly introduced by psychiatrists or psychologists.

Psychiatrists

Psychiatrists are physicians who specialize in the diagnosis and treatment of mental disorders.⁴⁴ After college, they complete four years of medical school, during which they spend approximately two years in preclinical studies (e.g., physiology, pharmacology, genetics, pathophysiology), followed by two years of clinical rotations in hospital and clinic settings (e.g., medicine, surgery, pediatrics, obstetrics/gynecology, orthopedics, psychiatry).⁴⁵ Graduating medical students who elect to specialize in psychiatry enter residency programs of at least four years.⁴⁶ Accredited residencies must currently offer at least four months in a primary-care setting in internal medicine, family medicine, or pediatrics and at least two months of training in neurology.⁴⁷

After completing four years of residency training, a psychiatrist is considered board eligible, that is, able to take the certification examination of the American Board of Psychiatry and Neurology in adult psychiatry.⁴⁸ After successful completion of this examination process, the psychiatrist is designated board certified. Psychiatrists who desire more intensive training in a subspecialty area of psychiatry—for example, child and adolescent or addiction psychiatry—can complete a one- or two-year fellowship working in that subspecialty. A psychiatrist who has completed

44. Narriman C. Shahrokh & Robert E. Hales, *American Psychiatric Glossary* 157 (2003).

45. Medical schools in the United States are accredited by the Liaison Committee on Medical Education, which establishes general curricular and other standards that all schools must meet. Standards are available at <https://perma.cc/9KT4-LED7>. Students can elect to extend their medical-school training by taking additional time to conduct research or to obtain complementary training (e.g., in public health).

46. Residents who choose to combine adult- and child-psychiatry training can do so in a five-year program, or can follow their four years of adult residency with two years of child training. Some residents will also extend their residency training by adding a year or more during which they conduct laboratory or clinical research.

47. Psychiatric residencies are accredited by the Accreditation Council on Graduate Medical Education. Program requirements are available at <https://perma.cc/QX6X-ZP6H>.

48. Information on qualifications for board certification and the examination process is available from the American Board of Psychiatry and Neurology at <https://perma.cc/EN4Y-QFA6>.

an accredited fellowship⁴⁹ is eligible for additional board certification in that subspecialty.⁵⁰

Forensic psychiatry is a subspecialty that focuses on the interrelationships between psychiatry and the law.⁵¹ It is the forensic psychiatrist who is particularly likely to offer evidence as part of legal proceedings. Fellowship training in forensic psychiatry involves a one-year program in which fellows are taught forensic evaluation for civil and criminal litigation and become involved in the treatment of persons with mental disorders in the correctional system.⁵²

Psychologists

Psychologists receive graduate training in the study of mental health processes and behavior.⁵³ Only a subset of psychologists—those trained in applied specialty areas—evaluate and treat persons with psychological or behavioral problems, including clinical, counseling, health, neuro-, rehabilitation, and school psychologists. Independent practice in applied specialty areas of psychology requires licensure from the appropriate state licensure board and generally requires a doctoral degree and postgraduate clinical experience. Although use of the term *psychologist* is restricted in many jurisdictions to licensed psychologists,⁵⁴

49. Accredited subspecialty training is currently available in addiction, child and adolescent, consultation-liaison, forensic, and geriatric psychiatry. Psychiatrists are also eligible for training in brain-injury medicine, hospice and palliative medicine, pain medicine, and sleep medicine. See subspecialty certification standards at <https://perma.cc/UB3S-7TCH>. Fellowship programs also exist in some subspecialty areas for which accreditation and board certification are not available (e.g., research, psychopharmacology, and public and community psychiatry).

50. Typically, when new subspecialties are recognized and accreditation standards are developed, a certain period of time (e.g., five years) is allowed for psychiatrists who have gained expertise in that area by virtue of experience or alternative training to achieve board certification; many psychiatrists who are today board certified in a subspecialty have not completed a fellowship.

51. See the definition of forensic psychiatry offered by the American Academy of Psychiatry and the Law: “Forensic psychiatry is a medical subspecialty that includes research and clinical practice in the many areas in which psychiatry is applied to legal issues.” <https://perma.cc/VPP2-22JF>. Psychiatrists who have been certified in adult or child psychiatry by the American Board of Psychiatry and Neurology, and who have completed a forensic psychiatry fellowship, can take the examination for subspecialty certification in forensic psychiatry. A description of the requirements for certification can be found at <https://perma.cc/T74N-N5NF>. Board certification must be renewed by taking a recertification examination every ten years or participating in an alternative maintenance of certification program, see details at <https://perma.cc/K3LR-33XM>.

52. See the accreditation standards in forensic psychiatry at <https://perma.cc/DW8U-EX6B>.

53. The American Psychological Association defines the field of psychology in this way: “Psychology is the study of the mind and behavior. The discipline embraces all aspects of the human experience—from the functions of the brain to the actions of nations, from child development to care for the aged. In every conceivable setting from scientific research centers to mental health care services, ‘the understanding of behavior’ is the enterprise of psychologists.” <https://perma.cc/PFV3-MJHQ>.

54. See, e.g., Mass. Gen. Laws ch. 112, § 122; N.Y. Educ. Law § 7601.

the term may be applied to those in academia or to those with master's-level training in psychology in certain contexts.⁵⁵

Those pursuing doctoral-level training as psychologists must complete a graduate program that typically takes four to six years. Those who intend to provide clinical services generally receive training in clinical psychology, counseling psychology, neuropsychology, or school psychology,⁵⁶ involving three to five years of graduate study plus a year of clinical internship.⁵⁷ Psychology graduate programs award either the Ph.D. or Psy.D. (professional psychology) degree.⁵⁸ Ph.D. programs that adhere to the scientist-practitioner training model emphasize both research and clinical training, and students are required to gain clinical experience and complete a research-based dissertation. Psy.D. programs ordinarily focus on clinical training and have less rigorous research requirements.⁵⁹

Postdoctoral fellowships have been developed in forensic psychology, generally involving a one-year program with didactic and clinical training in forensic evaluation.⁶⁰ Board certification is offered by several entities, but the most established is the American Board of Professional Psychology (ABPP),⁶¹ which provides certification in fifteen specialty areas. The American Board of Forensic Psychology (ABFP), one of the ABPP's specialty boards, provides board certification in forensic psychology. Board certification in forensic psychology through

55. Note that the American Psychological Association urges that the term be restricted to persons with doctoral degrees in psychology: "Psychologists have a doctoral degree in psychology from an organized, sequential program in a regionally accredited university or professional school . . . it is [the] general pattern to refer to master's-level positions as counselors, specialists, clinicians, and so forth (rather than as 'psychologists')." <https://perma.cc/S38C-54YG>.

56. Other psychology programs offer training in experimental, social, and cognitive psychology, for example, with the intent of producing graduates who will pursue research or teaching careers but will not engage in clinical work. *United States v. Fishman*, 743 F. Supp. 713, 723 (N.D. Cal. 1990) (excluding the expert testimony of a social psychologist holding a Ph.D. in sociology).

57. Accreditation of programs in clinical, counseling, and school psychology is undertaken by the Commission on Accreditation of the American Psychological Association. Accreditation standards are available at <https://perma.cc/Q3YM-5U9Y>.

58. See sample Ph.D. program curricula for programs at University of Illinois at Urbana-Champaign, <https://perma.cc/MBL5-8TX9>; Indiana University, <https://perma.cc/82JY-66L3>; and University of California at Los Angeles, <https://perma.cc/MN2Q-KFPJ>. See sample Psy.D. curricula for programs at William James College, <https://perma.cc/6CQ7-FNHW>; and Wisconsin School of Professional Psychology, <https://perma.cc/LZ4F-6G5P>.

59. For a discussion of the so-called Vail model on which Psy.D. training is based, see John C. Norcross & Patricia H. Castle, *Appreciating the PsyD: The Facts*, 7 *Eye on Psi Chi* 22 (2002), <https://doi.org/10.24839/1092-0803.Eye7.1.22>.

60. See, e.g., Description of Program at University of Massachusetts Medical School, <https://perma.cc/YJD4-44Q4>.

61. See American Board of Professional Psychology website, <https://perma.cc/D2ES-YCRS>. ABPP is the oldest and best-established specialty certification organization for psychologists, with the most rigorous process for becoming board certified.

ABPP/ABFP is a rigorous process that includes a credential review documenting sufficient education, training, and experience; completion of a written examination; submission and review of forensic practice samples; and a three-hour oral examination.⁶²

Other Mental Health Professionals

Professionals with a variety of other types of training also provide mental health services, including services that are generally referred to as psychotherapy or counseling with individuals, couples, or groups. The best established of these professions is social work. Schools of social work offer two-year programs that lead to a master's degree (MSW), and students can elect a track that is often referred to as psychiatric social work, which involves instruction and experience in psychotherapy.⁶³ Graduate social workers can obtain state licensure after they complete a period of supervised practice and an examination, after which they become a licensed independent clinical social worker (LICSW), with variation in nomenclature across the states.⁶⁴ Social workers may offer psychotherapeutic or counseling services through social service agencies or in private practice. Recently, a subspecialty of forensic social work has begun to develop, involving social workers with experience in the criminal justice system.⁶⁵

Although psychiatrists and doctoral-level psychologists generally provide expert evidence related to mental health issues, courts will sometimes admit testimony from other mental health professionals.⁶⁶ Given that training and

62. The requirements for board certification in forensic psychology through ABPP/ABFP can be found at <https://perma.cc/PY8U-RBQD>.

63. See, e.g., curricula for social-work training at Columbia School of Social Work (<https://perma.cc/A5UP-NYQB>) and Smith College (<https://perma.cc/XGY2-N8UB>).

65. See the National Association of Forensic Social Work's description of forensic social work at <https://perma.cc/6ZDE-RL3H>. Postgraduate certification programs for forensic social workers are also being developed (e.g., University of Nevada at Las Vegas, <https://perma.cc/8Y2F-AMZX>).

66. *Leblanc v. Coastal Mech. Servs., LLC*, No. 04-80611-CIV, 2005 WL 5955027 (S.D. Fla. Sept. 7, 2005) (finding that a marriage and family counselor holding a Ph.D. in family therapy and bachelor's and master's degrees in psychology, and having a record of relevant publications, may be qualified to offer helpful testimony about a plaintiff's alleged psychological condition); *Jenkins v. United States*, 307 F.2d 637 (D.C. Cir. 1962) ("The critical factor in respect to admissibility is the actual experience of the witness and the probable probative value of his opinion. . . . The determination of a psychologist's competence to render an expert opinion based on his findings as to the presence or absence of mental disease or defect must depend upon the nature and extent of his knowledge. It does not depend upon his claim to the title 'psychologist.'"); *United States v. Azure*, 801 F.2d 336, 342 (8th Cir. 1986) ("The social worker was most likely qualified as an expert under Rule 702. . . ."); see also *United States v. Raya*, 45 M.J. 251 (1996) (finding that trial court's admission of expert testimony from a social worker on whether the victim suffered from post-traumatic

experience vary considerably, and titles may be used inconsistently, courts usually require an individualized inquiry into the qualifications of the proposed expert.

Differences Between Clinical and Forensic Contexts

The view of a psychologist or psychiatrist as a helping professional in a traditional clinical context can be contrasted with their roles in forensic contexts. Several of the key differences between clinical assessments and forensic assessments are described below.⁶⁷

Purpose

The primary distinction between traditional clinical assessments and forensic assessments is the different purposes of the evaluations. In a clinical context, the purpose of an assessment is to diagnose mental health problems and develop a treatment plan; the purpose of a forensic assessment is to assist a legal decision-maker in making a decision about a criminal offender or civil litigant. Ethical principles governing clinical practice emphasize benefiting the patient and avoiding harm, while the ethics of forensic evaluation center on a truthful

stress disorder (PTSD) was not an abuse of discretion) *and* United States v. Johnson, 35 M.J. 17 (1992) (holding social worker qualified to render opinion that child suffered trauma). Note, however, that not all courts have been receptive to social-worker testimony offered as expert opinion on the diagnosis of PTSD, e.g., *Blackshear v. Werner Enters., Inc.*, No. 2004-4—WOB, 2005 WL 6011291 (E.D. Ky. May 19, 2005); *Neely v. Miller Brewing Co.*, 246 F. Supp. 2d 866 (S.D. Ohio 2003). For more restrictive approaches to testimony by non-Ph.D. psychologists, *see also* *Parker v. Barnhart*, 67 F. App'x. 495 (9th Cir. 2003) (finding error in an administrative law judge's failure to call a licensed psychologist, rather than another expert, as an expert witness for appropriate testimony); *Earls v. Sexton*, No. 3:09cv950, 2010 U.S. Dist. LEXIS 52980 (M.D. Pa. May 28, 2010) (allowing a nurse practitioner to testify in a negligence action concerning whether a motor vehicle accident caused psychiatric injuries); *State v. Bricker*, 321 Md. 86 (Md. Ct. App. 1990) (rejecting expert testimony from a nonpracticing psychologist who did not hold a doctorate and did not qualify for a reciprocal license under state law); *People v. McDarragh*, 175 Ill. App. 3d 284, 291 (1988) (affirming the trial court's rejection as an expert witness of a doctoral candidate who did not have the experience level required for state registration as a psychologist); *but see* *United States v. Huber*, 603 F.2d 387, 399 (2d Cir. 1979) (affirming trial court's rejection of expert testimony on defendant's mental state from a professor of economics who was also a certified psychoanalyst).

67. *See* Kirk Heilbrun, *Principles of Forensic Mental Health Assessment* 9–14 (2001) (describing differences between clinical and forensic assessments).

presentation of the findings, which may be adverse to the interests of the evaluatee.⁶⁸

Client

In a clinical assessment, the client (often termed the patient) is the person being examined and/or treated by the mental health professional, but the client in a forensic context is the person or entity that requested the evaluation (e.g., an attorney, a court, an employer, an insurer).

Relationship

Therapeutic relationships between a psychologist or psychiatrist and a patient are often characterized by empathy, support, and emotional safety. In forensic contexts, however, mental health professionals typically strive to remain detached from examinees, and the focus is on obtaining complete and accurate information that is relevant to the legal question being addressed.

Voluntariness and Autonomy

In most traditional clinical relationships, the patient enters treatment voluntarily. By contrast, in forensic contexts, examinees may be compelled to undergo an evaluation by a court, employer, or insurer or may be strongly encouraged to do so by their attorney.

Confidentiality

A patient in a traditional clinical relationship can expect that the mental health professional will not disclose confidential information obtained during treatment (unless the mental health professional is required by law to disclose certain information), but the examinee in a forensic assessment should not expect the information they provide to remain entirely confidential. The results of a forensic evaluation may be divulged to opposing counsel and in open court; in some cases, the forensic report may become part of the public record.

68. Paul S. Appelbaum, *A Theory of Ethics for Forensic Psychiatry*, 25 J. Am. Acad. Psychiatry & L. 233 (1997).

Consent

In a clinical context, the mental health professional and patient share an understanding that the goal of the therapist-patient relationship is to reduce the patient's clinical symptoms and improve their functioning. Obtaining informed consent (or the patient's agreement to participate in treatment) is a necessary part of practice. In a forensic context, the examinee's legal interests can be affected by the results of the evaluation, so it is important that the examinee understand who requested the evaluation, the purpose of the evaluation, how the results of the evaluation will be used, and who will be able to see the report. If the forensic assessment is court-ordered, the examinee is legally compelled to participate in the evaluation but should still be provided with the information noted above. But if the evaluation is not court-ordered and instead requested by the examinee's attorney or an adverse party, the examinee must be given the opportunity to decline to participate in the evaluation.

Response Style

Treatment patients are typically not motivated to conceal or distort the information they provide to a mental health professional, so mental health professionals typically assume that information provided by a patient in a treatment context is not deliberately distorted. In contrast, some examinees involved in legal proceedings may have a motivation to distort information either by exaggerating or minimizing their symptoms. It is therefore not reasonable to assume that examinees undergoing forensic assessment necessarily provide reliable information unaffected by deliberate distortion.

Data Collection and Sources of Information

Treatment relationships focus on patients' experiences, beliefs, and perceptions so that the mental health professional can better understand how patients think, feel, and experience their environment, and many mental health professionals rely almost exclusively on information provided by their patients. In forensic contexts, mental health professionals routinely consider additional sources of information (beyond self-report), typically obtaining additional information from the examinee's records (e.g., mental health, medical, criminal, school, employment) and sometimes from collateral interviews with individuals who are well acquainted with the examinee (e.g., significant others, employers, probation officers, physicians, teachers, therapists).

Pace

Traditional clinical practice typically entails a relationship between the mental health professional and patient that develops over time. In forensic contexts, evaluations are subject to deadlines associated with legal proceedings, and mental health professionals may have limited time in which to conduct an evaluation and submit a report.

Setting

Treatment typically is delivered in private, quiet settings, such as an office or a patient's hospital room. By contrast, forensic assessments of criminal defendants are often conducted in jails or prisons that offer limited privacy and poor testing conditions.

Report

In a traditional clinical context, any written report is typically brief. In a forensic context, however, mental health professionals routinely write lengthy and detailed reports that may be reviewed by attorneys, judges, and administrative bodies.

Testimony

In a treatment context, there is no expectation that mental health professionals will provide expert testimony about their patients in a deposition, hearing, or trial. In fact, fulfilling two roles in one case—such as being a treating clinician and an expert witness—may be inconsistent with professional ethical guidelines because it can result in a conflict of interest (among other problems).⁶⁹ In a forensic context, by contrast, mental health professionals should assume testimony will be required (even though testimony occurs in only a small percentage of cases).

These differences strongly suggest that treating clinicians should avoid taking on the role of forensic evaluator for a variety of reasons. Among the most important are the different purposes, procedures, limits to confidentiality, and reasons for conducting the evaluation—all of which should be conveyed in the notification of purpose or informed consent that precedes the forensic assessment

69. Thomas G. Gutheil & Paul S. Appelbaum, *Clinical Handbook of Psychiatry and the Law* 245–47 (5th ed. 2020).

itself. Another involves the importance of impartiality, which is highly valued in forensic assessment but not in clinical treatment. These various considerations are addressed in the specialty ethics guidelines for psychiatry⁷⁰ and psychology,⁷¹ which generally discourage playing both roles in the same case.

Diagnosis of Mental Disorders

Nomenclature and Typology: DSM-5 and DSM-5-TR

The standard nomenclature and diagnostic criteria for mental disorders in use in the United States are embodied in the *Diagnostic and Statistical Manual of Mental Disorders*, published by the American Psychiatric Association and now in its fifth edition with revised text (DSM-5-TR).⁷² To qualify for a DSM diagnosis, a person must meet a set of criteria characteristic of the disorder. The DSM approach has been criticized on the grounds of relevance to the evidence likely to be presented in legal proceedings, as its major goal is to provide a typology useful to clinicians and researchers that reflects the latest psychiatric understanding of mental disorders. But the DSM recognizes—in a cautionary statement in the introduction to the text—that diagnostic criteria appropriate for clinical or research purposes may not map directly onto legally relevant categories.⁷³

70. American Academy of Psychiatry and the Law, Ethics Guidelines for the Practice of Forensic Psychiatry, May 2005 [hereinafter Forensic Psychiatry Guidelines], <https://perma.cc/P88W-F7T5>.

71. American Psychological Association, Specialty Guidelines for Forensic Psychology (2011) [hereinafter APA Specialty Guidelines], <https://perma.cc/MM83-6NPZ>.

72. American Psychiatric Association, *Diagnostic and Statistical Manual of Mental Disorders* (5th ed. text rev. 2022) [hereinafter DSM-5-TR]. An alternative nomenclature and set of criteria used internationally can be found in the *International Classification of Diseases*, now in its eleventh edition [hereinafter ICD-11], published by the World Health Organization and available at <https://perma.cc/JSE3-WSZC>. Although the DSM-IV-TR and ICD-11 nomenclature and criteria are generally similar, there are differences that can result in diagnostic variations in particular cases, depending on which criteria are applied. The DSM-5-TR was modified in part in an attempt to make it more closely align with ICD-11.

73. The cautionary statement reads in part,

Although the DSM-5 diagnostic criteria and text are primarily designed to assist clinicians in conducting clinical assessment, case formulation, and treatment planning, DSM-5 is also used as a reference for the courts and attorneys in assessing the legal consequences of mental disorders. As a result, it is important to note that the definition of mental disorder included in DSM-5 was developed to meet the needs of clinicians, public health professionals, and research investigators rather than the technical needs of the courts and legal professionals. . . . When DSM-5 categories, criteria, and textual descriptions are employed for forensic purposes, there is a risk that diagnostic information will be misused or misunderstood. These dangers arise because of the imperfect fit between the

Since the publication of DSM-5 in 2013, an iterative revision process was established, allowing modification of criteria or text as new evidence warranting changes becomes available.⁷⁴ Hence, other than immediately after the publication of a new hard-copy edition, the canonical version of the DSM is the online version.⁷⁵

Major Diagnostic Categories

The DSM-5-TR includes more than 300 diagnoses, but the characteristics of the major categories of disorders that are likely to be relevant in legal proceedings can be summarized concisely.⁷⁶

- *Schizophrenia* is a complex psychotic⁷⁷ disorder involving delusions, hallucinations, disorganization of thought, speech, and behavior, and social withdrawal. Social and occupational functioning are markedly impaired. There may also be a deterioration in cognitive functioning, with a loss of intellectual capacity experienced over the course of the disorder, that should be appraised when schizophrenia is present. The intensity of the symptoms may fluctuate, with periodic exacerbations and often slow deterioration over time.⁷⁸
- *Bipolar disorder* (formerly called manic-depressive disorder) is a disturbance of mood marked by episodic occurrence of both mania and depression. During manic periods, persons experience elevated,

questions of ultimate concern to the law and information contained in a clinical diagnosis. In most situations, the clinical diagnosis of a DSM-5 mental disorder . . . does not imply that an individual with such a condition meets legal criteria for the presence of a mental disorder or ‘mental illness’ as defined in law, or a specified legal standard (e.g., for competence, criminal responsibility, or disability).

DSM-5-TR, *supra* note 72, at 29.

74. The guidelines for the revision process are available at <https://perma.cc/R8CP-F993>.

75. Paul S. Appelbaum, Ellen Leibenluft & Kenneth S. Kendler, *Iterative Revision of the DSM: An Interim Report from the DSM-5 Steering Committee*, 72 *Psychiatric Services* 1348 (2021), <https://doi.org/10.1176/appi.ps.202100013>.

76. These brief summaries of complex and variable conditions are meant to provide an orientation to the nature and course of major mental disorders. The current edition of the DSM itself or standard psychiatric textbooks should be consulted for more complete descriptions. Note that for a diagnosis of any disorder to be made per the DSM, the symptoms must be deemed to “cause clinically significant distress or disability in social, occupational, or other important activities.” DSM-5-TR, *supra* note 72, at 14.

77. Psychotic conditions involve some degree of detachment from reality characterized by delusional thinking and hallucinatory perceptions. *Id.* at 113.

78. *Id.* at 117–18.

expansive, or irritable mood, accompanied by such symptoms as grandiosity, racing thoughts and pressured speech, decreased sleep, and hypersexuality. The course is chronic, but intermittent, though some patients experience a downward trajectory.⁷⁹

- *Major depressive disorder* involves one or more episodes of depression, typically involving depressed mood, loss of pleasure, weight loss, insomnia, feelings of worthlessness, diminished ability to think or concentrate, and thoughts of death. Episodes are often, but not always, recurrent.⁸⁰
- *Substance use disorders* can involve a variety of substances, both licit and illicit. Recent editions of the DSM moved away from the terms *abuse* and *dependence*, and instead use the term *substance use disorder* to describe the “wide range of the disorder, from a mild form to a severe state of chronically relapsing, compulsive pattern of drug taking.”⁸¹
- *Personality disorders* are enduring patterns of inner experience and behavior that deviate markedly from the norms and expectations of the individual’s culture, are stable over time, and lead to distress or impairment.⁸² Personality disorders tend to be long-standing and difficult to treat. *Anti-social personality disorder* is often seen in criminal courts because it is marked by a pervasive pattern of disregard for and violation of the rights of others.⁸³
- *Neurocognitive disorders*, which include the conditions previously referred to as *dementia*, are marked by impairment of cognitive abilities, including memory, language, motor functions, recognition of objects, and executive functioning.⁸⁴ The most common form of progressive neurocognitive disorder is Alzheimer’s disease, the incidence of which increases with age and the cause of which remains unclear, although in many cases, genetics seems to play a role.⁸⁵ Other causes of neurocognitive disorders include multiple small strokes (*multi-infarct dementia*), trauma, and infection with certain virus-like agents.
- *Intellectual disability* (formerly referred to as mental retardation) has onset during the developmental period and includes both intellectual and adaptive functioning deficits in conceptual, social, and practical domains.⁸⁶

86. DSM-5-TR, *supra* note 72, at 37–38.

- *Post-traumatic stress disorder* (PTSD) can develop following exposure to actual or threatened death, serious injury, or sexual violence. Symptoms may include avoidance of experiences that are associated with the trauma, intrusive and disturbing thoughts and feelings about it, negative changes in thinking and mood, and more frequently experienced arousal (e.g., fight-or-flight reactions). It may be seen in cases in which youth have experienced abuse and neglect, for example, or in cases involving intimate partner violence or sexual assault, combat, or accidental injury.

Additional disorders that may have special legal relevance include dissociative disorders (such as dissociative identity disorder, formerly multiple personality disorder), impulse-control disorders (such as kleptomania and pyromania), sexual-behavior disorders (especially the paraphilias, such as pedophilia), and delirium.⁸⁷

Response Style

Malingering and Exaggeration

Because the diagnosis of mental disorders rests heavily on the elicitation of symptoms from the person being evaluated and observations of the person's behavior, the possibility of malingering—the deliberate simulation of symptoms of mental disorder—must always be considered.⁸⁸ Most commonly, the likelihood of malingering is assessed as part of a clinical evaluation. The pattern of symptoms

Bell*, 89 F. Supp. 2d 922 (M.D. Tenn. 2000) (dissociative identity disorder); *United States v. Miller*, 146 F.3d 1281 (11th Cir. 1998) (impulse-control disorder); *United States v. McBroom*, 991 F. Supp. 445 (D.N.J. 1998) (person receiving treatment for bipolar disorder and impulse-control disorder sentenced for possession of child pornography); *United States v. Silleg*, 311 F.3d 557 (2d Cir. 2002) (pedophilia determination in a child-pornography case); *Fields v. Lyng*, 705 F. Supp. 1134 (D. Md. 1988) (kleptomania); *United States v. Warr*, 530 F.3d 1152 (9th Cir. 2008) (sentencing of an arsonist diagnosed with pyromania upheld); *Kansas v. Hendricks*, 521 U.S. 346 (1997) (upholding commitment of man unable to control pedophilic impulses); *United States v. Gigante*, 996 F. Supp. 194 (E.D.N.Y. 1998) (dementia); *Johnson v. City of Cincinnati*, 39 F. Supp. 2d 1013 (S.D. Ohio 1999) (estate of man who died from police restraint during a seizure sued the city under 28 U.S.C. § 1983); *Bertl v. City of Westland*, No. 04-CV-75001, 2007 WL 3333011 (E.D. Mich. Nov. 9, 2007) (finding that delirium tremens is an objectively serious medical need); *Atkins v. Virginia*, 536 U.S. 304 (2002) (banning the execution of the mentally retarded as a violation of the Eighth Amendment); *In re Hearn*, 418 F.3d 444 (5th Cir. 2005); *Hamilton v. Southwestern Bell Tel. Co.*, 136 F.3d 1047, 1050 (5th Cir. 1998) (recognizing PTSD as a mental impairment for the purposes of the Americans with Disabilities Act).

88. Malingering is defined as “the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining

reported by the person is compared with known syndromes, and the consistency of the person's behaviors is observed. Contrary to common belief, mental disorders are not easy to fake, especially when the deception must be sustained over a period of time.⁸⁹

When deception is suspected, efforts to confirm it should begin during the clinical examination, as the person is offered the opportunity to endorse symptoms that are unlikely to occur naturally (e.g., "Do you ever feel as though the cars on the street are talking about you?") or that do not fit the condition from which the patient is claiming to suffer.⁹⁰ Psychological testing can be helpful in detecting deception; the Minnesota Multiphasic Personality Inventory-3 (MMPI-3), for example, has scales that correlate with persons who are both "faking bad" (i.e., fabricating symptoms) and "faking good" (i.e., hiding symptoms that actually exist).⁹¹ Other instruments specifically for the assessment of malingering also have been developed, with varying degrees of validation.⁹² Information from records of previous psychiatric or psychological evaluations can be helpful in determining the congruence of a person's current symptoms with past reports and behaviors. In addition, given the difficulty in maintaining a consistent pattern of deception over a sustained period, data provided by collateral sources (e.g., family members, roommates, prisoners in adjoining cells, correctional officers, nurses and other hospital staff) who have observed the person informally can be crucial in distinguishing real from malingered disorders.⁹³

The difficulty of simulating a mental disorder does not imply that it is impossible to do. Indeed, a skilled and determined person can sometimes fool even an experienced evaluator. Thus, the only honest response that a clinician can give in almost every circumstance to a question about the possibility of malingering is that it is always possible, but is more or less likely in this particular case, given the characteristics of the person being evaluated.⁹⁴

94. Resnick, *supra* note 88.

Other Response Styles

The literature on response styles has expanded quite considerably in recent years, and researchers have now identified several different types.⁹⁵ For example, the response style of defensiveness is characterized as the polar opposite of malingering—that is, the denial or gross minimization of psychological and physical symptoms with the motivation of obtaining an unwarranted, yet desired, external incentive.⁹⁶ Social desirability is a response style in which individuals present themselves in the most favorable manner relative to social norms.⁹⁷ An uncooperative response style describes individuals who deliberately withhold information during the evaluation process.⁹⁸ An irrelevant response style describes an individual who does not sufficiently engage in the assessment process,⁹⁹ which can limit the evaluator's ability to draw valid conclusions. Acquiescent responding, which is sometimes called yea-saying, is when an individual responds in the affirmative to most or all questions/items, while disacquiescent responding, or nay-saying, is the opposite response style.¹⁰⁰ Hybrid responding describes an individual who uses more than one response style during an evaluation.¹⁰¹ All of these response styles are distinguishable from reliable responding, which is when individuals respond genuinely to evaluation items and questions.

Functional Impairment Due to Mental Disorders

Impact of Mental Disorders on Functional Capacities

Mental disorders can affect functional capacities in various ways. Among these, attention and concentration may be impaired by the preoccupations that appear in anxiety and depressive disorders, or the grosser distractions (e.g., auditory hallucinations) of psychotic disorders.¹⁰² Perception is often distorted in psychotic conditions, as manifested by hallucinations of the auditory, visual, tactile, or other

sensory systems.¹⁰³ Cognition, encompassing both the process and content of thought, is also often affected: Thought processes can be impeded by the slowing of thought in depression, its acceleration in mania, or the scrambling of thought among persons with schizophrenia or other psychotic disorders. Thought content may be altered by the odd reasoning to which persons with delusions appear to be prone.¹⁰⁴ Motivation to act, even in one's self-interest, is often globally reduced in states of intense depression and in schizophrenia.¹⁰⁵ Judgment and insight may be altered under the pressure of delusions.¹⁰⁶ Control of behavior can be weakened by the impulsivity seen in mania and psychosis, the drives of the impulse disorders, and the use of disinhibiting substances, especially alcohol.¹⁰⁷ Any of these impairments could affect a person's relevant decisional and performative capacities.

This necessarily incomplete list of the ways that mental disorders can affect functional capacities illustrates the vulnerability of almost every aspect of mental functioning to perturbation. And although it is common to divide mental functions into categories such as these for heuristic purposes, most neuroscientists recognize that the brain operates as a unified entity.¹⁰⁸ Thus, it is rare that impairments are limited to a single area of functioning. Impaired concentration, for example, inherently affects cognitive abilities, which in turn may alter judgment and therefore the person's choice of behaviors. Although focal deficits may occur, for example the anxiety associated with exposure to a phobic stimulus such as a spider, more severe disorders will have a broader impact on a person's functional capacities as a whole.¹⁰⁹

Assessment of Functional Legal Capacities

Determining the nature and extent of past, present, or future functional impairment, therefore, is usually the most critical aspect of a forensic mental health evaluation and subsequent presentation of mental health evidence.

109. The pervasive impact of schizophrenia on all aspects of personality and functioning is the most extreme example. See Ryan Lawrence et al., *Schizophrenia Spectrum and Other Psychotic Disorders*, in Joseph M. Roberts et al., *The Utility of the Trauma Symptom Inventory as a Primary and Secondary Assessment Instrument for Forensic Practice in Legal Settings* 257–78 (2022).

Clinical Examination

As in establishing a diagnosis, the core of the assessment of functional impairment remains the clinical examination.¹¹⁰ A diagnostic assessment may be integral to the functional assessment process, suggesting to the examiner areas of possible impairment to be explored in greater depth (e.g., attentional and concentration abilities in an anxiety disorder; impairments in motivation in a depressive disorder). Beginning in the 1970s, however, there was growing recognition among the mental health professions that merely establishing a diagnosis is not sufficient for drawing a conclusion about a legally relevant capacity, because a broad range of functional impairments can be associated with almost any mental disorder.¹¹¹

Thus, in addition to a diagnostic assessment, an adequate examination will explore the person's perspective on the alleged functional impairment and will probe for symptoms associated with such impairment. The process involves more than simply taking the person's word for the issue in question, for example, that someone was not able to comprehend the details of the contract to which they are a party or that they remain incapable of the careful calculations required in their job. Assessors compare the claimed impairments with the person's overall history and other areas of function, looking for congruence or incongruence. For example, the assertion by a plaintiff that because of being harassed on the job, the plaintiff has been unable to concentrate sufficiently to work will be more or less plausible depending on the consistency and extent of the symptoms and the degree to which the impairment may generalize to other areas of the person's life. Degrees of claimed impairment that are out of scale with the extent of symptoms or the person's functional history are inherently suspect.¹¹²

In addition to questioning the evaluatee directly, the use of collateral information can be essential to a valid assessment, particularly when the person has an incentive to malingering, which will often be the case in legal proceedings.¹¹³ Family members, coworkers, and others who have had an opportunity to observe the person can provide invaluable information about the nature and extent of impairments, although one must always be alert to the possibility that informants will be motivated to assist the person by distorting or exaggerating their accounts. Records of performance, such as educational test results and work evaluations, especially if generated prior to the filing of the legal claim, may shed somewhat more objective light on the person's capacities.¹¹⁴ To the extent that impairments may

112. Rogers & Bender, *supra* note 20.

113. Gutheil & Appelbaum, *supra* note 69.

114. Melton et al., *supra* note 1, at 53–55.

be rooted in disruptions of brain functions per se, neuropsychological testing can also be helpful in documenting their nature and extent. Increasingly, however, an unstructured clinical evaluation on its own, even when supplemented by collateral information, is not necessarily the most accurate tool for determining functional capacity.¹¹⁵

Structured Assessment Techniques

As with determination of diagnosis, the evaluation of the limitations of function due to mental disorders increasingly involves the use of structured assessment techniques.¹¹⁶ Most commonly, these are standardized interviews or data-gathering protocols (e.g., based on a person's psychiatric record) designed to ensure that all relevant information is obtained. In addition, where research has established the validity of the instruments by demonstrating a correlation between the results and actual impairments, these techniques may allow a quantitative estimate of the extent of actual functional deficiencies to be made. A compendium of assessment instruments includes structured evaluations that address criminal defendants' competence to stand trial, waiver of rights to silence and legal counsel, criminal responsibility, one's parenting capacity, competence to manage one's affairs (i.e., need for a guardian or conservator), and competence to consent to medical treatment and research.¹¹⁷ Given that this area is a rapidly developing focus of research, instruments to address other legally relevant functional capacities and states—propensity to commit violent or sexual offenses comes quickly to mind¹¹⁸—are continuously being tested and developed.

115. Grisso, *supra* note 3. Surprisingly few studies exist of the reliability of clinical forensic evaluations. An early U.S. study of actual assessments showed good interrater reliability of evaluations of competence to stand trial, although many of the reports were deficient in other ways. Jennifer L. Skeem et al., *Logic and Reliability of Evaluations of Competence to Stand Trial*, 22 L. Hum. Behav. 519 (1998), <https://doi.org/10.1023/a:1025787429972>. An Australian study found only fair to moderate reliability across assessments of competence to stand trial, but moderate to good reliability of criminal-responsibility evaluations. Matthew Large et al., *Reliability of Psychiatric Evidence in Serious Criminal Matters: Fitness to Stand Trial and the Defence of Mental Illness*, 43 Austl. N.Z. J. Psychiatry 446 (2009), <https://doi.org/10.1080/00048670902817745>. A systematic review and meta-analysis found relatively poor reliability in both competence-to-stand trial and insanity evaluations. See Lucy A. Guarnera & Daniel C. Murrie, *Field Reliability of Competency and Sanity Opinions: A Systematic Review and Meta-Analysis*, 29 Psych. Assessment 795 (2017), <https://doi.org/10.1037/pas0000388>.

116. See Grisso, *supra* note 3.

117. *Id.*

118. See, e.g., Kevin S. Douglas et al., HCR-20 V3 Assessing Risk for Violence User Guide, Version 3 (2013); Grant T. Harris et al., *Violent Offenders: Appraising and Managing Risk* (2015); John Monahan et al., COVR—Classification of Violence Risk, Professional Manual (2005).

Although most assessment techniques rely on information gathered from the person being evaluated or from existing records, some approaches involve direct testing of the person's capacity to perform particular tasks. Examples include computerized assessment of driving capacities,¹¹⁹ observation of tasks involving the handling and management of money¹²⁰ and of parenting skills,¹²¹ and direct measurement of such capacities as understanding and reasoning about medical information when a person's competence to decide about medical treatment is at issue.¹²² In general, these approaches reduce the degree of inference required in drawing conclusions about a person's functioning because the person is observed performing something close to the precise tasks in question. Of course, such techniques may not be relevant when the legal issue relates to the impact of mental disorder on functional abilities at some time in the past or future, especially if the person's mental state at present may be different from what it was or will be. Nonetheless, these can be useful approaches to evaluation in appropriate legal contexts.

The advantages that attend the use of structured assessment instruments include the thoroughness of the evaluation, and in many cases, a research base exists from which conclusions can be drawn about the degree of an assessed person's functional impairment.¹²³ In some jurisdictions, the use of structured assessments is even required for particular purposes (e.g., evaluation of sex offenders).¹²⁴ Still, the use of structured assessments performed for the purpose of being introduced in legal proceedings is variable and far from universal.¹²⁵ Grisso, a leading scholar in this area, suggests three reasons why: (1) it is easier and may be more lucrative (e.g., where a fixed rate is being paid per evaluation) for an examiner to avoid the frequently time-consuming use of a structured instrument; (2) many cases involve persons whose functional impairments—or lack of impairment—are obvious, and use of a structured assessment instrument would be overkill; and (3) perhaps paradoxically, the use of an assessment tool

Code Ann. § 37.2-903-C: “Each month the Director shall review the database and identify all such prisoners who are scheduled for release from prison within 10 months from the date of such review who receive a score of five or more on the Static-99 or a like score on a comparable, scientifically validated instrument designated by the Commissioner. . . .”

125. Grisso, *supra* note 3, at 481.

makes experts more vulnerable to attack on cross-examination.¹²⁶ That many expert witnesses lack knowledge of the existence of these instruments and that a sense that their use denigrates the evaluator's expertise should be added to this list.

The vulnerability of testimony based on assessment instruments to cross-examination is worth special emphasis. Opinions offered on the basis of "clinical experience," which appears to be the norm, are difficult to challenge when expert witnesses in fact have appropriate training and a good deal of experience with the condition in question.¹²⁷ On the other hand, assessment instruments can be subjected to scrutiny with regard to the empirical database that supports their use, including their reliability and validity, their acceptance by the relevant professional community, and their probative value in a particular case. There may also be questions regarding the examiner's training and experience with the instrument and whether it was administered in the manner intended by its developers. All of these are legitimate questions, of course, and an argument can be made that the introduction of data from assessment instruments into evidence should be held to a more rigorous standard, because factfinders may give such data greater credence than unassisted clinical judgment.¹²⁸ But the undoubted consequence is that the arguably more reliable and perhaps more valid data from empirically derived assessment techniques are less likely to be introduced in evidence than evaluators' subjective judgments of unknown validity.¹²⁹

Predictive Assessments

As noted above,¹³⁰ predictive assessments are the most challenging evaluations performed by mental health professionals.¹³¹ The most common predictive tasks involve the prediction of violence and of future functional impairment and

131. Yogi Berra, New York Yankees' Hall of Fame catcher and philosopher of everyday life, is purported to have said, "It's tough to make predictions, especially about the future." See <https://perma.cc/5FLR-WJ6T>. For a discussion of the origin of the Berra phrase, see Henry T. Greely and Anthony D. Wagner, *Reference Guide on Neuroscience*, in 3 Reference Manual on Scientific Evidence (2011).

responses to treatment. A variation on the question of prediction involves appraising the domains of risk, need, and responsivity. These professional activities are discussed in the sections that follow.

Prediction of Violence

The risk that a person may commit a violent act at some point in the future may come into play in the criminal process when courts are making determinations of suitability for diversion, bail, sentencing, probation, and parole, and in the civil process in hearings for civil commitment to psychiatric facilities and sex-offender treatment programs and when considering the imposition of liability on clinicians and facilities for failing to protect victims of patients' violence.¹³² Not all persons for whom such assessments must be made will have mental disorders, but psychiatrists and psychologists are seen by the courts as having expertise in this area and hence are almost invariably called upon for these evaluations.¹³³

Persons with serious mental disorders, such as schizophrenia or bipolar disorder, are often considered by the general public to be at high risk for violence.¹³⁴ However, data on the relationship between serious mental disorders and violence are variable (schizophrenia is the disorder most frequently studied). Although most studies suggest a moderately elevated risk, the proportion of violence accounted for by individuals with serious mental disorders is small, probably 3% to 5%, based on the best available U.S. estimates.¹³⁵ Data also suggest that the stereotype of individuals with serious mental disorders who assault strangers in

132. See, e.g., *Kansas v. Hendricks*, 521 U.S. 346 (1997); *White v. Johnson*, 153 F.3d 197 (5th Cir. 1998). A unanimous U.S. Supreme Court in *Chambers v. United States*, 129 S. Ct. 687, 691–93 (2009), pointed to the importance of considering empirical data when identifying circumstances associated with increased risk of violence.

Violence can be defined in different ways. One definition frequently used in criminal law involves the commission of an offense against persons. Another definition employed by researchers is some variation on *serious acts of violence* (battery that resulted in physical injury; sexual assaults; assaultive acts that involved the use of a weapon; or threats made with a weapon in hand) and *other aggressive acts* (battery not resulting in physical injury or threats without a weapon in hand), a distinction used by the MacArthur Violence Risk Assessment Study Group. See <https://perma.cc/45H2-3YK9>.

Corrigan et al., *Implications of Educating the Public on Mental Illness, Violence, and Stigma*, 55 Psychiatric Servs. 577 (2004), <https://doi.org/10.1176/appi/ps.55.5.577>.

135. Eric Elbogen & Sally Johnson, *The Intricate Link Between Violence and Mental Disorder*, 66 Arch. Gen. Psychiatry 152 (2009), <https://doi.org/10.1001/archgenpsychiatry.2008.537>; Paul S. Appelbaum, *Violence and Mental Disorders: Data and Public Policy* (editorial), 163 Am. J. Psychiatry 1319 (2006).

public places is inaccurate: Most violence by persons with serious mental disorders is directed at family members and friends and occurs in the living quarters of the perpetrator or the victim.¹³⁶ Much higher rates of violence are associated with substance use,¹³⁷ especially alcohol use, and with psychopathy, a subcategory of antisocial personality disorder.¹³⁸ Indeed, most of the strongest predictors of violence are common to both persons with serious mental disorders and those without, suggesting that the impact of the disorders per se is slight.¹³⁹

Approaches to Prediction of Violence

Clinical evaluation of violence risk ordinarily focuses on those variables that have been shown in empirical research to have the strongest relationship to future violence,¹⁴⁰ whether the information is gleaned directly from the person or derived from collateral informants or from a review of relevant records. These variables include a history of previous violence, age (violence risk peaks in the late teens and early twenties, declines slowly through the twenties and thirties, and drops off precipitously after age forty), male sex, lower socioeconomic status, employment instability, substance misuse, psychopathic personality traits, and childhood victimization.¹⁴¹ The evaluation process is complicated by the fact that literally scores of variables show some significant relationship with future violence—but this relationship is not strong enough or sufficiently independent of other variables to contribute to the aggregation of an accurate prediction of violence.¹⁴² However, beginning with the variables noted above, the evaluator estimates the baseline risk of violence for the person and then adjusts that value by taking into account foreseeable changes in relevant areas during the outcome period. When previous violence has occurred, the risk estimate is adjusted to include those specific variables that have been associated with violence by this person in the past (e.g., being left by a girlfriend), including whether they are present at the time of evaluation or likely to recur in the future.¹⁴³

143. Gutheil & Appelbaum, *supra* note 69.

A growing number of structured assessment instruments specific to the prediction of future violence risk have been developed in the past several decades. Among the best known of these are the Historical Clinical Risk Management–20, Version 3 (HCR–20–V3),¹⁴⁴ the Violence Risk Assessment Guide (VRAG),¹⁴⁵ and the computerized Classification of Violence Risk (COVR).¹⁴⁶ A set of instruments also exists for the prediction of future sex offending.¹⁴⁷ Violence risk-assessment instruments have been developed in one of three ways: by assembling known predictors from the research literature and applying them using professional judgment (e.g., HCR–20–V3), by assembling known predictors from the research literature and applying them using empirically guided rules using data from large subject populations (e.g., the Violence Risk Scale¹⁴⁸), or drawing and applying known predictors using statistical analysis of research data from large subject populations (e.g., VRAG and COVR). After a measure is developed, researchers validate it using populations similar to the ones with which it is anticipated they will be used. The more sophisticated measures yield estimates of the degree of risk, using either categories (e.g., high, medium, and low risk) or probabilities (e.g., 10%, 25%, or 40% likely) rather than dichotomous predictions that violence will or will not occur. Validation research must demonstrate a relationship between the estimated degree of risk and the probability of future violence for the instrument to be considered empirically supported.¹⁴⁹

The literature on prediction is marked by strong and unresolved differences of opinion over the best basis for the ultimate risk estimate. Those who support exclusive reliance on the quantitative predictions generated by structured assessment instruments, which is often referred to as actuarial prediction, argue that any attempts to modify the resulting risk estimates would necessarily reduce accuracy.¹⁵⁰ Proponents of using professional judgment to contribute to risk assessment note that exclusive reliance on instrumentation is unwise because of the inevitable questions about how applicable the group data, on which an instrument is based, are to the person being evaluated. They also argue that a fixed set of questions can never capture all the variables that may be relevant in a particular

situation and that evaluatees are sometimes uncooperative with a structured process.¹⁵¹ Compromises include using an actuarial measure but allowing clinical judgment in interpreting the results in light of additional considerations, or using a measure that has been designed to structure the evaluation around relevant risk factors but that requires the user to reach a final structured professional judgment (SPJ) on the basis of the totality of the information. There is a robust literature on actuarial and SPJ approaches to risk assessment, with the most recently aggregated evidence suggesting that they are comparable in predictive accuracy regarding future violence.¹⁵²

Limitations of Violence Prediction

There is voluminous research literature on violence prediction. Studies of predictions by psychiatrists and psychologists in the 1960s and 1970s showed poor accuracy in judging whether persons with mental disorders and sex offenders would be likely to be violent at some point after release.¹⁵³ Indeed, the most frequently cited conclusion was Monahan's statement that when mental health professionals predicted that a person would be violent, they were twice as likely to be wrong as right.¹⁵⁴ The cumulative impact of these findings stimulated a great deal of research to identify variables that predict violence and incorporate them into both clinical predictions and the structured assessment instruments described above.¹⁵⁵

At this point, it is possible to identify several items of consensus from the research literature. Violence is not a unitary phenomenon; that is, it occurs for different reasons, related both to the motivations of the perpetrator and to the environmental context.¹⁵⁶ A bar room brawl has different roots than a mugging; the precipitants of spouse abuse bear little similarity to the motivations underlying a killing that has been premeditated as an act of revenge. Thus, no single variable or set of variables can be relied upon in all cases to appraise violence risk. Long-term prediction of violence is less accurate, both because some kinds of violence are rare¹⁵⁷ and because it is difficult for clinicians to anticipate changes in the person and the environment over time and their effects on the person's

behavior.¹⁵⁸ On the other hand, shorter-term prediction (i.e., days to weeks) has more potential to be accurate. It is worth noting that even when the leading actuarial instruments are used to make dichotomous judgments of future violence—that is, a cutoff is set to simulate the clinical prediction process—their rates of accuracy are similar.¹⁵⁹ Mental health professionals, therefore, have been encouraged to move away from attempting to make dichotomous judgments of dangerousness and toward predictions couched in terms of the risk of future violence,¹⁶⁰ and the field has moved strongly in this direction. Even here, though, high degrees of accuracy have not been attained—and may be unattainable. The state of the art probably allows well-trained clinicians, especially if they are using structured assessment instruments, to assign persons into high-, medium-, and low-risk groups with reasonable accuracy. At present, the hope of designating risk categories with greater precision for most categories of persons with mental disorders is likely illusory.¹⁶¹ When quantitative data are available, however, precision in communication of risk would undoubtedly be enhanced if the data were utilized and if assessors specified their definitions of the categories being employed.¹⁶²

The studies on the accuracy of prediction, whether clinical or actuarial, have typically involved the direct evaluation of the person about whom the prediction was being made. Opinions about the risk of future violence by persons whom the evaluator has not examined are more problematic. Although risk can

161. One method for determining the accuracy of risk-assessment measures such as those discussed in this reference guide is receiver operating characteristics (ROC), a statistical means of distinguishing between those who have the outcome (e.g., violence) and those who do not. The area under the curve (AUC) value summarizes ROC-calculated discriminatory capacity, and most good risk-assessment measures have AUC values between .70 and .80. An AUC value of .80 means that the risk-assessment measure in 80% of cases assigns a higher risk to individuals who eventually show violence than to individuals who do not. See Douglas & Otto, *supra* note 147.

162. See Kelly M. Babchishin & R. Karl Hanson, *Improving Our Talk: Moving Beyond the "Low," "Moderate," and "High" Typology of Risk Communication*, 16 Crime Scene 11 (2009). Suggestions for improving the clarity of risk communications include distinguishing between the likelihood of future violence and the anticipated severity of the offense, specifying the period for which the prediction is being made (e.g., "over the next six months"), indicating the comparison population for the estimate (e.g., "risk is high compared with the general population" or "risk is high compared with the population of persons with similar histories of violence"), and providing both absolute and relative risks when quantitative data are available (e.g., "risk of future violence over the next year is between 8 and 12%, which is between 4 and 6 times greater than would be expected for the general population").

be calculated from records only using some measures such as the STATIC-99¹⁶³ or the Psychopathy Checklist—Revised,¹⁶⁴ personal contact with an individual as part of a professional risk assessment is important for several reasons. First, it allows the evaluator to obtain informed consent or provide notification of purpose. Second, it permits the evaluator to “individualize” the appraisal by considering the individual’s appearance, responses to detailed questions, severity of symptoms, life circumstances, and other considerations, which is important in legal settings but recognized within the field as challenging (having been termed the group-to-individual problem).¹⁶⁵ Third, it facilitates the process by which the evaluator considers various possibilities and accepts or rejects them depending upon the observed clinical data. For these reasons, personal contact can reduce reliance on inaccurate information and make the overall conclusion more accurate and credible.

Opinions about the future dangerousness of individuals who have not been personally evaluated have been introduced, for example, in death penalty cases in which the prosecution sought to prove that further violence was likely, but the defense denied the prosecution expert direct access to the defendant.¹⁶⁶ If such evidence is to be introduced, at a minimum, one would expect the assessor to note the limitations on the assessor’s knowledge of the evaluatee and on the certainty with which conclusions can be reached.

Predictions of Future Functional Impairment

Cases involving claims of emotional harms, along with disability and workers’ compensation claims, often require estimates of the plaintiff’s future functional impairment so that damages can be determined accordingly.¹⁶⁷ Techniques for the assessment of function were described above.¹⁶⁸ However, these cases call for something more: predictions of the degree of change in functional impairment

due to mental disorders that are likely to occur over time. In contrast to the structured assessment tools that assist in the prediction and management of future violence, no instruments have been developed and validated to predict future functional status.¹⁶⁹ Such predictions are complicated by the need for simultaneous estimates of several parameters that affect long-term functional outcomes: variables intrinsic to the person (e.g., symptomatic fluctuation, changes in motivation to work), variables that relate to the environment (e.g., divorce, availability of new categories of jobs), and responses to treatment.¹⁷⁰ Research exists that is aimed at identifying variables associated with some types of future functional impairment, but it is largely focused on progressive disorders (e.g., Alzheimer's disease), and even in those circumstances the accuracy of the predictions of forensic evaluators has not been determined.¹⁷¹ Acknowledgment of the uncertainties inherent in these predictions is therefore essential for experts undertaking this task.

Risk-Need-Responsivity (RNR) Assessments

Two related questions have also been addressed in the risk-assessment literature: whether there are risk-relevant needs (risk factors that are potentially changeable and, if changed, would affect the overall appraisal of risk), and how an individual might respond to interventions targeting these needs (responsivity). Risk-need-responsivity (RNR) was originally proposed as an approach to assessing the risk and rehabilitation needs of individuals who had already been convicted and sentenced to incarceration.¹⁷² Since its inception, however, it has influenced other approaches to risk assessment in legal contexts, in part because it can address questions that are not necessarily answered by predictions but may be of interest to the judge. Appraisal that focuses on RNR can be distinguished from assessment focusing only on prediction: Although both strive to identify the likelihood that the outcome of interest will occur, RNR considers the additional questions of whether that likelihood can be changed through planned intervention—and whether such intervention is likely to have the desired

169. Such instruments can be very helpful to forensic clinicians, as they summarize the available scientific evidence, provide procedures that apply that evidence, guide the conclusions of the evaluator by structuring the gathering of evidence and translating that raw information (using scoring and/or professional judgment), and provide a manual summarizing the relevant information in a single source.

170. See discussion in section titled “Prediction of Responses to Treatment” below.

171. See, e.g., Roy Martin et al., *Declining Financial Capacity in Patients with Mild Alzheimer Disease: A One-Year Longitudinal Study*, 16 Am. J. Geriatric Psychiatry 209 (2008), <https://doi.org/10.1097/JGP.0b013e318157cb00>.

risk-reducing effect. Depending on the questions associated with the legal decision, one of these two approaches might be a better fit. An RNR appraisal also focuses on criminal offending generally rather than violence specifically.

Appraising Risk

Risk factors can be variables that do not change through planned intervention (called static risk factors, e.g., sex or age) or variables that have the potential to change through such intervention (called dynamic risk factors, e.g., substance use disorder). Predictive approaches can use either static or dynamic risk factors, although the former change little in their level of appraised risk over time. RNR, by contrast, uses mostly dynamic risk factors—also termed needs. Appraisals using both static and dynamic risk factors yield an overall risk category that may change over time and with the delivery of planned rehabilitative interventions. It was once accepted that static risk factors provided a stronger basis for accurate prediction, but current evidence suggests that this superiority is smaller than was once believed and may not exist.¹⁷³ In other words, the risk of future violence or other criminal offending is subject to change for many individuals, and the risk assessment that is provided should reflect that.

Appraising Need

Areas of need differ across different justice-involved populations. For individuals who have been termed general offenders, who are not selected for particular characteristics (e.g., clinical characteristics such as symptoms of severe mental illness; offending characteristics such as being charged with a specific type of offense), risk-relevant needs have been identified in the following areas: criminal thinking, antisocial personality, antisocial peers, substance misuse, family, education/employment, and leisure time.¹⁷⁴ When combined with the static historical variable of antisocial conduct, these risk factors have been called the central eight.¹⁷⁵ Among individuals with severe mental illness, research has identified two of these needs (severe substance use/dependence and criminal thinking) as particularly important, as well as some other dimensions that are not among

173. See Mara J. Eisenbert et al., *Static and Dynamic Predictors of General and Violent Criminal Offense Recidivism in the Forensic Outpatient Population: A Meta-Analysis*, 46 *Crim. Just. Behav.* 732 (2019), <https://doi.org/10.1177/0093854819826109>.

174. See James Bonta & Donald A. Andrews, *The Psychology of Criminal Conduct* (6th ed. 2017).

175. See, e.g., David DeMatteo et al., *Problem-Solving Courts and the Criminal Justice System* 34 (2019).

the original central eight (self-management, social skills, and life skills). The identification of risk-relevant needs varies somewhat according to population (e.g., general offenders, severely mentally ill individuals, specialized offenders such as those charged with sex offenses) and outcome of interest (e.g., violence, serious violence, sex offending, any offending).

Appraising Responsivity

When considering the need for risk-reducing interventions in different areas, a question arises: How are individuals likely to respond to such interventions? This is the key question in appraising responsivity, the third domain of risk-need-responsivity. Two types of responsivity have been identified: general and specific.¹⁷⁶ General responsivity refers to the importance of using interventions that have been demonstrated through research to be effective. This means that interventions with demonstrated effectiveness in reducing antisocial behavior (e.g., medication, therapeutic communities, cognitive behavioral therapy) should be preferred, while those without such evidence (e.g., psychoanalysis) should be viewed with skepticism if proposed for this purpose. Specific responsivity underscores the importance of matching the demands of the intervention with the capacities and learning style of the individual. For example, an individual with identified intellectual limitations in verbal skills and verbal memory should not receive an intervention that depends on the individual's ability to describe and recall complex ideas; rather, the focus should be on developing and strengthening adaptive behavior.

RNR may be particularly relevant at sentencing. Toward that end, a set of national guidelines for postconviction risk and need assessment has been developed with the assistance of numerous experts in the field.¹⁷⁷

Treatment of Mental Disorders

The nature of available treatments for mental disorders, the probability that the treatments will be effective, the side effects they may induce, and the existence of alternatives are likely to be material to a variety of legal cases. In criminal proceedings, for example, the continued confinement of a defendant in a psychiatric hospital on the basis of incompetence to stand trial will be based in part on the probability that treatment will restore capacity;¹⁷⁸ involuntary treatment of

178. See *Jackson v. Indiana*, 406 U.S. 715 (1972).

the defendant will turn on a number of factors, including the likelihood of treatment success, treatment side effects, and the potential for side effects to impair the defendant's defense.¹⁷⁹ Decisions about probation and parole of mentally disordered offenders may also depend on the likelihood that symptoms will remain in check, and courts may order ongoing treatment as a condition of release.¹⁸⁰ Among the civil cases for which treatment-related questions will be at issue are liability claims for malpractice and failure to protect third parties from patient violence, claims involving emotional harms (e.g., in calculating the cost of future care), and issues related to the deprivation of rights of prisoners in correctional facilities to have adequate mental health treatment.¹⁸¹ Treatment of mental disorders today offers multiple options for most disorders, often with different levels of likely effectiveness and varying side-effect profiles. Planning treatment has become an increasingly complex task.

Treatment with Medication

The past seventy years have seen the ongoing introduction of new medications for the treatment of mental disorders. Currently, medications are a mainstay in the treatment of schizophrenia and bipolar disorder; it is a rare patient who can be treated successfully for these disorders without medication as part of the treatment plan.¹⁸² Medications are also used commonly to treat and prevent the recurrence of depression, anxiety disorders, attention-deficit/hyperactivity disorder (ADHD), and a large number of other conditions.¹⁸³ The field of psychopharmacology, as the treatment of mental disorders with medications is known, has become a complex and challenging part of psychiatric practice.¹⁸⁴

Psychological Treatments

Although medications are a mainstay for treatment of serious mental disorders, a variety of psychological treatments may be important as either primary or adjunctive treatments.

184. *See generally* Herbert Mwebe, *Psychopharmacology: A Mental Health Professional's Guide to Commonly Used Medications* (2018).

Behavioral Therapy and Cognitive Behavioral Therapy

The goal of behavioral therapy is to reduce maladaptive behaviors (e.g., substance use, impulsivity) by reinforcing desirable behaviors and eliminating unwanted behaviors.¹⁸⁵ Behavioral therapy is based on the idea that people learn behaviors based on their environment and experiences; it seeks to help people understand, among other things, the antecedents and consequences of their behaviors, thereby motivating them to change unwanted behaviors.¹⁸⁶ Cognitive behavioral therapy (CBT) is based on the idea that patterns of thought determine how one feels and behaves.¹⁸⁷ CBT is generally shorter-term (weeks to months), highly structured, and focused on helping patients recognize and control maladaptive patterns of thinking. Patients are often given homework assignments to complete between sessions. A strong database supports its use in anxiety disorders, depression (where it can be as effective as medications and may be more likely to prevent relapse), and for control of some psychotic symptoms, and its use is steadily being extended to additional conditions.¹⁸⁸

Specialized Treatments

Given the effectiveness of CBT, several specialized forms of CBT have been developed for certain populations (e.g., individuals who commit sex offenses) based on a model that is often termed relapse prevention, which teaches patients to recognize and avoid situations that are likely to lead to recidivism.¹⁸⁹ Dialectical behavior therapy (DBT) is an offshoot of CBT that has shown success with patients with borderline personality disorders, a disorder otherwise difficult to treat.¹⁹⁰ Mindfulness-based interventions, which can range from meditation to more formal interventions that incorporate CBT techniques, are designed to increase intentional attention and cultivate different strategies for dealing with distressing thoughts and emotions,¹⁹¹ with research suggesting that they are effective for certain psychiatric disorders.¹⁹²

Treatment of Functional Impairments

Control of positive symptoms does not necessarily address deficits in function, particularly in the psychotic disorders. What may be required are techniques that focus on functional difficulties per se. For example, given that schizophrenia often affects the ability to function socially and occupationally, persons with the disorder may need to be taught how to interact with other people, an approach known as social-skills therapy.¹⁹³ Occupational therapy can provide them with a graded introduction (or reintroduction) to the workplace, with patients taught how to maintain focus and deal with the demands of the work setting.¹⁹⁴ More focal impairments can be addressed, as well. Thus, defendants found incompetent to stand trial can be taught about the nature of the courtroom, the role of key legal players, and the expectations they must meet to be found competent to proceed. Studies of such programs have shown higher rates of restoration of competence than occurs with treatment of the primary disorder alone.¹⁹⁵ Comparable programs are available for anger management,¹⁹⁶ control of spousal abuse,¹⁹⁷ and training in parenting skills,¹⁹⁸ among other areas of function that are often the target of legal proceedings.

Prediction of Responses to Treatment

In a number of legal contexts, experts are called on to anticipate the response to treatment of persons with mental disorders. These projections are difficult to make because of several parameters inherently challenging to predict:

193. Alex Kopelowicz, Robert Paul Liberman & Roberto Zarate, *Recent Advances in Social Skills Training for Schizophrenia*, 32 *Schizophrenia Bull.* S12 (2006), <https://doi.org/10.1093/schbul/sbl023>.

194. See generally Jennifer Creek, *Occupational Therapy and Mental Health: Principles, Skills and Practice* (2002).

195. See, e.g., Alex M. Siegel & Miriam Elwork, *Treating Incompetence to Stand Trial*, 14 *L. & Hum. Behav.* 57 (1990), <https://doi.org/10.1007/BF01055789>; Kirk Heilbrun et al., *Jackson-Based Restorability to Competence to Stand Trial: Critical Analysis and Recommendations*, 27 *Psych. Pub. Pol. & L.* 370 (2021), <https://doi.org/10.1037/law0000307>; Barry W. Wall et al., *Restoration of Competency to Stand Trial: A Training Program for Persons with Mental Retardation*, 31 *J. Am. Acad. Psychiatry & L.* 189 (2003).

196. Raymond DiGiuseppe & Raymond C. Tafrate, *Anger Treatment for Adults: A Meta-Analytic Review*, 10 *Clinical Psych.: Sci. & Prac.* 70 (2006), <https://doi.org/10.1093/clipsy.10.1.79>.

197. Julia C. Babcock et al., *Does Batterers' Treatment Work? A Meta-Analytic Review of Domestic Violence Treatment*, 23 *Clinical Psych. Rev.* 1023 (2004), <https://doi.org/10.1016/j.cpr.2002.07.001>. Note that in contrast to anger management and parenting training, the data on the efficacy of treatment for batterers indicate that effects are limited at best.

198. Kathryn M. Bigelow & John R. Lutzker, *Training Parents Reported for or at Risk for Child Abuse and Neglect to Identify and Treat Their Children's Illnesses*, 15 *J. Fam. Violence* 311 (2000), <https://doi.org/10.1023/A:1007550028684>.

- *Effectiveness of Treatment.* Even highly effective treatments do not work in all cases, and when they do work, they may provide varying levels of relief.¹⁹⁹
- *Adherence.* Treatment has no chance of being effective if a person declines to pursue or to continue it, a particular issue in cases where the court lacks control over the person's future behavior.²⁰⁰ Tolerability of side effects may play an important role in these decisions.
- *Fluctuations in the Course and Responsiveness of the Disorder.* Many mental disorders are chronic and tend to wax and wane in intensity. Although adjustments in treatment can sometimes bring more severe symptoms under good control, that is not always possible. For reasons that are not understood, previously responsive disorders may also become resistant to the therapeutic effects of medication.²⁰¹
- *Environmental Conditions.* Unpredictable stresses in a person's life may exacerbate symptoms, reduce the effectiveness of treatment, or lead to diminished adherence.

However, given that estimates sometimes must be made of probable treatment effects, there are several indicators to which clinicians can turn.²⁰² Previous treatment response is the best predictor of future response; it is likely, for example, that someone whose previous delusions have rapidly resolved with antipsychotic medication will have a similar response in the future. In the absence of a documented history of successful treatment, estimates should be

199. For example, only 45% to 60% of patients receiving antidepressant medication for uncomplicated major depression show clinically significant responses to the first medication they receive, and of those who fail to respond, a similar percentage will respond positively to a second medication. Rates of response in unselected populations of patients with depression are lower. Madhukar H. Trivedi et al., *Evaluation of Outcomes with Citalopram for Depression Using Measurement-Based Care in STAR*D: Implications for Clinical Practice*, 163 Am. J. Psychiatry 28 (2006), <https://doi.org/10.1176/appi.ajp.163.1.28>.

200. Rates of nonadherence to medications among patients with psychiatric disorders are in the range of 50% or more. Although these figures are perhaps somewhat higher than those seen in other chronic conditions, long-term treatment with medication in general is marked by high rates of noncompliance with prescribed medications. Lars Osterberg & Terrence Blaschke, *Adherence to Medication*, 353 New Eng. J. Med. 487 (2005), <https://doi.org/10.1056/NEJMra050100>.

201. So-called poop-out during treatment of depression is a commonly encountered example. See, e.g., Sarah E. Byrne & Anthony J. Rothschild, *Loss of Antidepressant Efficacy During Maintenance Therapy: Possible Mechanisms and Treatments*, 59 J. Clinical Psychiatry 279 (1998), <https://doi.org/10.4088/jcp.v59n0602>.

202. For predictors of response to treatment for depression, see, for example, Stuart M. Sotsky et al., *Patient Predictors of Response to Psychotherapy and Pharmacotherapy: Findings in the NIMH Treatment of Depression Collaborative Research Program*, 148 Am. J. Psychiatry 997 (1991), <https://doi.org/10.1176/foc.4.2.278>; for predictors of response to treatment for schizophrenia, see Delbert G. Robinson et al., *Predictors of Treatment Response from a First Episode of Schizophrenia or Schizoaffective Disorder*, 156 Am. J. Psychiatry 544 (1999), <https://doi.org/10.1176/ajp.156.4.544>.

based on evidence indicating base rates of response for the person's disorder, along with any specific prognostic factors present in the person's case (e.g., a schizophrenic disorder that develops slowly over many years and that is associated with gradual functional decline generally has a poorer prognosis than one with rapid onset and good premorbid functioning). To some extent, however, there is always uncertainty associated with these predictions.

Treatment to Reduce Risk of Reoffending

A number of treatments have been developed specifically to reduce the risk of reoffending among justice-involved individuals. As a starting point, it is important to note that mental illness has a modest and indirect impact on criminal offending, and although mental illness can lead to increased contact with law enforcement (due, for example, to odd or disruptive behavior), mental illness is not a strong risk factor for violent behavior.²⁰³ Of note, mental illness is not one of the key risk factors for offending in the RNR model discussed earlier in this reference guide. Although mental illness is weakly associated with criminal offending, it can affect other risk factors; for example, offenders who are mentally ill may be disproportionately exposed to other risk factors that can increase reoffense risk, such as unstable housing, unemployment, substance misuse, criminal peers, and victimization.²⁰⁴ Several interventions have been designed to reduce the risk of reoffending.

Treatment with Medications

A variety of medications have some impact on reducing impulsive and/or aggressive behavior.²⁰⁵ The use of antipsychotic medications among people with schizophrenia who are not justice-involved has been shown to have a minimal

203. See D. A. Andrews, James Bonta & J. Stephen Wormith, *The Recent Past and Near Future of Risk and/or Need Assessment*, 52 *Crime & Delinquency* 7 (2006), <https://doi.org/10.1177/0011128705281756>; Jacques Baillargeon et al., *Psychiatric Disorders and Repeat Incarcerations: The Revolving Prison Door*, 166 *Am. J. Psychiatry* 103 (2009), <https://doi.org/10.1176/appi.ajp.2008.08030416>; Kristin G. Cloyes et al., *Time to Prison Return for Offenders with Serious Mental Illness: A Survival Analysis*, 37 *Crim. Just. Behav.* 175 (2010), <https://doi.org/10.1177/0093854809354370>.

204. See Jennifer L. Skeem, Sarah Manchak & Jillian K. Peterson, *Correctional Policy for Offenders with Mental Illness: Creating a New Paradigm for Recidivism Reduction*, 35 *L. & Hum. Behav.* 110 (2011), <https://doi.org/10.1007/s10979-010-9223-7>.

205. See Peter W. Schofield et al., *Pharmacotherapy to Reduce Violent Offending? Offenders Might Be Interested*, 53 *Austl. & N.Z. J. Psychiatry* 697 (2019), <https://doi.org/10.1177/0004867419835937>.

effect in reducing violence, largely because schizophrenia is not a major risk factor for violent behavior,²⁰⁶ although it may be useful when a person's psychotic symptoms are linked directly to their violence. Some other medications, including selective serotonin reuptake inhibitors (SSRIs), have shown some promise in reducing (albeit modestly) aggressive and antisocial behavior.²⁰⁷ The use of any medication to reduce the risk of reoffending among those without mental illness raises ethical concerns that must be balanced against the desired objective.

Psychological Treatments

There are several interventions that target empirically supported risk factors for offending and violence. For example, interventions that address the risk factors identified in the RNR model can be effective in reducing the incidence of antisocial behavior. Specifically, interventions that teach problem-solving skills, anger management, prosocial thinking, and coping skills can reduce antisocial behavior, as can educational/vocational training and interventions designed to reduce antisocial associations, improve conflict-resolution skills, reduce substance use, and increase involvement in prosocial pursuits.²⁰⁸

In recent years, manualized treatments designed to reduce recidivism have been developed. Changing Lives and Changing Outcomes (CLCO) is a manualized treatment designed for justice-involved individuals with serious mental illness, including those with a dual diagnosis of mental illness and substance use.²⁰⁹ CLCO is a CBT-based approach that helps justice-involved individuals to understand and cope with their disorders, identify and challenge antisocial thought patterns, learn basic social skills, abstain from substance use, and proactively manage their disorders.²¹⁰ The dual focus on risk factors (or criminogenic needs) and relevant clinical needs provides a strong foundation for reducing risk. CLCO is associated with higher treatment engagement, clinically meaningful reductions in mental-disorder symptoms and criminal thinking, increased

knowledge of treatment-related information, and increased medication adherence.²¹¹

Limitations of Mental Health Evidence

There are certain limitations to mental health evidence that there may not be with other types of scientific evidence. Both retrospective assessments of past mental states and prospective estimates of future behavior depend on estimates of variables that are inherently difficult to make with a high degree of certainty. Even contemporaneous assessments of functional abilities depend in part on the evaluatee's self-report of such difficult-to-measure attributes as distress, motivation, and judgment. Where empirically validated assessment tools are used, there are the usual concerns about measurement error. Two other key issues relate to ultimate-issue testimony and the standard to which expert testimony is typically held—that is, reasonable degree of certainty.

Ultimate-Issue Testimony

Whether mental health experts should testify—or be permitted to testify—to the ultimate legal issue in a case has been a subject of long-standing controversy.²¹² The question arises, for example, in criminal cases where experts often have commented directly on whether a defendant is competent to stand trial or whether the legal standard for insanity has been met.²¹³ Similar issues can arise in civil settings, in which experts may be asked to testify directly about a person's capacity to manage affairs or to serve as a custodial parent, or regarding whether a person was competent to sign a contract at an earlier point in time.²¹⁴

Attorneys and judges are often proponents of ultimate-issue testimony. They may be concerned that an expert who provides a clinical formulation without tying it directly to the ultimate legal issue will confuse jurors, who may

211. See, e.g., Monika Gaspar et al., *Therapeutic Outcomes of Changing Lives and Changing Outcomes for Male and Female Justice Involved Persons with Mental Illness*, 46 *Crim. J. & Behav.* 1678 (2019), <https://doi.org/10.1177/0093854819879743>; Stephanie A. Van Horn et al., *Changing Lives and Changing Outcomes: “What Works” in an Intervention for Justice-Involved Persons with Mental Illness*, 16 *Psych. Servs.* 693 (2019), <https://doi.org/10.1037/ser0000248>.

212. See Fed. R. Evid. 704; Anne Lawson Braswell, *Resurrection of the Ultimate Issue Rule: Federal Rule of Evidence 704(b) and the Insanity Defense*, 72 *Cornell L. Rev.* 620 (1987); Christopher Slobogin, *The “Ultimate Issue” Issue*, 7 *Behav. Sci. & L.* 259 (1989).

213. But see discussion below regarding the current prohibition on this practice in federal courts.

214. See Restatement (Second) of Contracts § 15.

be unable to discern the connection on their own.²¹⁵ Many experts share similar concerns or worry that mental health issues will simply be ignored if their relevance to the legal question at hand is not made clear; they further note that courts have applied such rules erratically.²¹⁶ They counter concerns about such testimony having an undue impact on jurors' deliberations by noting that jurors appear to be little influenced by whether ultimate-issue testimony is offered by an expert.²¹⁷

In addition to the argument that ultimate-issue testimony invades the province of the decision maker,²¹⁸ opponents often point to the legal and moral nature of the question of whether someone is, for example, criminally responsible.²¹⁹ Although mental health expertise may be helpful in determining the person's mental state at the relevant time, determining whether the resulting impairment was sufficient to negate responsibility requires the application of the relevant legal standard and a moral judgment of the fairness or unfairness of punishing a person for the behavior. Psychiatrists and psychologists have no particular expertise on legal or moral issues; hence, opponents of ultimate-issue testimony urge that mental health experts should not be permitted to speak to those issues. Such preclusion may also reduce the much bemoaned "battle of the experts," because a good deal of disagreement may derive from views of how data from the evaluation should be applied to the ultimate legal question rather than from differences regarding the person's mental state. Although testimony on the ultimate legal issue is now barred in federal courts in insanity-defense cases (18 U.S.C. § 17; Federal Rule of Evidence 704(b)), ultimate-issue testimony is permitted in many states, and, even in federal jurisdictions, it may be offered in other cases.²²⁰

215. Ralph Slovenko, *Commentary: Deceptions to the Rule on Ultimate Issue Testimony*, 34 J. Am. Acad. Psychiatry & L. 22 (2006). Cases involving issues related to medical causation can be particularly confusing for fact finders if experts are not permitted to address the ultimate legal issue. See Slobogin et al., *supra* note 1, at 624.

216. Alec Buchanan, *Psychiatric Evidence on the Ultimate Issue*, 34 J. Am. Acad. Psychiatry & L. 14 (2006).

217. Solomon M. Fulero & Norman J. Finkel, *Barring Ultimate Issue Testimony: An "Insane" Rule?* 15 L. & Hum. Behav. 495 (1991), <https://doi.org/10.1007/BF01650291>.

218. Insanity Defense Workgroup, *American Psychiatric Association Position on the Insanity Defense*, 140 Am. J. Psychiatry 681, 686 (1983), <https://doi.org/10.1176/ajp.140.6.681>; American Bar Association, ABA Criminal Justice Standards: Mental Health, Standard 7–6.6 (1984). See also Grisso, *supra* note 3, at 208; Fulero & Finkel, *supra* note 217, at 496.

Rev. 867 (2005); Michele Cotton, *A Foolish Consistency: Keeping Determinism Out of the Criminal Law*, 15 B.U. Pub. Int. L. J. 1, 21–23 (2005); Ric Simmons, *Conquering the Province of the Jury: Expert Testimony & the Professionalization of Fact-Finding*, 74 U. Cin. L. Rev. 1013 (2006).

220. Fed. R. Evid. 704. Pennsylvania's law offers a typical formulation: "Testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact." Pa. R. Evid. 704.

“Reasonable Degree of Certainty”

How much confidence do experts need in their opinion before they can state it in court? In many jurisdictions, experts are required to state their opinions to a “reasonable degree of certainty” within the standards of the relevant field, although such terminology is not required by the Federal Rules of Evidence, the Federal Rules of Criminal Procedure, or the Federal Rules of Civil Procedure. Further, such language is not mandated by *Frye*,²²¹ *Daubert*,²²² or *Kumho Tire*,²²³ and it is not clearly defined by any case law.²²⁴ Some state courts have held that the phrase is required as a prerequisite to the admissibility of expert evidence regardless of how certain an expert is in the opinion,²²⁵ while other state courts require a high degree of certainty and use of the phrase.²²⁶ The high courts of at least two states have indicated that the phrase is not required.²²⁷

There are several concerns with requiring use of the phrase “reasonable degree of [scientific, medical, psychological, etc.] certainty.” The phrase lacks a common definition across scientific disciplines and jurisdictions, and it has alternatively been defined or equated with more likely than not, more probable than not, 51% likelihood, preponderance of the evidence, clear and convincing evidence, and beyond a reasonable doubt.²²⁸ Such phrasing may also lend more credence to the testimony than is actually deserved, particularly when the testimony is presented in probabilistic terms, and it can be misleading to the factfinder about the level of objectivity involved in the analysis, its scientific reliability and limitations, and the ability of the expert to reach an

221. *Frye v. United States*, 293 F. 1013 (1923).

222. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993).

223. *Kumho Tire Co. v. Carmichael*, 526 U.S. 137 (1999).

224. The phrase “reasonable degree of certainty” was first applied to scientific evidence in 1935 when a witness was asked if he could determine, with reasonable scientific certainty, the cause of the capsizing of a boat. See *Herbst v. Levy*, 279 Ill. App. 353 (Ill. App. Ct. 1935). In that case, such phrasing was not a legal mandate but the stylistic approach of the lawyer. The phrase was linked to admissibility in 1969 in *Twin City Plaza, Inc. v. Central Surety & Insurance Corp.*, 409 F.2d 1195 (8th Cir. 1969), in which the U.S. Court of Appeals for the Eighth Circuit held that a witness’s testimony should only be admitted if, inter alia, it was based on reasonable scientific certainty.

225. In *Bertram v. Wunning*, 385 S.W.2d 803 (Mo. Ct. App. 1967), a medical expert’s testimony that he was 90% certain in his opinion was held to be insufficient because he refused to state that his opinion was offered to a reasonable degree of medical certainty.

226. In *Griffin v. Univ. of Pittsburgh Med. Center-Braddock Hosp.*, 950 A.2d 996 (Pa. Sup. Ct. 2008), an expert’s opinion, despite being offered to a reasonable degree of medical certainty, was held to be insufficient because the expert acknowledged being only 51% sure of his opinion.

227. See *Hawaii v. DeLeon*, 319 P.3d 282 (Haw. 2014); *Nebraska v. Johnson*, 290 Neb. 862 (2015).

228. See Gutheil & Appelbaum, *supra* note 69.

individualized conclusion. In short, such phrasing, without proper definition and guidance, is a relic of custom and practice that can invite confusion.²²⁹

Evaluating Evidence from Mental Health Experts

Up to this point, we have considered the kind of evidence that is likely to be offered by mental health experts and some of the challenges that such testimony presents. The remainder of the reference guide addresses the factors that should enter into the consideration of the value and impact of such testimony.

What Are the Qualifications of the Expert?

The appropriate qualifications of a mental health professional whose testimony is proffered will depend on the nature of the evidence to be presented. However, there are a number of relevant parameters that can be identified.

Training

Most mental health expert testimony is given by psychiatrists or doctoral-level clinical psychologists. Given the differences in the education and training of each profession, their testimony is not necessarily interchangeable. As a rule, psychiatrists are prepared by their training to speak to the diagnosis of mental disorders, including medical issues that may play a role in a particular case, and to treatment approaches, including psychopharmacological treatment.²³⁰ They

229. In 2016, the National Commission on Forensic Science made several recommendations to the U.S. attorney general regarding use of the phrase: (1) the attorney general should direct all attorneys appearing on behalf of the Department of Justice (DOJ) (a) to forego use of such phrases when presenting forensic testimony unless required by judicial authority as a condition of admissibility for a witness's opinion, and (b) to assert a legal position that such terminology is not required and is misleading; (2) the attorney general should direct all forensic experts employed by the DOJ not to use such language in reports or couch their testimony in such terms unless directed to do so by judicial authority; and (3) the attorney general should develop appropriate language that may be used by experts when reporting or testifying about results or findings based on observations of evidence and data derived from evidence. The full text can be found at <https://perma.cc/7GPX-C4RX>.

230. See discussion of psychiatrists' training in section titled "Psychiatrists" above.

should be capable of testifying, within the limits of existing knowledge and the information available to them, regarding the impact of a disorder on a person's behavior and functional abilities. Psychologists' training, in contrast, may provide deeper knowledge of the theoretical and experimental bases for understanding the function of the mind and the influences on behavior, both normal and abnormal.²³¹ As a general matter, doctoral-level clinical psychologists will be prepared by their training to provide evidence regarding diagnosis and psychotherapeutic treatment of mental disorders, the results of psychological and neuropsychological testing, and the roots of normal and abnormal behavior. More specifically, both psychiatrists and psychologists can subspecialize in forensic psychiatry and forensic psychology, respectively. These specializations include training in mental health evaluations conducted in the course of litigation, for the purpose of informing the court and/or helping the retaining attorney to present their case. Psychiatrists may formalize this specialization through a forensic psychiatry fellowship.²³² Psychologists can receive specialty training as part of their predoctoral or internship work and can also do a postdoctoral forensic fellowship.²³³

Although the core elements of training in psychiatry and psychology may be similar across training programs, the variability is substantial.²³⁴ Moreover, variation in subspecialty (in psychiatry) or specialty (in psychology) training—for example, in geriatric psychiatry or neuropsychology—contributes to further differentiation among experts. Thus, it may be necessary to inquire into the specific training of an expert. This is particularly true when an expert is testifying about topics that would ordinarily fall outside disciplinary boundaries—for example, a psychiatrist discussing the results of psychological testing or a psychologist offering evidence regarding the effect of medication on a person's behavior. The same is true for experts who are testifying beyond the range of their specialty or subspecialty training. In addition, in recent years expert testimony on mental health issues at times has been admitted from nonpsychiatric physicians and mental health professionals of other disciplines.²³⁵ These include

231. See discussion of psychologists' training in section titled "Psychologists" above.

232. American Academy of Psychiatry and the Law, Directory of Forensic Psychiatry Fellowships, <https://perma.cc/M9BG-ZEK3>.

234. See, e.g., Helena Hansen, Joel Braslow & Robert M. Rohrbaugh, *From Cultural to Structural Competency—Training Psychiatry Residents to Act on Social Determinants of Health and Institutional Racism*, 75 JAMA Psychiatry 117 (2018), <https://doi.org/10.1001/jamapsychiatry.2017.3894>; David A. Ross, Michael J. Travis & Melissa R. Arbuckle, *The Future of Psychiatry as Clinical Neuroscience: Why Not Now?*, 72 JAMA Psychiatry 413 (2015), <https://doi.org/10.1011/jamapsychiatry.2014.3199>; *The Oxford Handbook of Education and Training in Professional Psychology* (Nadine J. Kaslow & W. Brad Johnson eds., 2014).

235. *Campbell v. Metro. Prop. & Cas. Ins. Co.*, 239 F.3d 179 (2d Cir. 2001) (professor of pediatrics with substantial relevant publications found qualified to testify on neurological injuries resulting from lead paint exposure); *Carroll v. Otis Elevator Co.*, 896 F.2d 210 (7th Cir. 1990)

social work and nursing and could include other disciplines as well (e.g., master's-level psychologists, marriage and family therapists, physician assistants). One reasonable suggestion for qualifying experts involves applying a standard like that set forth in Rule 702²³⁶ (probable assistance to the trier of fact), in which the judge could consider both general training and more specific influences, such as specialized forensic training and/or experience, in deciding whether to qualify a given professional as an expert.²³⁷ These additional influences are considered in the following sections.

Experience

Experience is relevant to the qualifications of mental health experts in at least two ways. First, as the Federal Rules of Evidence recognize, experience may substitute for training as a basis for concluding that a witness has special expertise.²³⁸ Some experts in forensic psychiatry and forensic psychology, for example, lack formal training in conducting evaluations of the sort provided in forensic fellowships, because such training programs were not widely available at the time when senior forensic psychiatrists and psychologists were trained. In addition, formal training is difficult to obtain in some substantive areas of clinical psychiatry and psychology. Some professionals who acquire special knowledge about particular mental disorders will do so by pursuing their interest through reading, following the literature, continuing professional education, and through clinical contact with patients with the disorders, as opposed to formal training at the residency, fellowship, and/or predoctoral levels. Thus, experience must sometimes be relied upon as a stand-in for more formal training in some areas.

(experimental psychologist found qualified to give expert testimony on likelihood that product design would cause children to press escalator's emergency stop button); *United States v. Withorn*, 204 F.3d 790 (8th Cir. 2000) (trial court properly admitted testimony from midwife on alleged sexual assault on basis of bachelor's degree, some postgraduate work, and clinical experience). *But see* *United States v. Moses*, 137 F.3d 894 (8th Cir. 1998) (social worker lacked expertise to opine that victim of alleged child abuse would suffer trauma from facing the accused abuser in the courtroom).

236. "If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case." Fed. R. Evid. 702 (2000).

237. See Melton et al., *supra* note 1.

238. This may apply particularly to psychiatrists and psychologists who have not received formal forensic training but who have experience with individuals similar to the criminal defendant or civil litigant before the court.

The second way in which experience can be material to expert qualifications relates to the attrition of skills and knowledge over time. Mental health professionals often complete their training within several years of their thirtieth birthdays and may engage in practice, including the provision of expert testimony, over the subsequent four or five decades. Brief exposure to information about a particular disorder²³⁹ or some experience in evaluating and treating the condition may fade from memory several decades later without continued experience. Just as important is the possibility that additional knowledge about the condition has been gained in the interim and that additional knowledge will make an important contribution to the expert's evaluation. Training on a mental disorder or treatment, therefore, may be a necessary but insufficient aspect of an expert's qualifications in the absence of ongoing experience. Ongoing experience may include evaluating or treating patients with the disorder, teaching trainees how to assess or treat the disorder, systematically reviewing the literature on the disorder, attending continuing-education sessions about the disorder, conducting research on the disorder, and conducting forensic evaluations on individuals with the disorder.

But there is also a danger that experience can be overemphasized as a criterion of expertise. Assuming a baseline degree of adequate training and some ongoing experience in a field or with a condition, it is not clear that additional experience necessarily enhances an expert's authoritativeness. Experts will sometimes cite the number of evaluations they have performed of a particular type of evaluatee (e.g., alleged or convicted murderers) or of a given kind (e.g., assessments of competence to stand trial). However, if evaluations are performed inadequately or are unduly influenced by various cognitive biases,²⁴⁰ mere experience may

239. Although this discussion is framed in terms of a particular disorder, the condition at issue may not be a disorder in the formal sense. It may instead involve a symptom (e.g., auditory hallucinations), a mental state not linked to a specific disorder (e.g., dissociation), or a behavioral propensity (e.g., violent behavior). The argument in this section is generally applicable to all these categories of phenomena.

240. Cognitive biases in this context involve the systematic influence on human decision-makers under conditions of uncertainty, which describe the context in which forensic mental health assessments are conducted. Examples of such biases include confirmation bias (the tendency to selectively emphasize evidence consistent with an established position and de-emphasize evidence that refutes it), retention bias (favoring the side retaining the expert), and blind spot bias (the belief that cognitive biases do not apply to oneself in the same way they do to others). See, e.g., Itiel E. Dror, Saul M. Kassir & Jeff Kukucka, *New Application of Psychology to Law: Improving Forensic Evidence and Expert Witness Contributions*, 2 J. Applied Rsch. Memory & Cognition 78 (2013), <https://doi.org/10.1016/j.jarmac.2013.02.003>; Tess M. Neal & Stanley L. Brodsky, *Forensic Psychologists' Perceptions of Bias and Potential Correction Strategies in Forensic Mental Health Evaluations*, 22 Psych. Pub. Pol. & L. 58 (2016), <http://dx.doi.org/10.1037/law0000077>; Tess M. Neal et al., *A General Model of Cognitive Bias in Human Judgment and Systematic Review Specific to Forensic Mental Health*, 46 L. Hum. Behav. 99 (2022), <https://doi.org/10.1037/lhb0000482>. See generally, Tess M. Neal et al., *Psychological Assessments in Legal Contexts: Are Courts Keeping "Junk Science" Out of the Courtroom?* 20 Psych. Sci. Pub. Int. 135 (2020), <https://doi.org/10.1177/1529100619888860>.

only reinforce bad practice. Studies of the relationship between experience and the performance of mental health professionals in areas such as diagnosis²⁴¹ and bias management²⁴² have not demonstrated a relationship between superior performance and experience in either area. It may be that, despite having less clinical experience, recently trained clinicians are more familiar with the contemporary diagnostic framework and the research on cognitive bias and are less tempted to use their clinical experience as a substitute for generally accepted criteria (e.g., “I know schizophrenia when I see it, regardless of what the criteria say.”).

Licensure and Board Certification

Licensure

Possession of a valid professional license is usually a threshold requirement for an expert to be considered qualified in legal proceedings. Licensure of physicians (including psychiatrists) is governed by a licensure board in each state.²⁴³ Although criteria may differ, generally a physician who has graduated from an accredited American medical school, passed a sequence of tests designed to ensure adequate levels of knowledge and clinical judgment,²⁴⁴ and completed one or two years of residency training is eligible for full licensure.²⁴⁵ Prior to that, a temporary license allowing practice under supervision is usually issued. Graduates of medical schools that are not in the United States are usually subject to different standards, often being required to spend longer periods in residency training and undergoing individual review of qualifications. Once a physician attains licensure in a state, the process to acquire a license in another state varies. Some states grant additional licenses fairly easily; others, such as California, require that physicians take and pass a test of general medical knowledge if a certain period of time has passed (e.g., ten years in California) since the original sequence of testing was completed.²⁴⁶

241. Here, reliability is being used in its technical sense of agreement across more than one rater. For an example of the failure to find a consistent effect of previous experience, see, e.g., Sean H. Yutzy et al., *DSM-IV Field Trial: Testing a New Proposal for Somatization Disorder*, 152 Am. J. Psychiatry 97 (1995).

242. See Patricia A. Zapf et al., *Cognitive Bias in Forensic Mental Health Assessment: Evaluator Beliefs About Its Nature and Scope*, 24 Psych. Pub. Pol. & L. 1 (2018), <http://dx.doi.org/10.1037/law0000153>.

243. A summary of the requirements for medical licensure in each jurisdiction is available from the Federation of State Medical Boards at <https://perma.cc/8UG4-CQU8>.

244. See a description of the tests and the examination process at <https://perma.cc/J362-C26L>.

245. Federation of State Medical Boards, *supra* note 243.

246. Calif. Bus. & Pro. Code § 2184 (2021).

For clinical psychologists, standards for licensure differ somewhat by state, but generally after completion of an accredited Ph.D. program in the United States (including a one-year internship), they are required to complete one year of clinical work under the supervision of a licensed psychologist and pass a national licensure examination.²⁴⁷ Because the states do not restrict the practice of psychotherapy per se, but instead regulate the use of professional titles, an unlicensed psychologist can engage in many aspects of the clinical practice of psychology, including all forms of psychotherapy, but will not be able to use the title of psychologist. For psychologists who are seeking licensure in another jurisdiction, some states will grant reciprocity—that is, they will not engage in an independent process of reviewing the applicant’s credentials, relying instead on the review conducted by the initial licensure board.

Board Certification

Board certification represents qualifications beyond those required for licensure in either medicine or psychology. Although well-trained, competent psychiatrists may have reasons for not attaining board certification (e.g., examination anxiety that interferes with performance; a career centered on nonclinical research, for which clinical board certification is thought to be unnecessary), the tests are designed to be passed by a competent psychiatrist and do not require exceptional levels of clinical skill. Thus, in most cases, one can consider board certification as reflecting that a psychiatrist has attained adequate clinical competence for independent psychiatric practice. Whether a court chooses to admit testimony from a psychiatrist who has not been board certified may depend on the reasons a psychiatrist has not been certified and on the specific question(s) that the psychiatrist’s testimony will address.²⁴⁸

Professional psychology also has a board-certification process, administered by the American Board of Professional Psychology.²⁴⁹ Certification is only offered in psychology specialties, but these include such general clinical fields as

247. Details of requirements in each state can be found at the website of the Association of State and Provincial Psychology Boards at <http://www.asppb.net>.

248. For examples of the scope of judicial discretion on this issue, see, e.g., *Hall v. Quarterman*, 534 F.3d 365 (5th Cir. 2008) (finding that a state requirement that only a licensed expert may testify in a civil commitment hearing as to mental retardation did not extend to expert testimony on the same topic); *Oberlander v. Oberlander*, 460 N.W.2d 400 (1990) (reversing as abuse of discretion the trial court’s exclusion of expert testimony from a psychologist who was licensed in the neighboring state); *Williams v. Brown*, 244 F. Supp. 2d 965 (N.D. Ill. 2003) (finding that psychiatrists who were not board-certified child psychiatrists may nonetheless testify about the condition of juvenile plaintiffs).

249. A description of the process and eligibility requirements for the examination process can be found at <https://perma.cc/D2ES-YCRS>.

clinical, counseling, and group psychology. As in subspecialty certification in psychiatry, candidates are expected to demonstrate advanced competence in the specialty area, defined specifically for each specialty. Board certification is far less common among psychologists than psychiatrists, in part because board certification is an expected part of the credentialing process in psychiatry, but it is not in psychology.²⁵⁰ It is therefore less likely that certification will be applied as a minimum standard for expert testimony in psychology than in psychiatry or other areas of medicine.

Specialty credentialing can be obtained in forensic psychiatry (from the American Board of Psychiatry and Neurology²⁵¹) and forensic psychology (from the American Board of Professional Psychology²⁵²). This particular specialization is often the most relevant to legal proceedings, as candidates must demonstrate the requisite post-training experience, competence in clinical areas, and knowledge of relevant law that guides forensic evaluations.²⁵³ Other board certification specialty areas in psychology (e.g., clinical psychology, clinical neuropsychology, police and public safety) and psychiatry (e.g., adult psychiatry, addiction psychiatry, child and adolescent psychiatry) may also be applicable, depending on the nature of the legal questions.

Prior Relationship with the Subject of the Evaluation

Some attorneys, judges, and jurors may presume that a mental health professional who has had a treatment relationship with the person whose mental state is in question is better qualified to testify about aspects of that mental state than an evaluator who is meeting the person for the first time. The logic seems strong: A professional who has known the person for some period of time should be better able to offer conclusions about the person's diagnosis and treatment requirements and the impact of the person's mental state on function and behavior. So it may seem surprising that the ethics guidelines of both the American Academy of Psychiatry and the Law (the leading organization of forensic psychiatrists) and the American Psychological Association point to problems

250. Approximately 85% of psychiatrists become board certified in the eight years following completion of residency training. Dorthea Juul, James H. Scully Jr. & Stephen C. Scheiber, *Achieving Board Certification in Psychiatry: A Cohort Study*, 160 Am. J. Psychiatry 563 (2003), <https://doi.org/10.1176/appi.ajp.160.3.563>. In contrast, it was estimated that in 2000 only 3.5% of psychologists had achieved board certification. Frank M. Dattilio, *Board Certification in Psychology: Is It Really Necessary?* 33 Pro. Psych. Rsch. & Prac. 54 (2002), <https://doi.org/10.1037/0735-7028.33.1.54>.

251. See <https://perma.cc/VH4H-6GUW>.

252. See <https://perma.cc/D2ES-YCRS>.

253. See, e.g., Melton et al., *supra* note 1; Gutheil & Appelbaum, *supra* note 69.

inherent in such situations (the *Ethical Principles of Psychology and Code of Conduct*,²⁵⁴ broadly applicable to all psychology, and the *Specialty Guidelines for Forensic Psychology*,²⁵⁵ which applies to the practice of psychology in legal contexts).²⁵⁶ Although none of these guidelines state that giving testimony about current or former patients is clearly unethical, they each offer words of caution and discourage clinicians from playing both clinical and expert roles.²⁵⁷

The professional literature on this issue, and the ethics guidelines themselves, cite several reasons why having a treating professional perform the evaluation for legal purposes may not be prudent.²⁵⁸ First, offering testimony, even if it is supportive of the patient's legal claim, may interfere with the therapeutic relationship.

254. American Psychological Association, *Ethical Principles of Psychologists and Code of Conduct* (2017). See <https://perma.cc/YYP9-3NR6>.

255. APA Specialty Guidelines, *supra* note 71.

256. *Id.*

257. The forensic psychiatry guidelines explicitly discourage this practice:

Psychiatrists who take on a forensic role for patients they are treating may adversely affect the therapeutic relationship with them. Forensic evaluations usually require interviewing corroborative sources, exposing information to public scrutiny, or subjecting evaluatees and the treatment itself to potentially damaging cross-examination. The forensic evaluation and the credibility of the practitioner may also be undermined by conflicts inherent in the differing clinical and forensic roles. Treating psychiatrists should therefore generally avoid acting as an expert witness for their patients or performing evaluations of their patients for legal purposes.

Forensic Psychiatry Guidelines, *supra* note 70, at IV. In contrast, the *Specialty Guidelines for Forensic Psychology* could be seen as somewhat more permissive:

A multiple relationship occurs when a forensic practitioner is in a professional role with a person and, at the same time or at a subsequent time, is in a different role with the same person; is involved in a personal, fiscal, or other relationship with an adverse party; at the same time is in a relationship with a person closely associated with or related to the person with whom the forensic practitioner has the professional relationship; or offers or agrees to enter into another relationship in the future with the person or a person closely associated with or related to the person (EPPCC Standard 3.05). Forensic practitioners strive to recognize the potential conflicts of interest and threats to objectivity inherent in multiple relationships. Forensic practitioners are encouraged to recognize that some personal and professional relationships may interfere with their ability to practice in a competent and impartial manner and they seek to minimize any detrimental effects by avoiding involvement in such matters whenever feasible or limiting their assistance in a manner that is consistent with professional obligations.

APA Specialty Guidelines, *supra* note 71, at 4.02.

258. Larry H. Strasburger, Thomas G. Gutheil & Archie Brodsky, *On Wearing Two Hats: Role Conflict in Serving as Both Psychotherapist and Expert Witness*, 154 Am. J. Psychiatry 448 (1997), <https://doi.org/10.1176/ajp.154.4.448>; Ronald Schouten, *Pitfalls of Clinical Practice: The Treating Clinician as Expert Witness*, 1 Harv. Rev. Psychiatry 64 (1993), <https://doi.org/10.3109/10673229309017058>; Stuart Greenberg & Daniel Shuman, *Irreconcilable Conflict Between Therapeutic and Forensic Roles*, 28 Pro. Psych.: Rsch. & Prac. 50 (1997), <https://doi.org/10.1037/0735-7028.28.1.50>; Gutheil & Appelbaum, *supra* note 69, at 243–47.

Second, the underlying assumption about the desirability of having the clinician testify may be flawed. Although the clinician may have known the person as a patient, the clinical process may never have required the clinician to collect the type of information that would be relevant to the legal question. Even if that information were discussed, the treating clinician is less likely to have approached it with the degree of caution that a forensic evaluator would be likely to employ or to have attempted to verify the information through collateral sources. Even after agreeing to participate as an expert witness, a clinician may be unaware of the importance of assessing the veracity of the person's claim or may be afraid that doing so could lead to strains in the therapeutic relationship.

A third problem is that the clinician, having formed an alliance with the person as a patient perhaps over a considerable period of time, may feel a natural allegiance to that person and a desire, even if not conscious, to support the person's contentions in the case. Thus, evidence presented may be subtly distorted or consciously manipulated by clinicians who see their role as being a patient's advocate.

Fourth, there is an ethical problem when a clinician is subpoenaed to testify over the patient's objection. The preexisting therapeutic relationship was premised on the information that the patient revealed being used for treatment purposes. Being subpoenaed to testify over the patient's objection places a clinician whose testimony cannot support the person's legal claim in an extremely awkward position, compelled now to use that information potentially to the patient's detriment.²⁵⁹

In contrast, therefore, to what might seem like the logical assumption—that a treating clinician is best qualified to testify regarding the patient—there are multiple reasons not only to avoid relying on treating clinicians, but to discourage them from serving as expert witnesses.

How Was the Assessment Conducted?

The reliability and validity of an expert's opinion on mental health issues depends greatly on how the assessment that forms the basis for the conclusions was conducted.

259. Although all states have psychotherapist-patient and/or physician-patient testimonial privilege statutes that limit testimony by treating psychiatrists and psychologists (and often other mental health professionals) without the patient's consent, the exceptions in many of these statutes—including the so-called patient-litigant exception that is invoked when patients place their mental state at issue in a case—are sufficiently numerous that this situation cannot be ruled out. *Jaffee v. Redmond*, 518 U.S. 1 n.13 (1996); Christopher B. Mueller et al., § 5.35 Psychotherapist-Patient Privilege, GWU Legal Studies Research Paper No. 2018–68 (2018).

Was the Evaluatee Examined in Person?

Given the range of cases in which mental health experts provide testimony and the various questions they must respond to, there are situations in which experts provide evidence without having examined the person about whom they are testifying.²⁶⁰ These circumstances may arise when direct evaluation is impossible—for example, in contests over testamentary capacity, where often a claim regarding a testator’s capacity will be litigated only after the person is deceased. Other civil litigation that can raise questions about the state of mind of a deceased person includes contractual capacity, wrongful death, and medical malpractice claims.²⁶¹ Testimony about a person who cannot be evaluated directly is less likely in criminal cases, but highly contentious examples occurred in death penalty cases in Texas: Defendants have the right to decline evaluation by prosecution experts,²⁶² but those experts may testify on the basis of a hypothetical question that incorporates some of the facts of the defendants’ history and behavior.²⁶³

Conclusions about persons who have not been directly examined may be drawn on the basis of available records, including medical, mental health, police, educational, armed services, and other records; information from informants who have been or are in contact with the person, which the expert may derive from interviews, prior testimony, depositions, police reports, and other sources; and on some occasions, the expert’s observations of the person’s behavior, for example, in a prison or courtroom setting.²⁶⁴ Although it may be possible to draw valid conclusions on the basis of such data, these conclusions are generally

260. On some occasions, testimony will provide contextual information for the decision-maker—for example, how a person in a given situation or with a given disorder would usually respond, without being applied directly to a specific person. John Monahan & Laurens Walker, *Social Science in Law: Cases and Materials* (10th ed. 2022).

261. Farnsworth, *supra* note 9, § 3:11. For a case study of the use of postmortem analysis in the USS *Iowa* explosion investigation, see Charles Patrick Ewing & Joseph T. McCann, *Minds on Trial: Great Cases in Law and Psychology* 129–39 (2006); *Moon v. United States*, 512 F. Supp. 140 (D. Nev. 1981) (finding that hospital psychiatrists were negligent in diagnosing with schizophrenia a patient who later committed suicide); *Urbach v. United States*, 869 F.2d 829 (5th Cir. 1989) (finding no medical malpractice where a mental patient on furlough from a VA hospital was arrested and beaten to death in a Mexican prison). See also Norman Poythress et al., *APA’s Expert Panel in the Congressional Review of the USS Iowa Incident*, 48 Am. Psych. 8 (1993), <https://doi.org/10.1037/0003-066X.48.1.8>.

262. *Estelle v. Smith*, 451 U.S. 454 (1981).

263. *Barefoot v. Estelle*, 463 U.S. 880 (1983); *Satterwhite v. Texas*, 486 U.S. 249 (1988).

264. Kirk Heilbrun et al., *Third-Party Information in Forensic Assessment*, in 11 *Handbook of Psychology: Forensic Psychology* 69 (Alan M. Goldstein ed., 2003). Testimony offered in capital sentencing contexts without examining the defendant has been particularly controversial. See, e.g., *Bennett v. State*, 766 S.W.2d 227, 232 (Tex. Crim. App. 1989) (Teague, J., dissenting) (“[W]hen Dr. Grigson testifies at the punishment stage of a capital murder trial he appears to the average lay juror . . . to be the second coming of the Almighty. . . . Dr. Grigson is extremely good at

more limited and have a lesser degree of certainty than when a direct evaluation has taken place. The ethics statements of the major forensic psychiatry and forensic psychology organizations offer words of caution about such testimony,²⁶⁵ and there are several reasons why caution is warranted.

One can think of expert knowledge in mental health as comprising two components: knowing how to conduct an evaluation to obtain relevant information and knowing how to weigh that information to reach a conclusion.²⁶⁶ When an expert cannot carry out an examination of the person, the expert must rely on information accumulated by others, sometimes for other purposes. It is very unlikely that all the data that the expert would have wanted to obtain will be available in such circumstances. This is true even with data gathered by another mental health professional (e.g., in medical or mental health records), because that person may not have asked all the questions that the testifying expert would have asked, fully recorded the responses, and considered the possibility of exaggeration or minimization by the individual being evaluated. The intangible aspects of an evaluation, including the person's relatedness, emotions, and degree of cooperation, may be especially difficult to convey. Because many of the diagnostic categories require that other possibilities have been excluded first,²⁶⁷ the

persuading jurors to vote to answer the [future dangerousness] issue in the affirmative.”); *They Call Him Dr. Death*, Time, June 1, 1981; Rosenbaum, *supra* note 166.

265. In the *Ethics Guidelines for the Practice of Forensic Psychiatry*, the American Academy of Psychiatry and the Law notes:

For certain evaluations (such as record reviews for malpractice cases), a personal examination is not required. In all other forensic evaluations, if, after appropriate effort, it is not feasible to conduct a personal examination, an opinion may nonetheless be rendered on the basis of other information. Under these circumstances, it is the responsibility of psychiatrists to make earnest efforts to ensure that their statements, opinions and any reports or testimony based on those opinions, clearly state that there was no personal examination and note any resulting limitations to their opinions.

Forensic Psychiatry Guidelines, *supra* note 70, at IV.

The comparable guidelines for forensic psychology state,

Forensic practitioners recognize their obligations to only provide written or oral evidence about the psychological characteristics of particular individuals when they have sufficient information or data to form an adequate foundation for those opinions or to substantiate their findings (EPPCC Standard 9.01). Forensic practitioners seek to make reasonable efforts to obtain such information or data, and they document their efforts to obtain it. When it is not possible or feasible to examine individuals about whom they are offering an opinion, forensic practitioners strive to make clear the impact of such limitations on the reliability and validity of their professional products, opinions, or testimony.

APA Specialty Guidelines, *supra* note 71, at 9.03.

266. Paul S. Appelbaum, *Hypotheticals, Psychiatric Testimony, and the Death Sentence*, 12 Bull. Am. Acad. Psychiatry & L. 169 (1984); see also Am. Psychiatric Ass'n amicus brief in *Barefoot*, 463 U.S. at 880.

267. For example, DSM-5-TR criteria for major depressive disorder require both that the symptoms on which a diagnosis is based not be due to the direct physiological effects of a drug (licit

absence of pertinent negative information (e.g., the person does not misuse substances) can restrict the ability to make definitive diagnoses and draw other relevant conclusions. Moreover, these problems are compounded when the data available to the expert have been shaped by someone with an interest in the outcome of the case, as when an expert testifies in sole reliance on information in a hypothetical question that is constructed to support the interests of one party in the litigation.

Thus, the major professional organizations in forensic mental health agree that evidence based on sources other than direct evaluation of the person should be framed with due regard for its limitations and that experts should make those limitations clear in their reports or testimony. An expert witness's failure to do so may be unethical and should probably cast doubt on the credibility of the evidence presented.

Did the Evaluatee Cooperate with the Assessment?

Even when a direct evaluation has taken place, the evaluatee's degree of cooperativeness may affect the validity of the data.²⁶⁸ Civil plaintiffs and criminal defendants have obvious reasons to distrust experts who are examining them on behalf of adverse parties and may be less than forthcoming (or provide information that is inaccurate). But even when an evaluation is being conducted by an expert retained by the person's own attorney, the person's cooperativeness may be limited by the symptoms of the disorder. For example, a person who is experiencing paranoid delusions may be suspicious and fearful even of an expert with whom that person's own attorney encourages cooperation (and even of the attorney). It is therefore important for the expert to clarify, when presenting evidence and conclusions based on the evaluation, the extent to which the evaluatee cooperated with the examination process. If the examinee was less than cooperative, it is also useful for the evaluator to explain why that might have been, and to describe the impact on the information gathered and the steps taken (often relying on other sources of information) to compensate for this lack of cooperation.

or illicit) that has been ingested or to a general medical condition; that they not be better accounted for by bereavement after the death of a loved one; and that the person has never experienced a manic or hypomanic episode. DSM-5-TR, *supra* note 72, at 183. Other major diagnostic categories carry similar requirements to rule out the possibility that the person's presentation is due to other causes before making the diagnosis in question.

268. Melton et al., *supra* note 1.

Was the Evaluation Conducted in Adequate Circumstances?

Mental health evaluations often involve discussions of sensitive material, including histories of abuse, use of illegal substances, sexual practices, intimate fears and fantasies, and potentially embarrassing symptoms. Some evaluations may also involve discussion of alleged or acknowledged criminal conduct. Although some persons may be reluctant to speak freely about these issues with an evaluator they barely know—and who may reveal this information in the courtroom—the reassurance that they are talking with a mental health professional often substantially mitigates those concerns.²⁶⁹ However, an evaluation conducted in a setting that is less than private lowers the likelihood of examinee disclosures.²⁷⁰ This is often a problem in correctional institutions, where interviews may be conducted in a place where correctional officers or other inmates can overhear them. Medical hospitals are another location where privacy may be compromised, with nursing staff or other patients nearby. Even if no one is within earshot, interview sites that are noisy or subject to other distractions may interfere with the evaluatee's ability to attend to the questions and respond accurately; this can be a particular problem for people with mental disorders that may impair concentration and attention. Whenever possible, a competent evaluator tries to obtain a venue that is free of these intrusions, and when it is not possible, the situation should be noted as a limitation on the completeness of the evaluation in the report or testimony. This challenge was exacerbated during the Covid-19 era, during which time remotely conducted evaluations became more frequent. During remote evaluations, an examiner can be less certain about who is within hearing range and may need to rely on the account of the individual examined as well as any available staff member regarding whether there is privacy.

Attorneys sometimes ask to sit in on an evaluation. Their presence can raise similar concerns, even when they are representing the person being evaluated, because the type of information discussed in a mental health evaluation may be quite different from what a client usually discloses to an attorney.²⁷¹ Particularly

269. There is some research on the question of whether evaluatees may too easily be induced to speak frankly with someone who is introduced as a mental health professional, but whose role is very different than would obtain in treatment settings and who may reach opinions adverse to the person's interests. See, e.g., Daniel Shuman, *The Use of Empathy in Forensic Evaluations*, 3 *Ethics & Behav.* 289 (1993), <https://doi.org/10.1080/10508422.1993.9652109>; Strasburger et al., *supra* note 258; Greenberg & Shuman, *supra* note 258.

270. Melton et al., *supra* note 1. Distraction can be a particular problem when formal psychological tests are used; see, e.g., Kirk Heilbrun, *The Role of Psychological Testing in Forensic Assessment*, 16 *L. & Hum. Behav.* 257 (1992), <https://doi.org/10.1007/BF01044769>.

271. Robert I. Simon, "Three's a Crowd": *The Presence of Third Parties During the Forensic Psychiatric Examination*, 24 *J. Psychiatry & L.* 3 (1996), <https://doi.org/10.1177/009318539602400102>.

when the examination is being conducted by an expert for an adverse party, attorneys may be tempted to object to questions or signal their clients regarding their answers. To help mitigate this, if an attorney is present, as is sometimes unavoidable, the ground rules should include that the attorney sits out of the line of sight of the evaluatee and does not interrupt the examination. An alternative is to have the evaluation audiotaped or videotaped, a technique that some experts routinely use. There is a lack of data on the impact of taping on evaluatees' willingness to be forthcoming, but experienced forensic examiners have expressed the view that evaluatees rapidly adjust to the recording equipment, with little impact on the evaluation.²⁷²

A final consideration is the amount of time available for the examination.²⁷³ Time constraints may result from correctional rules (e.g., prisoners are available only during given periods of time; the availability of equipment used to conduct a remote evaluation is limited relative to the demand), medical illnesses or mental disorders (e.g., the evaluatee has limited strength or attention), or limitations on resources (e.g., the party employing the expert has funds only for a certain number of hours of work). Appropriate duration of an examination is likely to depend on the questions being asked, the complexity of the person's history and presentation, and the person's cooperation with the evaluation. The duration of an examination, standing alone, is not a good indicator either of its quality or of the validity of the conclusions that were drawn. But an expert should be able to assess the time necessary to perform an adequate evaluation and, if sufficient time is not available, should indicate the limitations on the resulting opinions.

Were the Appropriate Records Reviewed?

The importance of the evaluator having access to the person's records will vary somewhat depending on the legal question being addressed, but it can often be critical to the validity of the evaluation.²⁷⁴ When retrospective assessments are being conducted—for example, an evaluation of a defendant's state of mind at the time of a crime that occurred months to years before the examination, or an assessment of a person's capacity to enter into a contract at some distant prior date—reviewing contemporary or nearly contemporary records can provide crucial insights into the person's symptoms and functioning at that time. But even when contemporaneous function or future behavior is being assessed,

272. AAPL Task Force, *Videotaping of Forensic Psychiatric Evaluations*, 27 J. Am. Acad. Psychiatry & L. 345 (1999).

273. Melton et al., *supra* note 1, at 47.

274. Heilbrun et al., *supra* note 264; see also discussion in section titled "Data Collection and Sources of Information" above.

having access to available records may still be of great importance. Because distinctions between mental disorders can depend in part on the pattern of symptoms over time, accurate diagnosis is often dependent on having a view of the person's prior psychiatric history.²⁷⁵ In addition, when malingering or defensiveness are active considerations, as they often are, the consistency of the person's presentation over time can be an important factor in the assessment.²⁷⁶ And given that past behavior is generally the best predictor of future behavior, especially where violence is concerned, knowledge of a person's previous history can be essential for predictions of reasonable accuracy.²⁷⁷ Thus, regardless of the focus of the evaluation, an effort should be made to obtain all relevant available records.

Which records are relevant will depend somewhat on the legal question being asked.²⁷⁸ Whenever possible, records of past mental health evaluations or treatment should be obtained. Medical records often contain information about psychiatric symptoms, alcohol and drug use, and functional levels, and thus can be useful. Educational, work, and military records can usefully inform both patterns of symptoms and functional impairment. Educational records may be especially helpful where disorders of early onset are suspected, and work and military records are often useful when occupational disability is at issue. In criminal cases, particularly those involving assessments of the defendant's state of mind at the time of the crime, police records can often be valuable, including interviews with witnesses or the defendant, and the results of physical evaluations—including pictures—of the crime scene. It can be helpful to compare the data obtained by these means with the defendant's accounts of the episode that led to the arrest. Diaries or other accounts written by the person whose mental state is at issue are sometimes available and, to the extent they were generated prior to the initiation of legal proceedings, can be enlightening regarding the person's state of mind and motivation, the influence of third parties, and the like. When there has been prior litigation involving the person being evaluated, depositions or transcripts of testimony can be helpful for information about state of mind and factual data. Records of prior incarceration are useful in appraising likely adjustment and possibly response to rehabilitative interventions if the evaluatee is again incarcerated.

275. Diagnosis and subcategorization of bipolar disorder, for example, are dependent not only on assessing the person's current symptoms—whether manic or depressed—but also on ascertaining whether mania or depression was present in the past if it is not apparent at present. See DSM-5-TR, *supra* note 72, at 139–43.

276. See generally section titled “Response Style” above.

277. See generally section titled “Predictive Assessments” above.

278. See, e.g., Melton et al., *supra* note 1.

Was Information Gathered from Collateral Informants?

In addition to reviewing records, interviewing informants with relevant data can provide important perspectives on the person being evaluated.²⁷⁹ Family members, friends, and coworkers often can report on patterns of behavior indicative of symptoms of mental disorder or functional impairment. They may know about prior behavioral health treatment or histories of involvement with the criminal justice system. Current or former therapists can share useful impressions of diagnosis and comment on levels of function and response to treatment, although to the extent that their interactions with the person are subsumed under a psychotherapist-patient or physician-patient privilege, and do not fall under one of the exceptions in that jurisdiction, it may not be possible to contact them without the person's consent. Witnesses to an alleged crime or workplace harassment can similarly round out a picture of the person and help to confirm or disconfirm the evaluator's impressions. Access to collateral informants may be complicated by legal restrictions or, if they are close to the person being evaluated, by their reluctance to speak to an expert working for an adverse party. When contact does occur, the evaluator needs to consider possible distortions by the informant in the service of helping, or sometimes of harming, the interests of the person who is the subject of the evaluation. These challenges notwithstanding, collateral interviews can provide valuable historical and current information that is often difficult or impossible to obtain from records.

Were Medical Diagnostic Tests Performed?

Dualistic views of human behavior, in which mind and body are seen as distinctly separate entities, have been rejected by scientists who study thought and behavior and clinicians who treat behavioral health disorders.²⁸⁰ The relevant fields, including cognitive science, neuroscience, psychology, psychiatry, and philosophy, now acknowledge the brain as the seat of mentation and behavior and recognize that all mental phenomena, including abnormal mental states, result from perturbations in the function of the brain. At some level, there must be a physical concomitant of every mental phenomenon, and sometimes the physical influences on abnormal behavior are gross enough to be detected by existing techniques, which may reveal potentially treatable conditions. Thus, to identify the causes of abnormal thought or behavior and formulate a diagnosis

279. Heilbrun et al., *supra* note 264.

280. See, e.g., Kenneth S. Kendler, *Toward a Philosophical Structure for Psychiatry*, 162 Am. J. Psychiatry 433 (2005), <https://doi.org/10.1176/appi.ajp.162.3.433>.

may require an evaluation of a person's physical state, along with the mental state.²⁸¹ If there is any reason to suspect that an identifiable general medical disorder lies at the root of a person's condition (e.g., a sudden and unprecedented appearance of symptoms, disproportionate impairment of aspects of cognitive function), medical testing, including electroencephalograms (EEGs) and imaging studies, may be indicated.²⁸² Any medical diagnostic testing should be justified based on its relevance to the evaluation. Persons without medical training are typically not able to order or interpret the results of medical tests, which will require referral to a health professional if indicated.

Was the Evaluatee's Functional Impairment Assessed Directly?

As previously discussed, mental health evidence will often focus on the extent to which a person is capable of performing a particular task or set of tasks, and a person's impairment on one or more functional abilities.²⁸³ Sometimes an evaluator will be able to infer from an examination of the person's mental state and information from other sources whether the person is or was capable of performing the task at hand (e.g., standing trial, returning to work, managing property). However, direct assessment of the relevant function is another option for evaluation.²⁸⁴ Where a functional ability is at issue that relates to a discrete task or set of tasks, a competent evaluator should have considered using direct assessment of the person's performance of those tasks and should be able to explain any decision not to do so. It should be noted, though, that conclusions drawn even from direct assessments of function require some inference. A person claiming occupational impairment as a result of anxiety induced by long-standing harassment on the job, for example, might respond very differently to the demands of a

281. See generally section titled "Diagnosis of Mental Disorders" above.

282. Identification of structural or electrical abnormalities, however, does not necessarily imply that these things impaired the person's functioning or were responsible for the person's behavior. For discussion of a well-known case in which this issue was raised, see Stephen Morse, *Brain and Blame*, 84 Geo. L. J. 527 (1996). For a more general discussion of the introduction of findings of abnormalities demonstrated on brain imaging in court, see Dean Mobbs, *Law, Responsibility and the Brain*, 5 PLoS Biology 693 (2007), <https://doi.org/10.1371/journal.pbio.0050103>. As with structural findings, the mere presence of a functional abnormality is insufficient to establish a causal link to the person's mentation or behavior. There are growing legal and neuroscience literatures on the use of functional imaging data in court. See, e.g., Darby Aono, Gideon Yaffe & Hedy Kober, *Neuroscientific Evidence in the Courtroom: A Review*, 4 Cognitive Rsch. 1 (2019), <https://doi.org/10.1186/s41235-019-0179-y>; Jane Campbell Moriarty, *Neuroimaging Evidence in U.S. Courts*, in *Law and Mind: A Survey of Law and the Cognitive Sciences* (Bartosz Brozek et al. eds., 2021).

283. See generally section titled "Functional Impairment Due to Mental Disorders" above.

284. See section titled "Assessment of Functional Legal Capacities" above.

work-related task in the actual workplace compared to the safe confines of a mental health professional's office. Therefore, when employing direct assessment of functional capacity, the evaluator should be prepared to comment on the ecological validity of the test, that is, the degree to which the testing environment resembled the real-world environment in the person's life.²⁸⁵ Although observations in very different settings may have some value as part of the broader data set available in an evaluation, they do not carry the same weight as conclusions reached in environments similar to those at issue in the case.

Was the Possibility of Malingering or Defensiveness Considered?

In almost every mental health evaluation for legal purposes, the person being evaluated has an incentive to exaggerate or fabricate symptoms, to minimize or deny symptoms, or to distort the impact of actual symptoms on the person's functional abilities.²⁸⁶ The evaluator should consider the possibility of malingering or denial in every assessment, depending on the nature of the incentive. Techniques for appraising these different response styles were described earlier.²⁸⁷ Although these techniques are not foolproof, and well-prepared evaluatees can sometimes mislead mental health professionals on the existence or severity of disorders, successful malingering or minimizing over time are difficult tasks. Uncovering distortions of the degree of actual symptoms or of their impact is usually more challenging than detecting wholesale invention of disorders that are not present or adamant denials of disorders that are. Competent evaluators should be able to explain how they considered the possibility of distorted responding and why they believe that their conclusions are valid, while acknowledging that their degree of certainty can never be absolute.

285. Additional issues related to the use of functional tests are discussed below in the section titled "Was a Structured Diagnostic or Functional Assessment Instrument or Test Used?"

286. There are particular situations in which the incentive runs toward defensiveness rather than malingering. For example, a defendant facing relatively minor charges for whom an evaluation of competence to stand trial was ordered may have every reason to minimize the level of symptoms, preferring to go to trial quickly rather than spend an extended period of time in a psychiatric facility being treated to restore competence. A second example is a defendant whose risk for violence is being evaluated prior to a bail hearing, who also has a powerful incentive to downplay the presence of risk factors associated with violence and to minimize a past history of violence.

287. See section titled "Response Style" above.

Was a Structured Diagnostic or Functional Assessment Instrument or Test Used?

Notwithstanding the advantages of structured assessment techniques, they raise a set of concerns that must be addressed to determine their relevance to the question at issue and the weight that should be given to their results.

Has the Reliability and Validity of the Instrument or Test Been Established?

Reliability and validity are key concepts in test development.²⁸⁸ Each contains several subcategories. Reliability refers to the reproducibility of results obtained with a particular test. In other words, it is an estimate of the precision of an assessment technique. Interrater reliability is a measure of whether different examiners using the same test or instrument with the same subject obtain similar results, an important characteristic for an assessment approach that will be used by many raters. Test–retest reliability assesses the stability of results from an instrument or test over time; poor correspondence of results between time periods may indicate either an unreliable technique or a condition subject to periodic changes in status. It is an axiom of test and instrument development that good reliability is a prerequisite for having a valid assessment technique, but does not in itself guarantee validity.

Validity connotes the degree to which an instrument or test yields results that accurately reflect reality. Construct validity refers to the extent that an instrument or test reflects the theoretical construct that it purports to measure (e.g., anxiety or depression). Elements of construct validity include discriminant validity, which is the degree to which the test distinguishes between related conditions or states, and convergent validity, the extent to which the results of this test resemble results of other instruments that assess the same or a similar construct. Content validity describes the adequacy or thoroughness with which a test has sampled the variables associated with a given domain (e.g., does a measure of ability to work assess all relevant aspects of a given occupation?). Finally, predictive validity denotes the ability of an instrument or test to foretell a person's condition or behavior at some point in the future.

When the results of an evaluation using an instrument or test are offered in evidence, clarifying the extent to which reliability and validity have been

288. For the discussion in the following two paragraphs, see generally American Psychological Association, *Standards for Educational and Psychological Testing* (2014).

demonstrated is an essential aspect of determining admissibility and weight. In *Daubert*, when the U.S. Supreme Court referred to the reliability of a scientific technique, it was encompassing both reliability and validity as usually understood in the behavioral sciences.²⁸⁹ Which aspects of reliability and validity are relevant to a particular case will depend on the purpose for which the data from the test are being introduced. For example, if the evidence is addressing change in a person's test results over time, a measure's test-retest reliability becomes crucial. If more than one evaluator was involved, interrater reliability may be key. Discriminant validity will be relevant when two states or conditions must be distinguished from each other and predictive validity when forecasts of future mental state or behavior are being made. Careful evaluators will use only instruments or tests that have had the relevant types of reliability and validity confirmed in peer-reviewed publications, and they will be prepared to cite such data should questions be raised. Of course, some tests are so widely used over a sustained period that their reliability and validity are generally accepted (e.g., the MMPI-3). However, the reliability and validity of some long-standing tests (e.g., the Rorschach test) remain controversial,²⁹⁰ and data even from established tests can be used to reach conclusions of uncertain validity. Thus, novel uses of instruments or tests may also require demonstration of their psychometric characteristics for that purpose.

Functional assessment instruments are validated using outcomes involving the capacity to perform in a way that is directly relevant to the legal demands.²⁹¹ The reliability and validity of such a measure should be described in a manual that is either commercially available (along with the measure itself) to qualified professional purchasers, or available on a website or other publicly available source that describes the research establishing its reliability and validity.

Does the Person Being Evaluated Resemble the Population for Which the Instrument or Test Was Developed?

Even when present for one population, reliability and validity do not necessarily apply to those in a different population. If an assessment technique is being used

289. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579, 589 (1993).

290. Scott O. Lilienfeld, James M. Wood & Howard N. Garb, *The Scientific Status of Projective Techniques*, 1 Psych. Sci. Pub. Int. 27 (2000), <https://doi.org/10.1111/1529-1006.002>.

291. For example, a functional assessment instrument for competence to stand trial would measure capacities such as the ability to understand legal charges and how the legal system functions, assist counsel through communication and appropriate behavior during a legal proceeding, and make decisions regarding the options for plea. See, e.g., Grisso, *supra* note 3.

on someone from a different population than the one for which the instrument or test was developed, and the new group is likely to differ in some material way, reliability or validity may need to be reestablished. An example with regard to reliability might be using an instrument with a child that was developed to measure symptoms of mental disorders in adults.²⁹² Either the nature of the symptoms that adults experience or the ability of adults to describe their symptoms could be substantially different for children. Thus, it might be prudent for an evaluator to ascertain that data exist showing good reliability in this new population before using the assessment approach. An example involving validity is using predictive scales, such as instruments to assess violence risk, with a different group than the one on which the predictive algorithm was derived.²⁹³ Concretely, if a predictive test is based on a group of justice-involved individuals without serious mental illness, applying it to persons with serious mental illness—for whom different variables may affect behavior—is dubious in the absence of data demonstrating its validity in the latter group.

It should be emphasized, however, that reestablishing reliability and validity is necessary only when the original group and the new population are likely to differ in a relevant way. Why an instrument developed in California, for example, would not be as reliable and valid when used in Texas is not at all clear. The nature of the instrument or test also plays a role. Diagnostic tests are likely to differ in their characteristics across populations only if the disorders or the ways in which they manifest are different, which will not usually be the case. Predictive tests, however, may be more sensitive to cultural, socioeconomic, geographic, and other considerations that could introduce other influences on future conditions or behaviors. In addition, tests that involve comparisons with broader populations are said to be normed using those groups,²⁹⁴ and the comparative data (e.g., the evaluatee is in the lowest quartile of performance) may be invalid unless the test is renormed for the group of which the person is a member. The use of such tests in a clinical context, such as diagnosis for treatment-planning purposes, may differ from their use in legal settings. Thus, whether additional reliability and validity testing is required for a new use, or whether a test must be renormed before being used in this way, is necessarily a fact-specific determination.

292. The frequently differing presentations of mental disorders in children have led to the development of instruments intended specifically for use in that population. See, e.g., David Shaffer et al., *NIMH Diagnostic Interview Schedule for Children, Version IV (NIMH DISC-IV): Description, Differences from Previous Versions, and Reliability of Some Common Diagnoses*, 39 *J. Am. Acad. Child & Adolescent Psychiatry* 28, 28–38 (2000), <https://doi.org/10.1097/00004583-200001000-00014>.

293. See, e.g., John Monahan et al., *The Classification of Violence Risk*, 24 *Behav. Sci. & L.* 721 (2006), <https://doi.org/10.1002/bsl.725>.

294. For a good discussion of norming in the forensic context, see Grisso, *supra* note 3, at 56–59.

Was the Instrument or Test Used as Intended by Its Developers?

Established reliability and validity are necessary but not sufficient to determine whether an instrument or test has yielded reliable and valid results. Unless the assessment approach was applied in the manner intended by the developers, the data on reliability and validity may simply not be applicable to a particular use. Three possible areas of deviation relate to training in, administration of, and scoring of the assessment tool.

Training

Some instruments and tests are straightforward, requiring little specialized training. Familiarity with the manual accompanying the assessment tool might be sufficient. With other measures, though, training is required to ask the questions properly, especially when follow-up probing of responses is necessary or when evaluatees are asked to perform tasks that must be conducted in a particular way. Diagnostic instruments, in particular, may have complex “skip-out” rules, that is, procedures for determining when to include or omit certain questions based on the person’s responses to previous questions.²⁹⁵ When information is acquired at least in part from existing records rather than from the evaluatee directly, rules may exist for how the information should be identified and abstracted. These characteristics of an assessment approach may require training for proper administration, scoring, and interpretation.²⁹⁶ For more complex instruments or tests, assessors need face-to-face training with the opportunity to practice administration and receive supervision. Developers of such instruments or tests may offer training seminars for professionals.²⁹⁷ So a key question in assessing data based on an instrument or test is whether one requires special training to use it, and if so, whether the assessor was trained in the technique.

295. Structured diagnostic interviews have been widely used in epidemiological studies of mental disorders in the United States, as an example. See a description of a recent iteration of such a structured interview (the Structured Clinical Interview for DSM-5) at <https://www.appi.org/products/structured-clinical-interview-for-dsm-5-scid-5>.

296. Indeed, some psychological and neuropsychological tests should be administered only by psychologists trained in their use.

297. The creator of the popular Psychopathy Check List (PCL-R), for example, offers an extensive training program for clinicians and researchers desiring to learn how to properly administer the instrument. See <https://perma.cc/WSP8-JJJE>.

Administration

Even if the assessor was trained, the reliability and validity of an instrument or test will depend on whether it was administered properly. Many assessment tools require that questions be asked in a given sequence and phrased in a particular way. After an incorrect response, it may be permissible to ask the question again, but only a certain number of times. Probing of responses may be needed, but only certain probes may be permitted. Some tests are timed, with a given period allotted for the completion of a task. Deviations from any of these requirements could make the published data on the psychometric characteristics of the tool inapplicable to its use in a particular instance. Thus, a second crucial question is whether the instrument or test was administered in the same way as it was when its reliability and validity were established.

There are two ways this applies to the administration of tests used in forensic evaluations. First, these evaluations are often conducted in secure settings: jails, prisons, and detention centers. The evaluator must ensure that administration conditions are reasonably quiet, private, and distraction-free so that they do not deviate substantially from the conditions under which the test was validated. Second, the Covid-19 era witnessed an increase in the use of videoconferencing to conduct evaluations. When using such an approach, the evaluator must first determine whether conditions (as just discussed) *are* private, quiet, and distraction-free.²⁹⁸ Some tests for which the test-taker reads the items and responds on an answer sheet should not differ meaningfully whether administered in person or remotely; in fact, some such tests were administered via computer prior to Covid-19. Other tests cannot be translated as readily, and evaluators must consider the relevant research and the nature of the assessment to determine whether and to what extent such tests can be used during a remote evaluation.²⁹⁹

298. It is not unusual, for example, for the staff of a jail or prison to indicate to an evaluator that facility policy requires the presence of a correctional officer in the room. This is highly problematic, of course, as certain aspects of forensic evaluations involve very sensitive material. If this cannot be renegotiated with the facility, then the evaluator must make the difficult decision between conducting a modified evaluation under these circumstances or declining entirely.

299. Publishers of commercially available psychological tests (to qualified users) have worked since the onset of Covid-19 conditions in March 2020 to improve the technology that would address influences that adversely affect the conditions of remote administration, and hence make reliability and validity more comparable to in-person administration. *See, e.g.,* <https://perma.cc/6DLV-QV8F>. Yet there have not been innovations that would allow remote administration of tests requiring the observation of physical movements, hand-eye coordination, and the like—meaning that many neuropsychological tests cannot be administered remotely. *See, e.g.,* Kirk Heilbrun et al., *A Principles-Based Analysis of Change in Forensic Mental Health Assessment During a Global Pandemic*, 48 J. Am. Acad. Psychiatry & L. 293 (2020), <https://doi.org/10.29158/JAAPL.200039-20>.

Scoring

Assessment tools generally require that evaluatees' responses be scored in some way. For some instruments and tests, the scoring is simple and self-evident—for example, the number of positive responses is totaled to yield the score, or evaluatees themselves are asked to indicate the severity of their symptoms on a one-to-seven scale. Frequently the results are then calculated using computer software that automatically applies the relevant algorithm, generates statistical data, and even draws comparisons with broader groups, such as the general population or persons with a particular disorder. But there may be more complex scoring rules, particularly when evaluatees' verbal or narrative responses are elicited. An instrument assessing the severity of symptoms, for example, may require the person administering it to categorize responses along a numerical scale,³⁰⁰ and specific capacity-assessment tools frequently require similar judgments to be applied.³⁰¹ Published data on the reliability of scoring apply when the person administering the instrument adheres to the usual rules, and may not apply without such adherence. Without it, reliability may be adversely affected, and the results may be invalid as well. Hence, a third important question when such evidence is introduced is whether the rules for scoring responses were properly applied.

How Was the Expert's Judgment Reached Regarding the Legally Relevant Question?

As noted in the preceding sections, mental health experts' training and manner of conducting assessments is vital information when evaluating their testimony. However, the value of an expert's opinion also depends on the process by which the data were assessed and a conclusion was reached.

300. E.g., the Brief Psychiatric Rating Scale. See John E. Overall & Donald R. Gorham, *The Brief Psychiatric Rating Scale (BPRS): Recent Developments in Ascertainment and Scaling*, 24 *Psychopharmacology Bull.* 97 (1988), <https://doi.org/10.2466/pr0.1962.10.3.799>.

301. E.g., Grisso & Appelbaum, *supra* note 122.

Were the Findings of the Assessment Applied Appropriately to the Question?

Were Diagnostic and Functional Issues Distinguished?

Mental health professionals without experience in performing particular forensic evaluations may fail to recognize that the legal question being asked deals with a person's functional capacity, not with some aspect of their clinical state *per se*.³⁰² As a result, they may mistakenly base their opinions on the presence of a particular diagnosis or symptom cluster rather than on the person's capacity to perform in the legally relevant manner. Studies indicate that this has happened frequently in testimony on defendants' competence to stand trial, with experts often concluding that any psychotic defendant was *ipso facto* incapable of proceeding to trial.³⁰³ Similar problems may occur in hearings on guardianship or contests regarding testimonial capacity, where a person's ability to manage or dispose of assets might be thought incorrectly to turn solely on whether a neurocognitive disorder is present, as opposed to whether the person retains the necessary capacities despite the condition.³⁰⁴ This may be more likely to occur—and to go undetected—when experts are allowed or encouraged to address the ultimate legal issue in their testimony.³⁰⁵ When experts are permitted to testify to the ultimate question, the importance of probing their reasoning is magnified.³⁰⁶ Experts can be asked to identify the relevant functional capacities and to speak directly to the impact of the person's mental state on those capacities.³⁰⁷ This allows their reasoning processes and the correctness of their assumptions about the relevant functional standard to be tested.

302. See *Dusky v. United States*, 362 U.S. 402 (1960); Melton et al., *supra* note 1.

303. See, e.g., A. Louis McGarry, *Competency for Trial and Due Process Via the State Hospital*, 122 Am. J. Psychiatry 623 (1965), <https://doi.org/10.1176/ajp.122.6.623>. Subsequent studies suggested that this became a less common problem as educational efforts among mental health professionals who do such work had a positive impact. Robert A. Nicholson & Karen E. Kugler, *Competent and Incompetent Criminal Defendants: A Quantitative Review of Comparative Research*, 109 Psych. Bull. 355 (1991), <https://doi.org/10.1037/0033-2909.109.3.355>.

306. See Parry & Drogin, *supra* note 9, at 429–31.

307. Buchanan, *supra* note 216.

Were the Limitations of the Assessment and the Conclusions Acknowledged?

Assessments are imperfect. Evaluatees may be less than cooperative. Records are often unavailable. Evidence from witnesses is conflicting. Time available is inadequate. Or the evaluator may simply have forgotten to ask about some piece of information that would have been helpful. Experts should be able to identify the limitations of their evaluations and the possible impact of those less-than-optimal aspects of the assessments. An expert would be unlikely to offer testimony if the expert believed that the limitations rendered the opinions invalid. But competent experts should be able to explain why, despite the limitations (which occur even in the best evaluations by the most capable experts), their evaluations were adequate to allow them to draw the conclusions that they intend to present.

A comparable set of limitations can occur when conclusions are drawn and opinions formulated. Just as all assessment tools have error rates, so do expert witnesses, although their rates are difficult to subject to statistical analysis. Errors may be introduced by inadequacies in the data available or the uncertainties inherent in particular determinations, especially predictions of future mental states and behaviors. As noted earlier, it is often impossible to specify the contingencies that may arise in a person's life that could influence their mental states and actions. Thus, any prediction—no matter how firmly grounded in available data—has a degree of uncertainty attached to it that a competent expert should be expected to acknowledge.

Are Opinions Based on Valid Empirical Data Rather Than Theoretical Formulations?

From the development of Freud's theories in the late nineteenth and early twentieth centuries until the present, many mental health professionals have based their clinical approaches on psychoanalytically inspired concepts. Some of these concepts have been confirmed scientifically (e.g., the existence of unconscious mental states), whereas others have not (e.g., dreams always represent the fantasied fulfillment of wishes). Although psychoanalytical theories and the psychodynamic psychotherapies that derive from them have declined in popularity in recent decades, many mental health professionals have received psychodynamic training and use these concepts to assess and treat their patients. Regardless of the possible clinical utility of these theories, which is controversial and may depend on the condition being treated, they are arguably more problematic when they serve as the basis for conclusions offered as part of legal proceedings. Nor are psychoanalytical theories the only ones that mental health professionals use and that may have a greater or lesser degree of empirical support.

To the extent that expert opinions are introduced to inform the judgments of legal factfinders, it is important for them to be based insofar as possible on

empirically validated procedures rather than on untested or untestable theories. That appears to be the import of the U.S. Supreme Court's decision in *Kumho Tire*.³⁰⁸ As Slobogin plausibly maintains, some legal questions (such as those concerning past mental states) may not easily lend themselves to approaches based on scientific methods, but expert opinions may nonetheless be of assistance to factfinders.³⁰⁹ At a minimum, it would seem fair for an expert to indicate when that is the case, so that the factfinder can make an informed judgment about the appropriate degree of reliance on the expert's opinion. And when empirically tested approaches are available, it is good practice for an expert to use them, or to explain why they were not used.

Case Example

Facts of the Case

James Stallworth³¹⁰ is a forty-eight-year-old male who was charged with making false statements and with fraudulent use of an identity document, incurring federal charges to which he pled guilty. His attorney requested an evaluation to possibly support the defense's motion for a downward departure at sentencing. The evaluation requested by the defense was conducted by a Ph.D. psychologist board certified in clinical psychology and forensic psychology (Dr. A). The assistant U.S. attorney requested a second evaluation, which was conducted by a psychiatrist in private practice who was board certified in psychiatry and forensic psychiatry and whose work includes both forensic evaluations and psychiatric treatment (Dr. B).

Mr. Stallworth does not have a juvenile record, but he has a substantial arrest history as an adult, resulting in fifteen convictions for offenses such as trafficking cocaine, resisting arrest, trespassing, possession of marijuana, burglary, theft, making false report, disorderly conduct resisting arrest, DUI, and shoplifting. He is also a registered Step 2 sex offender, having been sentenced to three years in prison for a sexual offense.

He presented for evaluation with Dr. A., who interviewed him on two occasions; Mr. Stallworth was polite and cooperative. His speech was somewhat rambling during the first interview; it was very rambling and tangential during the second. He was largely calm throughout, displaying no difficulty with attention or concentration, and worked consistently on all tasks. Intellectual

308. *Kumho Tire Co. v. Carmichael*, 526 U.S. 137 (1999) (holding that the *Daubert* standard for admitting expert testimony also applies to nonscientists).

309. Slobogin, *supra* note 212.

310. See Kirk Heilbrun et al., *Forensic Mental Health Assessment: A Casebook* 100–109 (2d ed. 2014). This is a composite of several cases and has been fully deidentified. There is no “James Stallworth.”

functioning was not formally measured but appeared to be in the Average to High Average range, as suggested by his appearance, behavior, and academic skills measured by the Wide Range Achievement Test—4th edition (Word Reading, 13th grade equivalent; Sentence Comprehension, 13th grade equivalent; Math, 13th grade equivalent; Spelling, 11.6th grade equivalent). He did not report experiencing perceptual disturbances at the time of the evaluation, and there was no evidence of bizarre ideas, delusions, or other thought disturbances.

He described attending high school and a total of about three years of college at the University of South Florida and the University of Delaware. He said that he had never been married but was described by a friend as having a lot of acquaintances; his friend added that women in particular “really want to get to know him.” He reported holding several jobs as an adult, including waiter, cook, and construction worker. He apparently held a number of briefer jobs as well, and described himself as “king of the misers—I don’t need a lot to get by.”

Mr. Stallworth reported a significant medical history, including “enlarged heart ventricles” that result in “pains in my heart and I pass out” at times. He was also diagnosed with asthma and prescribed a steroidal inhaler that “seemed to work well,” he said. He reported a history of two concussions, in 1993 (when he was thirty-three) and 1995, the latter incurred during a “fight with a bunch of people over alcohol.”

His psychiatric history included a report of hospitalization during college and diagnosis of manic depression, with a prescription for lithium (a mood-stabilizing psychotropic medication) that he said he “never took” because he “did not like the side effects.” He described one subsequent episode of manic behavior about two years later and two episodes of significant depression (in 1988 and 2000). He said that he did not take medication to treat any of these three episodes. He also described a history of symptoms consistent with ADHD, although he reported that he had never been diagnosed with or treated for this disorder.

The results of a standard psychological test of mental and emotional functioning, the MMPI-2, yielded a valid profile that was consistent with an open response style neither exaggerating nor minimizing unusual experience. Individuals with such profiles are often described as interacting with others easily, although prone to taking advantage of others. Such profiles are also consistent with substance-use problems—consistent with Mr. Stallworth’s description of using marijuana, alcohol, and cocaine excessively and using other drugs (e.g., quaaludes, LSD) when in college.

Testimony in the Federal Sentencing Hearing

Dr. A described the following recommendations for treatment: (1) a medical expert’s evaluation for appropriateness of psychotropic medication to treat

symptoms of bipolar disorder and ADHD; (2) job-related services that could assist Mr. Stallworth in finding and keeping a job, reducing the pressure on him to obtain money by antisocial means; and (3) skills-based training and counseling to address deficits in problem solving and decision-making. His amenability to such interventions was described as mixed. He has the intellectual capacity to benefit from interventions relying on verbal memory and abstract concepts, and he has acknowledged that psychotropic medication has helped reduce the intensity of his manic symptoms. But he also has a history of declining or discontinuing prescribed medication, so he would need to be persuaded that it was advantageous to him under the circumstances.

Dr. B noted Mr. Stallworth's long history of antisocial conduct as an adult and concluded that his report of experiencing bipolar symptoms was exaggerated and self-serving. He concluded that Mr. Stallworth does not experience a severe mental illness but has a personality disorder (antisocial personality disorder) co-occurring with substance misuse. Dr. B also observed that he was glib, impulsive, and versatile in his antisocial conduct. He was pessimistic about the prospect of rehabilitation, concluding that no conventional psychiatric interventions (including psychotropic medication) were likely to reduce his risk of future offending.

Questions for Consideration: Dr. A

1. Given that Dr. A was based in a local university and devoted much of his work to research and teaching, including conducting forensic evaluations but doing relatively little work treating patients, should he have been considered qualified to offer opinions about Mr. Stallworth's treatment needs and amenability?³¹¹
2. Were the psychological tests administered appropriate in this context?³¹²
3. Are the following relevant to (a) whether Dr. A should be qualified as an expert, (b) the credibility of his opinions but not his status as an expert, or (c) neither?

311. The most important question involves this expert's knowledge, training, and experience in conducting similar forensic evaluations. Other sources of relevant information include whether the expert provides treatment to this population (although, as discussed in this reference guide, clinical treatment provision is a separate and distinct role from forensic assessment), whether he has conducted research and scholarship in related areas, whether he has trained peers and trainees, and other considerations that might inform his competence in conducting such an evaluation and reporting the results.

312. The psychological tests administered in this case were selected for relevance and reliability. This is not always the case with experts who administer such testing. Judges who have questions about this should ask the expert to justify an indicated measure in terms of relevance and reliability.

- a. psychologist (not a medical expert)³¹³
 - b. licensure to practice as a psychologist³¹⁴
 - c. board certification³¹⁵
 - d. experience treating patients³¹⁶
 - e. current work in forensic evaluations, treatment provision, and treatment of justice-involved individuals³¹⁷
 - f. retained by the defense³¹⁸
4. Dr. A described Mr. Stallworth in a way that included both strengths and limitations, and suggested that certain kinds of interventions might be appropriate for targeting his symptoms. Does that provide an accurate depiction in this case?³¹⁹

Questions for Consideration: Dr. B

1. Does Dr. B's primary employment as a private practitioner who conducts forensic psychiatric evaluations, along with consultation and treatment of

313. Psychologists are generally appropriate experts in such matters. Considering expertise via voir dire might reveal justification for clearly accepting or rejecting the proposed expert on other grounds.

314. This is important. Licensure in a jurisdiction indicates that the appropriate regulatory board has determined that the psychologist has the necessary training and experience to deliver psychological services to clients. Forensic assessment is a kind of psychological service that involves interviewing, testing, and expertise in mental health. Unlicensed psychologists have not demonstrated that they have the needed training and experience to provide this service. Some psychologists who specialize in nonclinical areas neither qualify for licensure nor are appropriate to provide forensic assessments.

315. This is a demonstration that the psychologist has obtained a credential that requires competence in the area of specialization. Some psychological experts have not sought board certification but are nonetheless competent to provide forensic services.

316. This is important to the extent that it furthers expertise with such individuals and promotes a better understanding of how treatment works, and its limits. It is less important that the expert have an active clinical treatment practice; experts engage in many activities that further their competence. Treatment provision is one. Research, training, and consultation are others.

317. Experience providing services with justice-involved clients is important. Such services include areas described in the previous footnote.

318. Experts can agree or decline to work with an attorney, but they generally do not control whether they receive such offers. The proportion of cases in which one has been retained by one side is less important than demonstrating some history of conducting evaluations at the request of both defense and prosecution or defense and plaintiff. Also important is the proportion of cases in which the expert can describe providing an opinion that was not favorable to the retaining party. Such unfavorable opinions typically are not used in litigation, so they do not become part of the discoverable record. But an expert should be able to answer a question about this.

319. Whether the described strengths and limitations are accurate depends upon the evidence presented, of course. But strengths and limitations always exist, and reports and opinions that do not describe both should be viewed with some skepticism with respect to the evaluator's impartiality.

- patients in different psychiatric facilities, give him an “expertise advantage” in this case?³²⁰
2. Is the evaluation limited by the absence of standardized psychological testing?³²¹
 3. Are the following relevant to (a) whether Dr. B should be qualified as an expert, (b) the credibility of his opinions but not his status as an expert, or (c) neither?
 - a. psychiatrist (a medical expert)³²²
 - b. licensure to practice as a physician³²³
 - c. board certification³²⁴
 - d. experience treating patients³²⁵
 - e. current work in forensic evaluations, treatment provision, and treatment provision with justice-involved individuals³²⁶
 - f. retained by the prosecution³²⁷
 4. Dr. B described Mr. Stallworth without particular attention to strengths and by observing that he does not experience a severe mental illness, instead concluding that he has a personality disorder that is very difficult to treat, with co-occurring substance misuse. Does that provide an accurate depiction in this case?³²⁸

320. It provides evidence that much of his time is spent with patients. This has advantages and disadvantages. To the extent that an expert spends the great majority of his time with patients, and is not involved in other professional activities (e.g., research, scholarship, training), that expert may be very familiar with patient behavior but less familiar with the supporting science and practice literatures.

321. Psychiatrists rarely administer psychological testing, as training in this area is not typically provided during residency or fellowship. This means they may not be well informed about what testing could provide. But such experts usually take alternative approaches to appraising important domains in forensic assessment.

322. Psychiatrists with appropriate expertise in areas relevant to the forensic questions should be qualified as experts.

323. This is simply an indication that this individual is medically trained, which may have certain advantages considering the nature and facts of the case.

324. Board certification is expected more often as part of medical and specialty training. It is a reflection of such specialization.

325. Having a clinical practice adds to the credibility and experience of an expert. There should be a recognition, however, that the forensic-assessment role is distinct from the clinical-treatment role. For reasons discussed in this reference guide, experts who have treated the litigant should not then be providing a forensic assessment of that litigant.

326. Specialized experience with justice-involved individuals is important.

327. Unless there is an identifiable pattern of only conducting evaluations and testifying at the request of one side, the particular side that retained the expert in this matter should make little difference.

328. Whether this is accurate will depend on the pattern of the evidence provided by both experts. But describing a litigant without reference to strengths, or in one-sided terms, should create skepticism with respect to the expert's impartiality.

Glossary of Terms

actuarial assessment. A form of structured assessment in which scores on assessment instruments are associated with outcomes (linked most often through empirical research) without requiring a judgment from the evaluator. This is one of the two most accurate approaches to prediction—the other being structured professional judgment.

behavior therapy. A form of treatment for individuals with psychological symptoms that focuses on the influence of different stimuli on these symptoms and the individual's response expressed in their behavior.

blind spot bias. A form of cognitive bias in which there is limited awareness that the influences that contribute to cognitive bias in others also apply to oneself.

board certification. Certification of competence in a particular specialization by a specialty board in psychiatry or psychology. It differs from licensure in its requirement of more specific measures of competence.

clinical versus forensic contexts. The delineation of the ways in which the roles of clinical treatment provision versus forensic mental health assessment differ. They include purpose, client, relationship, voluntariness, confidentiality, consent, response style, sources of information, pace, settings, report, and testimony.

cognitive behavioral therapy. A form of treatment of individuals with psychological symptoms that focuses on the influences of different stimuli, and individuals' thoughts and beliefs, on these symptoms, and on the individuals' responses expressed in their behavior, thoughts, and beliefs.

cognitive biases. Systematic influences on decisions made under conditions of uncertainty that may result in inaccuracy, illogic, and inconsistency with objective evidence. Such influences often operate outside the awareness of the decision-maker. For examples, see confirmation bias, retention bias, and blind spot bias (all in this glossary).

confirmation bias. The tendency to identify, interpret, and remember information in a fashion that is consistent with (or confirms) existing values or decisions.

construct validity. A form of validity that refers to a measure's accuracy in assessing what it is intended to assess.

contemporaneous evaluations. Expert evaluations appraising a party's relevant thinking, behavior, and capacities at present.

content validity. A form of validity referring to the representativeness of a measure's sample (the items used to provide empirical evidence about the measure) of the outcome (e.g., behavior, skill) being measured.

current-state evaluations. See contemporaneous evaluations.

- decisional capacity.** Ability to make a legally relevant decision in an acceptable way, which may be influenced by cognitive capacity and symptoms. Capacity references the process of decision-making rather than the final decision itself.
- diagnosis.** Categorization of mental disorder(s), most often using the current version of the *Diagnostic and Statistical Manual of Mental Disorders* published by the American Psychiatric Association.
- dialectical behavior therapy.** A form of treatment of individuals with psychological symptoms that focuses on helping people regulate their thoughts and feelings through identifying triggers and using skills to help them cope with problematic events and their responses to the events.
- DSM-5-TR.** *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision.* The most recent diagnostic manual published by the American Psychiatric Association.
- forensic mental health assessment.** An evaluation conducted by a mental health expert, typically a psychiatrist or a psychologist, with the purpose of informing the court about a party's symptoms, characteristics, and capacities relevant to a legal question involving that party, and/or assisting the retaining attorney in providing accurate evidence regarding that party.
- forensic psychiatric assessment.** Forensic mental health assessment conducted by a psychiatrist.
- forensic psychological assessment.** Forensic mental health assessment conducted by a psychologist.
- functional legal capacities.** A party's abilities to think and behave on tasks associated with the legal question. Along with psychological symptoms and characteristics, functional legal capacities are appraised and considered by the expert in evaluating a party on a specific legal question.
- intellectual disability.** Formerly called mental retardation, referring to a disability characterized by significant limitations in both intellectual functioning and adaptive behavior, with onset before age twenty-two.
- licensure.** Recognition by a regulatory board in a given jurisdiction that an individual has the requisite training and experience in a particular discipline to be authorized to function independently in the designated professional role.
- performative capacity.** Ability to carry out a legally relevant task, which may be influenced by cognitive capacity and symptoms.
- predictive validity.** A form of validity that refers to the capacity of a test or measure to accurately predict a specified future outcome.
- prospective evaluations.** Expert evaluations appraising a party's likely future mental states, cognitive function, behavior, and capacities.

psychiatrist. Mental health specialist trained in medical school and psychiatry residency. Some subspecialists also train in fellowships following residency.

psychologist. Mental health specialist who has obtained a doctoral degree and completed a clinical internship. Some specialists also train in fellowship following internship.

reliability. The scientific definition of reliability refers to the consistency of a given measure—the extent to which the same results are obtained and are not affected by error across different measurements or assessors. The legal definition of reliability combines both scientific reliability (measurement consistency) and scientific validity (measurement accuracy) into a single concept that refers to overall accuracy.

response style. The tendency of a person to provide self-referential information that is accurate (within limits of memory) versus deliberately distorted. Such distortions can include overreporting/exaggeration/fabrication of symptoms (called malingering or exaggeration), underreporting or denial of symptoms (called minimization or denial), or refusing to provide relevant information (through responding irrelevantly on psychological testing, failing to provide much information when questioned, or refusing to talk with an evaluator).

retention bias. A form of cognitive bias in forensic psychologists and forensic psychiatrists that involves identifying, interpreting, and remembering information in a way that favors the party retaining the expert.

retrospective evaluations. Expert evaluations appraising a person's relevant thinking, behavior, and capacities at a specified previous time. In some cases, it cannot involve direct contact with that person (e.g., testamentary or contractual capacity of a deceased individual).

risk-need-responsivity. A leading theory of correctional classification that includes risk of reoffending, needs for intervention for risk-relevant deficits, and likelihood of responding favorably to interventions, both generally (using empirically supported procedures) and specifically (with interventions consistent with the individual's capacities and learning style).

social-skills therapy. A form of behavior therapy used primarily with individuals with severe mental illness or developmental disability, focusing on learning and improving important social skills that help such individuals interact more effectively with others.

structured assessment techniques. Standardized interviews or data-gathering protocols designed to obtain clear responses to specific questions.

structured professional judgment. A form of semistructured assessment in which evaluators gather information in predefined relevant areas and, in light of that information, apply professional judgment regarding the likelihood

of a predefined outcome. This is one of the two most accurate approaches to prediction—the other being actuarial assessment.

validity. Being logically or factually accurate, an important consideration in science that refers to whether a measurement represents what it is supposed to measure. There are different kinds of validity. See construct validity, content validity, and predictive validity.

Introduction

Courts have a long history resolving disputes about the admissibility of opinion testimony from engineers proffered as expert witnesses.¹ In some cases, however, background guidance on how engineers think and go about doing their work, and on who qualifies as an engineer, would be helpful to both judges and lawyers. This reference guide aims to fill that need.² It builds upon similar guides, in the second³ and third⁴ editions of the *Reference Manual on Scientific Evidence*, that were added in the wake of the Supreme Court’s 1993 decision in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*⁵ and its 1999 decision in *Kumho Tire Co., Ltd. v. Carmichael*.⁶

In *Daubert*, as discussed below, the Court relied heavily on the philosophy of science to provide guidance for gatekeeper judges who must resolve disputes about what should or should not count as valid and admissible scientific evidence,⁷ but also explained how the actual practice of science is more nuanced and complex than the textbook scientific method. “Scientific conclusions are subject to perpetual revision . . . The scientific project is advanced by broad and wide-ranging

1. *Folkes v. Chadd*, 3 Doug. 157, 99 Eng. Rep. 589 (1782), an eighteenth-century English case often cited as the first in which a court allowed expert opinion testimony, involved engineering experts who provided conflicting explanations for what had caused a harbor to become clogged with silt. See Tal Golan, *Revisiting the History of Scientific Expert Testimony*, 73 Brook. L. Rev. 879, 886–904 (2008).

2. Based on a Westlaw search of engineering expert cases decided during the 18 months from January 2021 through June 2022 (discussed in detail below, in the section titled “Analysis of the Case Law Based on an Understanding of Engineering and How It Differs from Science”), federal courts currently decide about 240 cases a year involving engineering experts, of which only 134 involve the kind of complex engineering testimony on which this reference guide focuses. In just over 20% of the 240 cases, the experts were accident investigators, an area with which courts have become quite familiar and comfortable after a history going back more than a hundred years. See, e.g., *Grand Trunk Ry. Co. of Canada v. Ives*, 144 U.S. 408, 412 (1892) (expert testified that the distance traveled by a train after colliding with a buggy indicated “it must have been going at the rate of 25 or 30 miles an hour”); *Shugart v. Atlanta, K. & N. Ry.*, 133 F. 505, 507–08 (6th Cir. 1904) (allowing conflicting expert testimony about whether condition of railroad tracks had caused a derailment). Fifteen percent of the cases involved insurance coverage issues, and about 7% involved matters like employment claims or criminal law issues that don’t really implicate complicated engineering questions. Again, this reference guide focuses on the more complex engineering issues that arise in the remaining 58% of the cases, the majority of which involved products liability claims.

3. Henry Petroski, *Reference Guide on Engineering Practice and Methods*, in *Reference Manual on Scientific Evidence* 579–624 (2d ed. 2000).

4. Channing R. Robertson, John E. Moalli, & David L. Black, *Reference Guide on Engineering*, in *Reference Manual on Scientific Evidence* 897–959 (3d ed. 2011).

5. 509 U.S. 579 (1993).

6. 526 U.S. 137 (1999).

7. *Daubert*, 509 U.S. at 593–95; Liesa L. Richter & Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual at 5–13 (hereinafter Richter & Capra).

consideration of a multitude of hypotheses, for those that are incorrect will eventually be shown to be so, and that in itself is an advance.”⁸

Daubert also provided a “five-factor, nondispositive, nonexclusive, ‘flexible’ test” for trial courts to use when determining the validity of scientific evidence, as required by Rule 702.⁹ The five factors, generally referred to as the “*Daubert* factors,” are:

1. whether the technique or theory can be or has been tested;
2. whether the theory or technique has been subject to peer review and publication;
3. the known or potential rate of error;
4. the existence and maintenance of standards and controls; and
5. the degree to which the theory or technique has been generally accepted in the scientific community.

In the immediate aftermath of *Daubert*, there was uncertainty about whether its gatekeeping mandate applied to all expert testimony or just to scientific experts, and if it did apply more broadly, whether the five factors should be used for non-scientific experts.¹⁰ *Kumho Tire* resolved the uncertainty about broader applicability of *Daubert* by extending judicial gatekeeping to all expert evidence, but provided no analogous general guidance or list of factors to consider when evaluating the engineering expert testimony (from a tire failure expert) at issue in that case. Instead, the Court’s decision focused on the specific evidence the trial court had excluded and concluded the trial court had not abused its discretion. The Court’s reluctance to delve into general guidance or factors for fields of expertise other than science reflects the fact that except for science (the field of human endeavor focused on expanding our knowledge of the natural world), there exists no extensive literature on the philosophical underpinnings for the knowledge experts may develop or acquire. For engineering, however, there is a wealth of practical guidance that forms the basis for this reference guide, which addresses three fundamental questions: (1) What is engineering, and how does it differ from science? (2) Who is an engineer? and (3) How do engineers think? In particular, how do they create, test, and evaluate designs? As explained in the

8. *Daubert*, 509 U.S. at 597. See also Michael Weisberg & Anastasia Thanukos, *How Science Works*, in this manual, which makes clear that textbook and media versions of the scientific method (hypothesis, followed by experimental testing, followed by publication, followed by acceptance and consensus in the scientific community) is far too linear and simple, and does not reflect how science actually works in practice. *How Science Works*, at 50–56.

9. For more on *Daubert*, Rule 702, and admissibility, see Richter & Capra, *supra* note 7.

10. Compare *Watkins v. Tel Smith, Inc.*, 121 F.3d 984, 991 (5th Cir. 1997) (“the nonexclusive list of factors relevant under *Daubert* to assessing scientific methodology . . . are also relevant to assessing other types of expert evidence”) with *McKendall v. Crown Control Corp.*, 122 F.3d 803, 806 (*Daubert* factors “are relevant only to testimony bearing on ‘scientific’ knowledge”).

following section, the creation and analysis of designs is the central feature of engineering practice, and it is the primary focus of this reference guide.

What Is Engineering and How Does It Differ from Science?

Engineers do often use or apply scientific knowledge, but that does not mean engineering is in any way subsidiary to science. Indeed, the practice of engineering pre-dates science by thousands of years. There is, however, an interplay between the fields, which means judges sometimes may have to decide whether to apply some or all of the *Daubert* scientific evidence criteria or different engineering criteria when determining the admissibility of an engineer's testimony.¹¹ Thus, the necessary starting point for this reference guide is a discussion of how the two fields differ and how they relate to each other. What, then, distinguishes engineering from other fields, especially science? Theodore von Kármán, an eminent aerospace engineer (also a mathematician and physicist) once explained that “scientists study the world as it is, engineers create the world that never has been.”¹²

More precisely, engineering and science differ in three important ways:

1. Historically, many engineering products and technologies have preceded scientific understanding,¹³ and while this remains true today, the advent of modern science often allows engineers to use scientific discoveries as part of their tool kit when they create new designs.¹⁴ In no event, however,

11. For example, if called upon as an expert witness to determine the cause of an accident or the failure of a product, an engineer might take various approaches. This reference guide is most applicable when an engineering expert bases such a determination on the analysis of a design. *See, e.g.,* *Baugh v. Cuprum S.A. de C.V.*, 845 F.3d 838 (7th Cir. 2017) (in which a mechanical engineer relied on calculations based on centuries-old mathematical principles to determine the cause of a ladder failure). If, on the other hand, an engineering expert formulates a hypothesis that requires testing or other empirical corroboration, some of the *Daubert* factors used for evaluating science might be more applicable. *See, e.g.,* *Nease v. Ford Motor Co.*, 848 F.3d 219 (4th Cir. 2017) (in which the plaintiff's expert hypothesized that debris in a cable housing had caused an accelerator to stick but offered no analytical explanation and no testing of his hypothesis).

12. Petroski, *supra* note 3, at 579. Theodore von Kármán was the National Medal of Science recipient in 1962.

13. William S. Hammack & John L. Anderson, *Working in the Penumbra of Understanding*, *Issues in Sci. & Tech.*, Feb. 16, 2022, available at <https://perma.cc/48H5-WUCN>.

14. One good example is the use of discoveries by the Nobel Laureate Jacques Monod about how bacteria reproduce as part of the design process for wastewater treatment plants. Alexandru Braha & Ferdinand Hafner, *Use of Monod Kinetics on Multi-Stage Bioreactors*, 19 *Water Rsch.* 1217 (1985), [https://doi.org/10.1016/0043-1354\(85\)90174-5](https://doi.org/10.1016/0043-1354(85)90174-5).

should engineering be considered a lesser field or fully dependent on science. Engineering is not just “applied science.”

2. Engineering begins with a goal and proceeds to the design and creation or manufacture of an object or a process to achieve the goal, while science begins with a question and strives to find an answer.
3. Engineers are comfortable proceeding toward their design goal in the presence of uncertainty, which they allow for in various ways, including safety factors that account for approximations in making design calculations, and variability and uncertainty in the execution of designs. Engineering has also been described as a “set of tradeoffs,” and tradeoffs are the engineers’ way of adapting to constraints. In contrast, for scientists, reduction of uncertainty by increasing our knowledge and understanding of the natural world is the central objective.

Science and engineering do sometimes get lumped together, or even mistaken for each other, and this conflation has prompted many efforts to differentiate and contrast them.¹⁵ Petroski in the second edition and Robertson et al. in the third edition of the reference manual presented detailed contrasts between the two fields. Perhaps the most succinct description was given by Gilbert Ryle: science is about “knowing that” while engineering is about “knowing how.”¹⁶ Our intent here is to describe and contrast two major concepts: the scientific method and the engineering design process, and then to explain how the design process works in practice. The revisions to Rule 702 make this inquiry even more important than it would be otherwise. As explained in *The Admissibility of Expert Testimony*, in this manual, one goal of the changes is to make sure experts “stay within the bounds of what can be concluded from a reliable application of [their] basis and methodology.”¹⁷ While prompted primarily by concerns about forensic science experts,¹⁸ the revisions relate to all experts, and if the reliable use of the process for creating and analyzing designs is at issue, application of scientific criteria and the *Daubert* factors often will not be the best way to determine admissibility. The question should not be reduced to whether a witness is called an engineer or not, but whether the witness is formulating and testing hypotheses or creating or evaluating designs (based on established methods and the witness’s experience and training).¹⁹

16. Gilbert Ryle, *Knowing How and Knowing That*, Proceedings of the Aristotelian Society, XLVI (in Collected Essays 1929–1968, Collected Papers Vol. 2, pp. 212–25).

17. Richter & Capra, *supra* note 7, at 23, in this manual, quoting Advisory Committee’s note to 2023 amendment to Fed. R. Evid. 702.

18. *Id.*

19. The Supreme Court’s observation in *Kumho Tire* about engineering resting on a scientific foundation may have inadvertently created some confusion on this point. In one sense it could be

We shall see below in the section titled “How Do Engineers Think, Make, Test, and Evaluate” that there are three essential properties of the engineering mindset: the ability to see a structure where there’s nothing apparent; adeptness at designing under constraints; and understanding tradeoffs.

Engineering and Science as Complementary Fields

Engineering is actually a much older field of human endeavor than science. The creation of tools during the Stone Age involved the conception and execution of designs and took place long before humans began any scientific effort to understand nature. Thus, many engineering designs necessarily predate science, even in more recent times. A classic example is the development of the steam engine, which triggered the science of thermodynamics.²⁰ Contrary to the popular notion that science (first) discovers, and engineering (then) applies, the “relationship between science and engineering is . . . complementary, synergistic, and essential. Scientific practice and knowledge offer engineers . . . heuristics that work better than those based . . . on trial and error; but this scientific knowledge does not explain how to design or create an artifact or a system.”²¹ Moreover, scientists “use the products of engineering to investigate and discover.”²²

The Scientific Method

Scientists strive for a common explanation for a phenomenon they are investigating. They may start with competing hypotheses, but the scientific method should eliminate most, if not all, and yield a consensus on which explanation is most likely correct. For example, although a few scientists still dispute the validity of evolution as the explanation for how a huge variety of species developed, there is a broad consensus that it provides the most likely explanation today, keeping in mind that future experimentation may invalidate the current consensus.

Although science does not proceed in a linear process from hypothesis to testing to publication and acceptance, it is quintessentially about

taken to mean the criteria for scientific validity and reliability should be used to evaluate all engineering testimony, but the far better interpretation is that engineers sometimes use scientific discoveries in the course of creating designs. If the scientific underpinning were not well accepted and reliable, then the engineering use of it could be called into question, but that is not fundamentally related to the engineering design process.

22. *Id.*

figuring out what predictions are generated by a hypothesis and comparing those to evidence. Hypotheses are supported when the evidence matches predicted observations and are contradicted when they do not match. Observations are often made with the help of sophisticated tools and may be analyzed with statistical techniques to discern patterns. Other observations are entirely qualitative and nonnumeric.²³

This is consistent with Occam's razor (or the principle of parsimony), which states that the explanation that requires the fewest assumptions is usually correct.

Thus, one distinguishing characteristic of scientific explanations is that they have to be testable. The traditional conception of science formulated by philosophers like Karl Popper would have falsifiability as the foundational principle of science, but the current view is that science cannot prove any idea to be false (or true for that matter). Furthermore, "reviewing the logical arguments presented in any scientific journal will reveal that evidence can and does play a role in supporting particular hypotheses over others, not just in ruling some ideas out, as implied by the doctrine of falsification."²⁴ Testing and modification of even well-established scientific explanations is a more realistic basis for determining the validity of science.

The classic example is how Newtonian dynamics withstood the test of time, until experimental evidence showed its limitations, paving the way for Einstein's theory of special relativity. Matters did not end there, however. Experiments revealed limitations in Einstein's theory, which led to quantum mechanics—and another explanation, more consistent with observations and experimental data, may yet emerge. In fact, a frequently misunderstood and miscommunicated concept is that scientific truths are absolute and invariant—in fact, they're accepted as correct until they become inconsistent with what's revealed by further experimentation. Moreover, and as described by Pitt, scientific knowledge is produced by researchers "exploring the domain of a *theory* who aim to provide an account of the relations among the objects and processes of that domain, an account which provides the basis for an explanation of phenomena generally observed or detected in another domain." Thus, "scientific knowledge is theory-bound" and as theories are modified, scientific knowledge (i.e., consensus) also changes.²⁵

The Engineering Design Process

Engineering is a vast field of practice, consisting of many recognized subfields and specializations, such as electrical engineering, mechanical engineering, civil engineering, systems engineering, aeronautical engineering, and many more. The

Table 1. List of Engineering Fields

Aeronautical/aerospace/astronautical engineering	Industrial engineering
Agricultural engineering	Marine engineering
Bioengineering/biomedical engineering	Materials and metallurgical engineering
Chemical engineering	Mechanical engineering
Civil, including architectural/sanitary engineering	Mining and geological engineering
Computer engineering	Nuclear engineering
Electrical and electronics engineering	Petroleum engineering
Environmental engineering	Sales engineering

National Academy of Engineering Report, *Understanding the Educational and Career Pathways of Engineers (2018)*,²⁶ lists 16 engineering fields,²⁷ shown in Table 1.

It should be noted that the Accreditation Board for Engineering and Technology, Inc. (ABET) maintains a list of engineering programs that they review for accreditation,²⁸ and this list also includes fire protection engineering, geological engineering, optical engineering, software engineering, and systems engineering.

To further illustrate the breadth of engineering, the IEEE (Institute of Electrical and Electronics Engineers), one of the world’s largest professional organizations, comprises 39 technical societies ranging from Aerospace and Electronic Systems to Vehicular Technology.²⁹ Engineering specializations are ever changing as societal needs evolve along with new discoveries, inventions, and technologies. Specialties such as nuclear engineering and biomedical engineering are relative newcomers, while civil engineering was practiced by early civilizations.

All engineering disciplines, however, share certain common practices and processes for creating designs and solving problems. The engineering design process is the touchstone for all engineers, much as the scientific method is the touchstone for all scientists. Thus, understanding how engineering design is distinct from the scientific method is important to the Rule 702 gatekeeping task. While engineers may differ on their approach to solving a problem, “given certain assumptions about the contingencies involved—it is not the case that two

26. National Academy of Engineering, *Understanding the Educational and Career Pathways of Engineers (2018)*, <https://doi.org/10.17226/25284>.

27. The list includes sales engineering, defined in the standard occupational classification system used by the National Science Foundation (NSF) as those who “sell business goods or services, the selling of which requires a technical background equivalent to a baccalaureate degree in engineering.”

28. ABET, *Criteria for Accrediting Engineering Programs, 2023–2024*, available at <https://perma.cc/JZ2G-QNMU>.

29. IEEE Societies, available at <https://perma.cc/6N8T-J3JX>.

engineers similarly educated and experienced could be armed with sufficiently different perspectives that they would flat out contradict each other.”³⁰ This makes engineering testimony less about discovering or converging on “the one truth” and more about adherence to process and practice. Although neither the traditional conception of the scientific method nor any effort to precisely define the engineering process fully captures all the nuances of what happens in either field, a comparison of traditional simplified views of both science and engineering does help to highlight how the two fields differ. Table 2 shows this comparison.

Table 2. Steps of Scientific Method Versus Engineering Design Process

	Scientific Method	Engineering Design Process
Step 1	State your question	Define the goal
Step 2	Conduct background research	Conduct background research
Step 3	Construct a hypothesis	Specify requirements and constraints
Step 4	Design experiment	Consider possible design options; evaluate and choose among them
Step 5	Test hypothesis via experiment	Develop a solution
Step 6	Analyze results	Verify performance, safety, and economics through analysis, and/or testing, and/or comparison with existing solutions
Step 7	If results align fully with hypothesis, communicate results through publication	If solution fully meets requirements, communicate it to those who will execute the design
Step 8	If not, go back to step 3	If not, go back to step 4, 5, or 6 as appropriate

In addition to the points listed in Table 2, another salient difference between science and engineering is that engineered products are intended to interact with human users or as part of an engineered system. It is not enough that a phone or a bridge function properly in the controlled conditions of a laboratory or in simulation. Phones must work despite the day-to-day abuse by their users, and bridges have to withstand various weather and congestion conditions and function properly under those conditions. Engineered products must also be safe, ergonomically designed, and aesthetically pleasing, as well as functional. It is indeed the various requirements and constraints that make engineering a creative synthesis of art (idea creation), scientific knowledge of how the world works, and accumulated design experience. Science, on the other hand, is more about explanatory theories than about practical application of those theories.

30. Joseph C. Pitt, *What Engineers Know*, Techné 5 (3): 17 Spring 2001, available at <https://perma.cc/GA4X-5Q3E>.

It has been said that “to engineer is to contrive,” and as we described earlier, practical needs have often led to engineering solutions that preceded mathematical and scientific understanding. Engineering is also omnipresent but largely invisible. From everyday products such as household appliances and cars, to large systems such as power plants, engineering products and systems are often noticed only when they fail to perform as expected, leading to possible loss of property, money, or even lives. In addition, at the heart of many engineering designs is the concept of scale; engineering products are in general (exceptions include military systems) meant to be used by many users of varying sophistication and expertise.

Who Is an Engineer?

This section describes who may qualify as an engineer for the purpose of providing expert testimony. An academic degree is only the starting point and may not even be a requirement in some cases. The type of work proposed experts do on a day-to-day basis is usually more important in judging their qualifications.

Academic Education and Training

An earned bachelor’s degree in an accredited engineering curriculum³¹ is generally sufficient to enter the professional workplace and begin to solve a wide variety of problems. It is less so the case for students who graduate with degrees in the basic sciences such as physics, chemistry, and biology, or in mathematics. Typically, but not always, basic science students will go on to earn graduate degrees. Of course, students who have earned an engineering degree also sometimes continue to the master’s or even doctorate level of study. In 2021, U.S. colleges and universities awarded approximately 146,233 bachelor’s degrees, 63,319 master’s degrees, and 12,403 doctoral degrees in all areas of engineering.³²

31. Accreditation is performed by ABET (Accreditation Board for Engineering and Technology). Founded in 1932 as the Engineer’s Council for Professional Development (ECPD), it was later renamed ABET. In the United States, accreditation is a nongovernmental, peer-review process that ensures the quality of the postsecondary education that students receive. Educational institutions or programs volunteer to undergo this review periodically to determine if certain criteria are being met. ABET accreditation is assurance that a college or university program meets the quality standards established by the profession for which it prepares its students. The quality standards that programs must meet to be ABET-accredited are set by the ABET professions themselves. This is made possible by the collaborative efforts of many different professional and technical societies. These societies and their members work together through ABET to develop the standards, and they provide the professionals who evaluate the programs to make sure that the programs meet those standards.

32. Engineering & Engineering Technology by the Numbers, ASEE (2021), <https://perma.cc/5YXZ-HR2Y>.

One can think of the educational process as providing engineering students with a tool kit from which they select “tools” that enable them, either individually or in teams, to participate in designing products or processes to address specific needs or problems. Because recently graduated engineering students are educated (i.e., have only classroom knowledge) as opposed to being trained (i.e., taught how to put classroom knowledge to practical use), one can never be quite sure how they will choose to use their tools in practice. Also, once in practice they may add to their tool kit through experience, training, or additional education.

The importance of experience and training after graduation means that people without a formal engineering degree may become quite effective and successful engineers. Indeed, some of the confusion between science and engineering stems from the fact that people with a scientific background sometimes work as engineers and vice versa. The distinction between scientists and engineers is quite recent. For example, over 500 years ago, Leonardo da Vinci was at once an accomplished engineer and scientist, as well as a renowned artist. A century later, Christopher Wren was an engineer, an architect, a mathematician, an astronomer, and a physicist. Today, people tend to work in more siloed professions, but crossover between science and engineering continues.³³

Without knowing how an engineer or scientist will use the tool kit acquired in college, and to what extent it will be replenished or modified as time goes on, it is not possible to predict what any individual might do to shape her or his career as time passes. There is a great deal of truth to the notion of learning on the job. Indeed, as one’s career unfolds, the number of opportunities expands, and with that come additional skills and an ever-increasing ability to make wise and informed choices and decisions. This ongoing learning is made even more critical with the increasing adoption of machine learning and artificial intelligence (AI) tools in engineering designs. There is no universal path to becoming an engineer, and being an engineer affords one the opportunity to continually remodel oneself as new and unexpected problems and challenges become evident.

33. In the twentieth century, Buckminster Fuller seamlessly combined elements of geometry (“science”), structures (“engineering”), and architecture (“art”) to conceive and develop an entirely new approach to architectural design. Architects Norman Foster and Frank Gehry seized on recent advances in computer science and engineering to develop innovative platforms for architectural design that paved the way for radical changes in structural and visual renderings. Striking examples include the Guggenheim Museum in Bilbao, Spain; the Walt Disney Concert Hall in Los Angeles; the Experience Music Project in Seattle; the London City Hall; the Beijing Airport; and the Reichstag in Berlin. Other examples include the famous scientist Linus Pauling (Nobel Prizes in Chemistry and Peace), who was trained as an engineer, and Albert Michelson (first American to win a Nobel Prize in science), whose work designing instruments to measure the speed of light was more engineering than science.

And so it is with the passage of time that the “title” of one’s degree becomes an increasingly murky description of who one is and what one does. This is why it is critical that titles do not overshadow the actual context of a degree when evaluating whether an “engineer” is testifying within her or his realm of expertise and the experience base at hand (i.e., an expert’s title may not reflect the knowledge the expert can provide). Thus, an assessment of an expert witness’s qualifications to testify on an engineering matter needs to be done on a case-by-case basis. The assessment must be based on the witness’s education, years of experience as a practicing engineer, and prior experience and qualification as an expert witness. There also are examples of experts qualified to testify despite little if any formal education in engineering and despite having no engineering background.³⁴

Licensing, Registration, Certification, and Accreditation

After graduation from college, some practicing engineers may go on to obtain professional engineer (PE) licensure. Licenses are required for engineering professionals in all 50 states and the District of Columbia if their services are *offered directly to the public and they would affect public health and safety*.³⁵ To become licensed, in most states, engineers must have a college degree from an ABET-accredited engineering college or university, work under a PE for at least four years, pass two intensive competency exams,³⁶ and submit a license application to their state licensing board. Each state has its own set of conditions for taking the two exams. Each state engineering board has its own pricing, educational requirements, and license procedures. Most boards require candidates to be enrolled in or have completed an ABET-accredited engineering degree. Some states let students from other approved or even non-accredited colleges take the

34. See, e.g., *Guay v. Sig Sauer, Inc.*, 610 F. Supp. 3d 423, 427–32 (D.N.H. 2022) (former fire-arms instructor and armorer found qualified to testify on design of pistol even though he was not an engineer and had done no work on the design or manufacturing of guns).

35. In some states, businesses generally cannot offer engineering services to the public, or cannot have a name that implies that they do so, unless they employ at least one PE. For example, New York requires that the owners of a company offering engineering services be PEs. See <https://perma.cc/2WWD-9E56>.

36. The Fundamentals of Engineering (FE) exam, formerly called the Engineer in Training test, is typically taken during an undergraduate student’s last year in college. People who pass this examination and graduate with an engineering degree are called engineering interns (EIs) or engineers in training (EITs). They become eligible to take the second test, called the Principles and Practice of Engineering examination, after they’ve accumulated enough experience, typically four years of doing engineering work.

exam. However, this isn't always the case. One should make sure to determine the relevant state requirements.³⁷ To retain their licenses in most states, PEs must continually maintain and improve their skills throughout their careers. Obtaining a PE license may be critical in some fields, such as civil engineering,³⁸ but is less so in others. PEs have the authority to certify documents such as reports, drawings, or calculations by signing and sealing (or "stamping") them, thus attesting to the accuracy and correctness of the documents and taking legal responsibility for them.

Many engineering professionals do not seek a PE license because their services are not offered directly to the public or they have no need to certify engineering documents. Whether an individual is licensed as a PE is neither sufficient nor necessary to establish her or his competency as an engineer. Furthermore, the two examinations required for licensure test only for knowledge gained and assimilated at the undergraduate level. It is therefore common for professors of engineering not to have PE licensure, even though they are the ones who teach and prepare others who take the two required examinations.

PE licensure is thus quite different from board certification for a physician or bar admission for a lawyer. Physicians cannot practice medicine without board certification, and lawyers can't practice law if not admitted to the bar, but such strict limitations do not apply universally to engineers. While the title "engineer" is legally protected in many states (meaning that it is unlawful to use it to offer engineering services to the public without a PE license), there are numerous exceptions. People licensed as "operating engineers" are not PEs. There is an industrial exemption for "in house" engineers employed by a manufacturing company or other business not providing a service directly to the public. Employees of state or federal agencies may also call themselves engineers if that term appears in their official job title.

Courts generally have not required an expert to be a licensed PE in order to testify.³⁹ In some cases, however, PE licensure can be an important factor in determining if an expert is qualified.⁴⁰ In still other cases, courts have held that

37. See Eligibility Requirements for the PE Exam by State, available at <https://perma.cc/D9RV-XBNZ>.

38. Because they often are involved in public works projects, civil engineers are more likely than engineers in other fields to obtain PE licenses. This can be traced directly back to the legacy of the St. Francis dam collapse in southern California in the late 1920s. St. Francis Dam Disaster Revisited (D.B. Nunis, Jr., ed., 2002).

39. See, e.g., *Emig v. Electrolux Home Prods. Inc.*, No. 06-CV-4791 (KMK), 2008 WL 4200988 (S.D.N.Y. Sept. 11, 2008) (expert qualified to testify even though not a PE). Cf. *McRunnel v. Batco Mfg.*, 917 F. Supp. 2d 946 (D. Minn. 2013) (fact that expert licensed in Arkansas but not Minnesota was proffered in Minnesota did not make him unqualified).

40. See, e.g., *Clena Investments, Inc. v. XL Specialty Ins. Co.*, 280 F.R.D. 653, 661–62 (S.D. Fla. 2012) (Citing education and experience of plaintiff's expert and noting that like defendant's expert, he was a professional engineer. "Presumably [defendant viewed its expert's] professional engineering license as at least one relevant qualification . . . No less is true of [plaintiff's expert's]

a PE without adequate experience relevant to the issues at hand is not qualified.⁴¹

Just as an undue judicial gatekeeping focus on an expert's degree or licensure is inappropriate, gatekeeping based only on determining whether scientific or engineering expertise is required would be a futile endeavor. Rather, the inquiry ought to focus on the extent to which the *scientific* hypothesis testing or the *engineering* design process is at issue. As an example, fire investigators are often considered engineers, and some universities even offer courses in fire protection engineering. Yet the conduct of an investigation into the origin or cause of a fire involves the kind of hypothesis testing so essential to science. The National Fire Protection Association's Standard 921 "sets the bar for scientific-based investigation and analysis of fire and explosion incidents."⁴² Note, however, that while the *Daubert* hypothesis-testing factor is important for such investigations, peer review of every investigation would not be appropriate, nor would the general acceptance of every investigation.

By way of contrast, the investigation into the 1981 collapse of a hotel skywalk in Kansas City, which killed more than a hundred people,⁴³ provides a classic example of determination of cause through analysis of a design. Without any testing or peer-reviewed publication, and based only on a careful analytical review (using accepted methods and principles), engineers from the National Bureau of Standards quickly determined that the original design was safe, but that a modification made during construction had resulted in an unintended doubling of the load on one element of the support structure.⁴⁴

comparable license and experience."); *Urda v. Valmont Indus., Inc.*, 561 F. Supp. 3d 632 (M.D. La. 2021) (PE license one factor considered in finding expert qualified); *Klingenberg v. Vulcan Ladder USA, LLC*, 936 F.3d 824 (8th Cir. 2019) (PE license one factor considered in finding expert qualified).

41. See, e.g., *Dreyer v. Ryder Automotive Carrier Grp., Inc.*, 367 F. Supp. 2d 413, 426–27 (W.D.N.Y. 2005) (Although proffered expert held a doctorate in mechanical engineering and was a licensed professional engineer, he had no direct experience with the trailer securing system at issue in the case. When asked to explain how a designer would go about assessing the foreseeability of user risk in connection with a product, he could not answer clearly.); *Taber v. Allied Waste Sys., Inc.*, 642 Fed. App'x 801 (10th Cir. 2016) (PE excluded because of lack of relevant experience).

How Do Engineers Think, Make, Test, and Evaluate?

In his book *Applied Minds: How Engineers Think*,⁴⁵ Guru Madhavan explores the mental tools of engineers that allow engineering achievements. He builds his framework around a flexible intellectual tool kit he terms modular systems thinking. We focus on this framework to help explain how engineers think, and supplement our discussion with ideas from the book *The Nature of Technology*⁴⁶ by W. Brian Arthur.

Madhavan's thesis boils down to how engineers think in terms of systems, which means that an engineer can deconstruct (break down a larger system into its modules) and reconstruct (put it back together). The focus is on identifying the strong and weak links—how the modules work, don't work, or could potentially work—and applying this knowledge to engineer useful outcomes. Madhavan contends that there is no engineering method that is broadly applicable across all areas of engineering, so modular systems thinking varies with context. As an example, he describes how engineering the Burj Khalifa (the tallest building in the world, in Dubai) is different, say, from coding the Microsoft Office Suite. Whether used to conduct wind tunnel tests on World Cup soccer balls or to create a missile capable of hitting another missile midflight, engineering works in various ways. Techniques can differ even within a specific industry, but Madhavan identifies the three essential properties of the engineering mindset: the ability to see a structure where there's nothing apparent, adeptness at designing under constraints, and understanding tradeoffs.

Structured Systems-Level Models and Thinking

Our world relies on structure, and the engineering mind gravitates to the unseen portion of the structural iceberg underneath the water rather than what is seen on its surface. A good engineer can visualize and produce structures through a combination of rules, models, and experience. For engineers, the word “model” usually means a mathematical representation of “real world” phenomena. Engineers routinely use mathematical models to represent and conceptually manipulate what happens in the physical world. Once a mathematical model is established and validated, then it can be used to rapidly predict the outcome of an event from a set of inputs.⁴⁷

45. Guru Madhavan, *Applied Minds: How Engineers Think* (2016).

46. W. Brian Arthur, *The Nature of Technology: What It Is and How It Evolves* (2009).

47. Courts have addressed mathematical models in various contexts and generally admit evidence based on them so long as the inputs reflect the actual facts in a case. See, e.g., *Lapsley v. Xtec*,

A structured systems-level thinking process would consider how the elements of the system are linked in logic, in time, in sequence, and in function. Arthur makes a similar point, by describing technologies (i.e., engineering products) as constructions, or “combinations of components and assemblies.”⁴⁸ In addition, an engineer would consider under what conditions the constructions work and don’t work. An historian might apply this sort of structural logic decades after something has occurred, but an engineer has to do it preemptively, whether with the finest details or top-level abstractions. This need to think about what does not yet exist is one of the main reasons engineers often use mathematical models (and sometimes build actual physical models), which facilitate conversations based in reality. Critically, envisioning a structure also involves having the wisdom to decide when it is valuable, and when it isn’t—which is an essential engineering decision.

Adeptness at Designing Under Constraints

Madhavan expounds that, given the practical nature of engineering, the pressures on engineers are greater compared to the pressures experienced by many other professions. Constraints, whether natural or man-made, don’t allow engineers to wait until all matters are fully understood and explained. Engineers are expected to produce the best possible results under the given conditions. Even if there are no fundamental constraints, good engineers know how to apply practical solutions to help achieve their goals. Time constraints on engineers fuel creativity and resourcefulness. Financial constraints and physical constraints imposed by the laws of nature are also common, coupled with an unpredictable constraint—human behavior.

Moreover, because engineers can come up with different (sometimes very different) designs to achieve a specific goal, there is not a single “right” design that fits within given constraints. Proper application of the engineering design process can lead to different end points. For example, engineers have created a wide variety of products to make coffee. As described by Arthur, engineers usually engage in the “planning, testing, and assembly of a new instance of a

Inc., 689 F.3d 802, 816 (7th Cir. 2012) (admitting testimony based on a “mathematical model . . . used in place of physical re-creation”); Leibfried v. Caterpillar, Inc., Case No. 20-CV-1874, 2023 WL 7284795 at *4 (E.D. Wis. Nov. 3, 2023) (expert’s manipulation of “the virtual model to produce results that approximated the post-accident condition” did not preclude admissibility of his testimony); Sommerville v. Union Carbide Corp., Civ. Action No. 2:19-cv-00878, 2024 WL 1204094 at *1 (S.D. W. Va. Mar. 20, 2024) (testimony based on model excluded because the inputs were “speculative and . . . premised on assumptions that do not accurately represent the Defendants’ operations”).

48. Arthur, *supra* note 46.

known technology,” and not necessarily the invention of new technology.⁴⁹ Perhaps the utilitarian notion of providing “the greatest good for the greatest number” is apt here.

Understanding Tradeoffs

Engineering has also been described as a “set of tradeoffs,” and Madhavan introduces the notion of tradeoffs as a last pillar of engineering thought. Tradeoffs are how engineers adapt to constraints. Engineers adopt design priorities and allocate resources by eliminating less important goals and adapting to the more critical constraints in order to focus on achieving the more important goals. When working on the design for a product, engineers must therefore balance various design constraints such as usefulness, usability, cost, performance, aesthetics, and time limitation, all of which make the engineering task quite challenging. A tension exists between the various specifications of the customer. Famed bicycle parts engineer Keith Bontrager is well known for his aphorism: “Strong. Light. Cheap. Pick Two.”⁵⁰ In other words, customers can choose two of three characteristics: strong, light, and cheap. He specialized in designing strong, light, and expensive components. That kind of unavoidable tradeoff leads engineers to rely on their education and training, as well as on their experience and standards to achieve a successful outcome. If one or more of these constraints is relaxed or eliminated (e.g., unlimited time), then the engineering task becomes easier and more achievable, unless the constraint is a fundamental physical law. As another example, for a given airplane design, a typical tradeoff may be balancing the demands of cost, weight, wingspan, and lavatory dimensions within the constraints of the given flight performance specifications. This selection pressure may even lead to the question of whether passengers actually like the airplane they’re flying in and enjoy the experience. If designing within constraints can be viewed as walking a tightrope, then tradeoffs are akin to a tug-of-war among what’s available, what’s possible, what’s desirable, and what the fundamental physical limits are.

Thus, Madhavan’s three essential properties⁵¹ of the engineering mindset lead to the concept of “good engineering practice” or “best engineering practice,” which guides the practitioner of the art.

Arthur makes a different point as he describes engineering design as a matter of choice. As constraints limit possibilities, the design problem becomes more complicated, which leads to a need for a larger number of and more sophisticated components in order to achieve the design goals. Somewhat counterintuitively,

49. *Id.*

50. Grace on Wheels, “Strong, Light, Cheap. Pick Two,” available at <https://perma.cc/BE7H-DPAA> (accessed July 17, 2024).

51. Madhavan, *supra* note 45.

as long as they do not completely eliminate feasibility, constraints actually lead to a richer set of practical possibilities. In effect, “[a]ny new version of a technology is potentially the source of a vast number of different configurations.”⁵²

Engineering Systems

System analysis has become increasingly important in engineering design. Technologies must be evaluated in ever-broadening contexts that include their performance as intended by the designer, but also how they interact with other systems. An electric car, for example, has many mechanical and electrical components as well as software modules that are tested individually, then as subsystems, and finally as a whole system as described in the next section. The hierarchy continues, however, as the car is operating along with other cars over a transportation system. The safety and risk analyses must therefore be conducted at all levels of the hierarchy, from a failure analysis of components all the way up to avoiding accidents in a dynamic traffic environment. The analysis is made more difficult as more products are engineered, monitored, and controlled using machine learning and artificial intelligence.

Systems and Systems of Systems

As mentioned earlier, engineering is a human activity, and while some animals make tools and come together in groups to achieve simple engineering feats, humans are unique in their ability to design systems made of specifically designed components, which may then be assembled into larger systems and systems of systems. A distinguishing feature of engineering is that its products and technologies are intended for use by experts and non-experts alike and must therefore be useful *and* safe as they interact with living and nonliving objects. Understanding and/or operating sophisticated systems or high-complexity systems, such as flying an airplane, will of course require advanced training and certification, while driving a car requires much less. In addition, engineering systems interact with other systems, leading to systems of systems where the interactions between and among systems are just as critical as the behavior of each individual system.

Consider, for example, the social goal of transporting people and goods efficiently while keeping vehicular congestion at an acceptable level. A modern transportation system is composed of vehicles, road networks, railroads, shipping lanes, air traffic lanes, policies, governance structures, and more. A vehicle is one such system, composed of many electrical and mechanical subsystems.

52. Arthur, *supra* note 46.

Putting all the transportation system's subsystems together requires the expertise and contributions of civil engineers, mechanical engineers, electrical engineers, and computer engineers, as well as materials engineers, policy makers, psychologists, and financial and other experts.

Some courts have recognized that engineering products are a collection of components and systems, and the value of expertise in designing and analyzing such systems. *Campbell v. Fawber*⁵³ provides an outstanding example, and shows how engineers can address complex causation questions in the context of litigation. The plaintiff was a passenger in a sport utility vehicle (SUV) that rolled over when the driver lost control.⁵⁴ The plaintiff suffered catastrophic neck injuries that left her quadriplegic.⁵⁵ She sued both the driver and the manufacturer of the SUV, the latter on the theory that the vehicle was not crashworthy because the roof crushed too easily.⁵⁶ She introduced testimony from four experts—three engineers and a specialist in epidemiology and biostatistics. Making this testimony mesh was essentially a matter of systems analysis, and one of the engineering experts explicitly “employed standard scientific systems analysis techniques . . . [which took into account] all aspects of the automotive system through the full crash sequence.”⁵⁷

Complex Systems

The increasing significance of a systems approach to engineering reflects increasing complexity and interaction between products and product components. An article by Robert Lucky cites Samuel Arbesman to explain that there are three main reasons for increasing complexity: accretion, interconnection, and edge cases. Accretion, Lucky writes, “is the result of large systems being built on top of smaller and older systems, often via the incorporation of legacy code, producing what we call kludges.”⁵⁸ He further explains that when “these subsystems become interconnected, the resulting entanglement can change what was simply intricate to truly *complex*.”⁵⁹ “Complexity,” he writes, “is exacerbated by the inevitable existence of edge cases—that myriad of individually negligible exceptions and rarities that yet constitute the long tail of cases that must all be accounted for in system design. The complexity resulting from these factors has passed a tipping point where no single person can fully understand a

59. *Id.*

complete system.”⁶⁰ Complexity may also result from hidden causes, as well as from intentionally introduced design parameters.

Complexity also leads to a less understood phenomenon, namely emergent behavior. As discussed by Anderson,⁶¹ when many objects interact within a system, their overall behavior can no longer be understood using a reductionist approach. As the number of engineered devices multiply, such as within the Internet of Things (IoT), no amount of advanced modeling could *a priori* predict the devices’ ultimate performance. In such a case, there is no substitute for monitoring the actual system in its operational state and designing conservative guardrails. Complexity thus may lead to design flaws that escape detection in the engineering design process.⁶²

Ever since the advent of computing, simulation tools have been used in the design process. While historically, engineering products were designed “by hand,” computers are now ubiquitous as aids to the engineer, and computing tools are used throughout the design and manufacturing processes. The more complicated a system, the more insight may be gained into its behavior by using digital computer simulations. While some systems (such as chaotic systems) may defy causal and deterministic predictions under realistic conditions (slight variations in components), simulations still provide a relatively inexpensive way to model and test engineered components and systems. As more sophisticated tools become available, and with advances in the standard of practice, designers and engineers can model more realistic scenarios, allowing them to push the envelope of performance. Most recently, the availability of more powerful hardware, such as graphical processing units (GPUs), have made machine learning tools more widely available and as such have advanced software development and systems modeling. Below, we discuss two cases where engineering systems failed, and explain the lessons learned.

When Systems Fail

Many cases in which engineers testify arise because an engineered product, structure, or system has failed. Examples of such cases are discussed below in the section titled “Analysis of the Case Law Based on an Understanding of Engineering and How It Differs from Science.” Here we discuss, from an engineering

perspective, an aerospace systems failure associated with batteries in a Boeing airplane.⁶³

Among the various engineering challenges Boeing has faced in recent years is the grounding of the Dreamliner fleet because of lithium ion battery fires.⁶⁴

At 10:21 a.m. on [January] 7, 2013, about a minute after all 183 passengers and 11 crew members from Japan Airlines Flight 008 disembarked at Boston's Logan International Airport, a member of the cleaning crew spotted smoke in the aft cabin of the Boeing 787-8. A mechanic then opened the aft electronic equipment bay of the plane, parked at the airport gate, and saw billowing smoke and flames coming from the batteries for the 787's auxiliary power unit (APU).⁶⁵ . . . The culprit was a lithium-ion battery manufactured by GS Yuasa. [The battery] was found to be under a condition known as a thermal runaway, in which the heat from a failing cell causes itself and surrounding cells to fail, thereby generating more heat.

[In December 2014], the U.S. National Transportation Safety Board [NTSB] released its report on the Japan Airlines fire. The agency faulted Boeing, GS Yuasa and FAA for shortcomings in their respective roles in the 787 grounding. [This] episode highlights some of the emerging concerns around cutting-edge clean technologies, particularly those that store large amounts of energy. Saving electrons for later is important for applications like electric vehicles, and denser batteries mean vehicles can go farther with less weight, a major consideration for fuel-conscious airlines. Storing electricity is also crucial for smoothing over peaks and valleys in output from wind and solar [generation facilities]. Batteries, especially the lithium-ion variety, are largely filling this role. But doing so at larger scales and with new systems requires additional scrutiny and training for the unique challenges posed and the growing pains that may arise.

63. For information about Boeing, a global aerospace company that “develops, manufactures and services commercial airplanes, defense products and space systems for customers in more than 150 countries,” see Boeing in Brief, Boeing company website, at <https://perma.cc/CN8R-CGMS>.

64. The description of the Dreamliner batteries incident was reproduced from Umair Irfan, *Climatemire* (published in *Scientific American*, December 18, 2014, available at <https://perma.cc/4CSK-U2GH>).

65. The mechanic used a fire extinguisher to try to put out the flames, “but the blaze didn’t go out. Firefighters arrived at the scene at 10:37 a.m., and using a thermal imaging camera, they looked through the smoke in the equipment bay and saw a softball-sized glow. Responders attempted to extinguish the heat source with Halotron, a fire suppressant. The flames went out, but another firefighter saw that the batteries were still giving off heat and appeared to rekindle. The batteries hissed, leaked fluid and popped. . . . By 12:19 p.m., firefighters had declared the event ‘controlled,’ having removed the APU battery after extinguishing it with further doses of Halotron.” *Id.*

For the Dreamliner incident, the NTSB concluded Boeing did not “incorporate design mitigations to limit the safety effects that could result in such a case.”⁶⁶ Thus, it is evident that system design has to envision failure modes and provide for mitigation solutions that will provide the desired safety level for the system.

What this failure highlighted was the fact that for such complex systems with catastrophic consequences of a failure, the constraints placed on engineers might have led to inadequate solutions. Therefore, engineers testifying in such cases should be allowed to elaborate on the constraints that were placed on their design and on their work in general, as those might have been incompatible with the stated objective.

Computers, Artificial Intelligence, and Machine Learning

The increased use of data in every human endeavor has penetrated all engineering fields, and as a result machine learning (ML) and artificial intelligence (AI) tools have become increasingly important. Large language models (LLMs) (e.g., ChatGPT) have thrust these tools into our daily lives and into the engineering process. LLMs are being used to conduct patent searches and to assist in software writing. While this development has led to performance improvements, it has created new concerns as we try to evaluate engineered systems and to assign responsibility when systems fail to perform as expected. Moreover, systems designed using ML techniques often lack transparency in their internal workings and may become harder to explain and debug. In fact, the National Science Foundation’s Engineering Research Visioning Alliance (ERVA) has come out with a report that advocates creating AI engineering as a new discipline.⁶⁷

Even though these technologies are now seemingly ubiquitous, we shouldn’t overlook how truly revolutionary they are and the remarkable things they enable us to do today and will allow us to do tomorrow. For engineers, AI and ML might cause the tasks they perform to evolve, but these tools can also help them perform new tasks they couldn’t undertake before. There likely will be unintended and unforeseen consequences, however, as use of the new technologies becomes ever more common. As discussed in the *Reference Guide on Artificial Intelligence*, in this manual,⁶⁸ unwitting human bias “refers to the unintentional infusion into an application of human preferences, stereotypes, values, fears, or knowledge. Consider an algorithm intended to predict risk. An engineer might apply engineering

principles to a risk equation.” An excellent example of unwitting human bias is described in a study published in *Science*⁶⁹ in 2019. In that study, it was found that an algorithm widely used in U.S. hospitals to allocate health care to patients has been systematically discriminating against black people—the algorithm was less likely to refer black people than white people who were equally sick to programs that aim to improve care for patients with complex medical needs. The study states that hospitals and insurers use the algorithm and others like it to help manage care for about 200 million people in the United States each year. Engineers may unwittingly succumb to other unknown biases because ML algorithms are based on training data generated and selected by humans. Bias in the training data will lead to biased algorithms. For more detailed discussion of the use of AI in engineering and elsewhere, please see the *Reference Guide on Artificial Intelligence*,⁷⁰ in this manual.

Analysis of the Case Law Based on an Understanding of Engineering and How It Differs from Science

To gain insight into the kinds of cases in which engineering experts testify and the issues they address, we searched the Westlaw “All Federal” database for all cases decided over the 18 months from January 1, 2021, through June 30, 2022, in which “*Daubert*,” “*Kumho*,” or “702” appeared, along with “engineer” or “engineering” in the same sentence as “expert.” Of the 496 cases we found, only 201 (i.e., about 134 cases a year) required a court to address the question of what constitutes valid and reliable engineering testimony.⁷¹ An explanation of how we winnowed down to 201 cases is provided in the footnote below.⁷²

69. Ziad Obermeyer et al., *Dissecting Racial Bias in an Algorithm Used to Manage the Health of Populations*, *Science* 366, 447–53 (2019), <https://doi.org/10.1126/science.aax2342>.

70. See James E. Baker & Laurie N. Hobart, *Reference Guide on Artificial Intelligence*, section titled “Bias,” in this manual.

71. Of course, the sample did not include the many cases that settle or otherwise resolve without leaving any trace in the Westlaw system.

72. We first eliminated from the Westlaw sample all cases that were not on point. One hundred thirty-eight of 496 cases did not really relate to engineering at all, or were reversed. Of the remaining 358 cases, 76 involved the kind of simple accident investigations with which courts have a long history, and for which judges do not likely require any reference materials beyond what the parties provide. Taking out the 76 simple accident cases from the remaining 358 Westlaw search results left 282 cases for further consideration. The number was reduced yet further by taking out insurance coverage cases. The engineering issues in such cases are confined almost exclusively to causation and qualifications, and the use of experts goes back a long time. In *Peele v. Merchants’ Ins. Co.*, 19 F. Cas. 98, 102 (D. Mass. 1822), the court noted that with regard to the sufficiency of repairs to an insured ship, it would if necessary use “experts to report upon the whole evidence, what in their judgment is the true posture of the case in this respect.” After we removed the

In the discussion below, we have categorized the 201 relevant cases by the kind of litigation involved, and within each category (based both on the sample cases and further research) we consider how courts have distinguished between engineering and science, and when and how they have focused on some aspect of the design process or the way in which engineers evaluate designs. Products liability claims were at issue in the majority of the 201 cases, but there were a number of contract or construction litigation cases, intellectual property cases, and environmental or land use cases. We also discuss two other categories: cases involving failure analysis (which often overlap with products liability cases), and cases in which some kind of engineering test (e.g., a test for the strength of steel) was at issue. If and how to apply the *Daubert* factors to engineering is a recurrent theme in most of the categories, as exemplified by *AZZ, Inc. v. Southern Nuclear Operating Company, Inc.*,⁷³ in which the court found an engineer's testimony inadmissible as scientific evidence, but admissible because he employed an appropriate experience-based methodology.

Products Liability Cases

According to Professor David Owen, “Americans suffer some 200 million non-trivial product-related injuries and illnesses each year, at an annual cost to the nation approaching \$10 trillion.”⁷⁴ Most of these injuries are the result of product misuse, but “many product-related accidents result from dangers in or misrepresentations about products that manufacturers reasonably should have taken steps to avoid. It is cases involving these types of product deficiencies that are the realm of products liability law.”⁷⁵

In most American legal jurisdictions⁷⁶ there are four legal theories under which a products liability plaintiff can recover: (1) negligence, (2) tortious misrepresentation, (3) breach of warranty, and (4) strict liability.⁷⁷ Putting aside

accident and insurance coverage cases, 226 cases remained. Of these, another 25 involved matters like employment related claims, criminal law issues, or civil rights that similarly don't present difficult engineering evidence admissibility questions. That left 201 cases in which the admissibility challenge was potentially more complex, or about 134 per year. One hundred twenty-six of the 201 cases involved products liability. Twenty-four involved contract or construction litigation claims, 22 involved intellectual property, and 19 involved environmental or land use questions.

74. David G. Owen, *Products Liability in a Nutshell* 12–13 (10th ed. 2022).

75. *Id.* at 13.

76. In 1992, the American Law Institute commissioned two professors “to prepare a new *Restatement (3d) of Torts* on the specific topic of products liability law.” Owen, *Products Liability in a Nutshell*, *supra* note 74, at 19. The new *Restatement* was approved in 1997 and published in 1998, but most jurisdictions have not formally adopted it, and most courts at least nominally still adhere to the traditional products liability legal framework. *Id.* at 19–20.

77. *Id.* at 15–20.

tortious misrepresentation, a relatively rarely used theory, “the plaintiff in nearly every products liability case must prove that a product sold by the defendant contained an unnecessary hazard [or defect] that caused [physical] harm,”⁷⁸ and most engineering expert testimony in products liability cases relates to whether there was or wasn’t a defect, and if there was, whether it caused the plaintiff’s injury.

Modern products liability law dates from the late 1950s and early 1960s. Over the past 60 or so years, “courts and commentators [have come] to understand the distinctions between three very different forms of product defect.”⁷⁹ Manufacturing defects are “unintended physical irregularities that can occur during the production process.”⁸⁰ Design defects are “hazards in a product’s engineering or scientific conception that reasonably should be avoided by a different design or formula.”⁸¹ Warning defects occur when there is an “absence of important information about product hazards or how to avoid them.”⁸² Below, we discuss how engineering expert testimony is evaluated with regard to each kind of defect and with regard to the issue of causation. We also discuss engineering testimony on a manufacturer’s duty of care, an issue that arises when a plaintiff claims under a negligence theory.

Design Defects

Depending on the jurisdiction and the facts in a given case, the legal test for determination of a design defect can turn on either (1) what an ordinary consumer might reasonably expect, or (2) a balancing of a product’s risk versus its utility or benefit.⁸³ Plaintiffs generally may introduce expert testimony to establish a defect under either theory, but an expert will more often be necessary to prove a defective design under the risk–benefit test. See, for example, *Bradley v. Ameristep, Inc.*,⁸⁴ in which the court noted that under Tennessee’s products liability law, a plaintiff invoking the consumer–expectation test can prevail without any expert testimony at all. The consumer–expectation test generally does not apply to complex products, however. As explained in *Brown v. Raymond Corp.*,⁸⁵ consumers have no reasonable expectations about products so complex they can’t really be understood.

78. *Id.* at 20, and *Restatement (Second) of Torts* § 402A.

79. Owen, *supra* note 74, at 199.

80. *Id.*

App’x 435, 437 (9th Cir. 2017) (consumer–expectations and risk–benefit tests provide alternative means for a plaintiff to prove a design defect). See also Owen, *supra* note 74, at 186–87.

84. 800 F.3d 205, 211 (6th Cir. 2015).

85. 432 F.3d 640, 643 (6th Cir. 2005).

Given the limited use of experts in cases based on consumer expectations,⁸⁶ we only address risk–benefit cases here. In such cases, the predominant engineering issue is the proper way to develop and evaluate designs. Two of the most significant legal questions are (1) whether an expert has to identify a reasonable alternative design, and (2) whether testing is required to prove the existence of a defect or to validate a proposed alternative design. With regard to the *Daubert* factors, testing is the only factor typically at issue. The peer-review/publication process generally does not apply for designs, whether original or alternatives proposed in litigation. While they are reviewed and checked, designs typically do not go through peer-reviewed publication. Nor is the question of error rate meaningful in the analysis of most designs. Sometimes general acceptance of an alternative design may be considered, as well as design or performance standards, but of the *Daubert* factors, testing is what most often becomes an issue in products liability cases.

Reasonable alternative design

The *Brown v. Raymond Corp.* case is an example of requiring evidence of a safer alternative design. The plaintiff was injured in a forklift accident, which he claimed was caused by a defective design.⁸⁷ The trial court excluded testimony from the plaintiff’s design-defect expert because he “was not an expert in forklift design and had not proposed any alternative designs against which to test his conclusion that the Raymond forklift was unreasonably dangerous due to a design defect.”⁸⁸ The Sixth Circuit affirmed.⁸⁹ Note, however, that the case did not turn on any issue about engineering testimony because the plaintiff had asserted claims based on the consumer-expectation test, and there was no alternative design to evaluate.⁹⁰

Notwithstanding cases like *Brown*, an alternative design is not absolutely necessary even in risk–benefit cases. *Williams v. Tristar Products, Inc.*⁹¹ illustrates this

86. Also, as Professor Owen points out, courts increasingly are turning to the risk-benefit test. David G. Owen, *Products Liability in a Nutshell* 175 (10th ed. 2022).

87. *Brown*, 432 F.3d at 641–42.

88. *Id.* at 647.

89. *Id.* at 650. See also *Lara v. Delta Int’l Mach. Corp.*, 174 F. Supp. 3d 719, 736 (E.D.N.Y. 2016) (“In a products liability action, ‘the “touchstone” of an expert’s report should be a comparison of the utility and cost of the product’s design and alternative designs.’”); *Peck v. Bridgeport Machs., Inc.*, 237 F.3d 614, 618 (6th Cir. 2001) (reasonable alternative design required); *Willet v. Johnson & Johnson*, 465 F. Supp. 3d 895, 904 (S.D. Iowa 2020) (“plaintiffs . . . [must] demonstrate the existence of a reasonable alternative design”).

90. *Brown*, at 643 (plaintiff’s counsel conceded the case depended on applying the consumer-expectation test).

91. 418 F. Supp. 3d 1212 (M.D. Ga. 2019).

point. The plaintiff in the case suffered burns when the lid of a pressure cooker unexpectedly popped off. The court admitted testimony from her expert, who had “a Ph.D. in engineering and . . . extensive experience in design and development of products, fasteners, machines, tools, and latching and locking devices.”⁹² He had tested a pressure cooker like the one that injured the plaintiff, and explained his testing in detail.⁹³ “His familiarity with pressure cookers manufactured by defendant gained by testifying as an expert in similar litigation further demonstrate[d] his experience and knowledge of the product.”⁹⁴ The expert had not proposed any alternative design, but the court held that “it is not required that either plaintiff present evidence of reasonable alternative designs or that the evidence be in the form of expert testimony.”⁹⁵ Though it did not involve a proposed alternative design, *Williams* falls squarely within the kind of analysis suggested in this reference guide because the issue was the expert’s analysis of an *existing* design.⁹⁶

*Is testing required to prove existence of a defect
or the validity of an alternative design?*

The question of testing arises in many products liability cases, both to establish a defect and to validate a reasonable alternative design. The focus on testing usually derives from *Daubert*, not *Kumho Tire*, and while courts sometimes do suggest testing is part of engineering practice as well as science, they also may confuse or miss the distinction between scientific testing of hypotheses and engineering analysis and testing of designs. For example, in *Colon ex rel. Molina v. BIC USA, Inc.*,⁹⁷ the court held that “[w]hile testing is not an ‘absolute prerequisite’ . . . it is usually critical to show that an expert ‘adhere[d] to the same standards of intellectual rigor that are demanded in their professional work.’”⁹⁸ The court then discussed what *scientists* typically do, stating that “[a]dherence to *engineering* standards of intellectual rigor almost always requires testing of a *hypothesis*.”⁹⁹

96. *Cf. Bullock v. Volkswagen Grp. of Am., Inc.*, 107 F. Supp. 3d 1305, 1315 (M.D. Ga. 2015) (court more or less reasoned in reverse to hold that testimony about a reasonable alternative design was sufficient to establish a design defect, even though the plaintiff’s expert was reluctant to describe the problem he saw as a design defect).

97. 199 F. Supp. 2d 53 (S.D.N.Y. 2001).

98. *Id.* at 76 (quoting *Cummins v. Lyle Indus.*, 93 F.3d 362, 369 (7th Cir. 1996)).

99. *Id.* (emphases added).

While the decision may well have been sound, it appears to conflate science and engineering.¹⁰⁰

*Nease v. Ford Motor Co.*¹⁰¹ provides an example of testing to establish if there really was anything at all wrong with the product in question. The plaintiffs claimed that a cable housing design was defective because it allowed dirt and other contaminants to interfere with the operation of a pickup truck accelerator cable. They claimed a crash had resulted when a stuck cable prevented the truck in question from decelerating after the driver let up on the gas pedal. The trial court admitted the testimony of the plaintiffs' expert, an electrical engineer, but the Fourth Circuit reversed, holding that the expert's analysis of the design was inadequate. "Testing was of critical importance in this case . . . [but the expert had] conducted no testing whatsoever to arrive at his opinion. . . . [He had not determined] whether it is actually possible for enough debris to accumulate in the casing cap during normal operation to resist the . . . force exerted by the return springs to pull the throttle closed."¹⁰²

By way of contrast, in *Lapsley v. Xtek, Inc.*,¹⁰³ an expert's opinion on a design defect was admitted without testing. The plaintiff was severely injured when a high-intensity jet of grease spurted from a bearing on a huge steel rolling mill machine. His expert explained how the design of the bearing lubrication system differed from a design used on similar rolling mills manufactured both before and after the accident. The expert also explained how this difference caused grease

100. *Cf. Amica Mut. Ins. Co. v. Electrolux Home Prods., Inc.*, 440 F. Supp. 3d 211, 217–18 (W.D.N.Y. 2020) (referring to quintessentially engineering tests as scientific tests while applying *Daubert* to engineering testimony); *Morasch Meats, Inc. v. Ludwick*, Case No. DK 18–02714, 2019 WL 5616261, at *2 (W.D. Mich. Sept. 11, 2019) (engineering expert's testing "is the staple of scientific method, even if his assistance in this matter will not be, strictly speaking, scientific").

101. 848 F.3d 219 (4th Cir. 2017).

102. *Id.* at 231–32. *See also* *Elkharroubi v. Six Flags Am. LP*, Civ. Action No. TJS-17–2169, 2020 WL 1043304, at *6–7 (D. Md. Mar. 4, 2020) (plaintiff claimed a malfunctioning trap door on a water slide caused his injury, but expert could not "point to a single observation of the trap door mechanism that would render his opinions plausible"); *Kesse v. Ford Motor Co.*, Case No. 14-cv-6265, 2020 WL 832363 (N.D. Ill. Feb. 20, 2020) (theory that electromagnetic interference could cause sudden acceleration was untested); *Graves v. Mazda Motor Corp.*, 675 F. Supp. 2d 1082, 1102 (W.D. Okla. 2009) (In case involving design of automobile gear shift mechanism, expert's conclusion that shifter was unsafe because it was different from other designs was excluded because it was "not grounded in any objective data or specifically applicable engineering standards. Although [his] Rule 26 report recites his substantial experience with engineering testing in a variety of contexts . . . he did no testing to quantify . . . any exceptional propensity of the gated shifter on the Mazda6 to cause driver confusion about the actual position of the shift lever."). *Cf. Alfred v. Caterpillar, Inc.*, 262 F.3d 1083, 1088–89 (10th Cir. 2001) (expert should have been allowed to testify that a rotary dial speed control on a paving machine was not in compliance with SAE standards, but his testimony on whether this non-compliance made the machine defective was properly excluded because he had done nothing more than cite to the standard; court affirmed summary judgment for the defendant).

103. 689 F.3d 802 (7th Cir. 2012).

to spurt out. The trial court admitted his testimony, noting that he had employed “commonly known methodologies and physics calculations,” which “included the use of Bernoulli’s equation regarding energy in moving fluids and reference to ‘widely accepted factors concerning the force necessary to penetrate human skin.’”¹⁰⁴ The Seventh Circuit affirmed, holding that “the math and science here are within the comprehension of judges and lawyers without extraordinary assistance. Xtek disputes the completeness and therefore the relevance of [the expert’s] calculations, but it has not identified, and we have not detected, any grave questions about the reliability of the calculations [he] actually performed.”¹⁰⁵

Sometimes an engineer’s experience alone may suffice for admissibility purposes without a requirement for testing of the product at issue or explaining how the analysis of a design supports an expert’s conclusions. In *Bullock v. Volkswagen Group of America, Inc.*,¹⁰⁶ the plaintiffs claimed a defective turbocharger on a Volkswagen Passat had caused the vehicle to crash when it accelerated uncontrollably. The court denied the defendant’s *Daubert* motions and allowed a mechanic to testify that a leaking seal had caused the unintended acceleration. He had “investigated and diagnosed unintended acceleration events in cars, and [had] designed a solution to fix a problem with unintended acceleration in prior model Volkswagen turbocharged engines.”¹⁰⁷ He “formed his opinions by observing the physical evidence, testing an exemplar vehicle, and drawing on his extensive experience in the field.”¹⁰⁸ Another expert, a materials engineer, was allowed to

104. *Id.* at 807–08.

105. *Id.* at 809–10. See also *Russell v. Howmedica Osteonics Corp.*, No. C06-4078-MWB, 2008 WL 913320, at *5–7 (N.D. Iowa Apr. 2, 2008) (on the question of whether a certain titanium alloy was properly used in a spinal fixator, plaintiff’s expert was allowed to testify based on articles about the relative merits of various metals, even though there was little evidence about when one metal should be used instead of another, or about her opinion that the alloy in question should not be used in patients weighing more than 180 pounds); *Dunton v. Arctic Cat, Inc.*, 518 F. Supp. 2d 296, 300 (D. Me. 2007) (mechanical engineer and a product designer who worked for defendant were allowed to testify about the adequacy and safety of design for snowmobile steering and suspension components); *Freitas v. Michelin Tire Corp.*, No. CIV. 3:94CV1812 (DJS), 2000 WL 424187, at *2 (D. Conn. Mar. 2, 2000) (expert on tire design defect allowed to testify based on “mathematical calculations and experience conducting burst tests on mismatched tires, as well as upon his review of burst tests performed by other reliable testers, sworn testimony and reports of other experts, and industry and tire company documents”). Cf. *Shreve v. Sears, Roebuck & Co.*, 166 F. Supp. 2d 378, 424 (D. Md. 2001) (expert testimony excluded, but “under the unique circumstances of this case, a lay jury could reasonably conclude without the aid of expert testimony that the snow thrower purchased by [plaintiff] was defective [in design] and unreasonably dangerous”); *Valente v. Textron, Inc.*, 932 F. Supp. 2d 409, 426–27 (E.D.N.Y. 2013) (computer simulation not reliable because expert used the wrong coefficient of friction).

106. 107 F. Supp. 3d 1305 (M.D. Ga. 2015).

107. *Id.* at 1310.

108. *Id.* at 1311.

testify based only on his experience with automotive component analysis and aviation turbochargers that there were safer seal designs.¹⁰⁹

The three lines of cases: *Nease* (testing required to prove defect); *Lapsley* (explanation of analysis is sufficient); and *Bullock* (reliance on expert's experience is sufficient) are not inconsistent. All three relate to the question of what caused an unwanted event, and the different legal analyses reflect the fact that different kinds of experts in differing cases can address the question in different ways. Sometimes the answer is evident to a person with adequate experience, and no testing or analysis is required. In such cases, neither the engineering design process nor the scientific method would be implicated. Sometimes the expert has essentially formulated a hypothesis, and admissibility properly would require *Daubert*-like testing against observational or experimental data. And sometimes an engineering analysis will suffice if it properly reflects the way engineers review and analyze designs. Thus, before deciding on the admissibility of expert testimony, a court needs to first identify what approach the expert has taken, and then apply the appropriate legal analysis.

For plaintiffs in products liability cases, a requirement that an expert must test an alternative (likely by having to build a prototype) can be difficult if their expert has come up with a new design rather than citing to another existing product. In *Lara v. Delta International Machinery Corp.*,¹¹⁰ the expert testified that a table saw without an interlocking safety device was inherently dangerous, but he conceded that “other than some theoretical musings made during his deposition as to how such a design could be accomplished . . . he [had] never actually designed such an interlock system for use in a table saw.” Nor had he done any testing, which the court held should be part of the “utility versus cost comparison.”¹¹¹ Thus, the testimony was excluded.¹¹²

112. *Id.* at 738. *See also* *Colon ex rel. Molina v. BIC USA, Inc.*, 199 F. Supp. 2d 53, 75–78 (S.D.N.Y. 2001) (requiring testing of alternative design); *Wright v. Case Corp.*, 2006 WL 278384,

Not all courts have required testing of an alternative design, however, especially when it is clearly explained or related to existing designs by analogy. In *Lynn v. Yamaha Golf-Car Co.*,¹¹³ for example, testimony about an alternative design for passenger restraint features on a golf cart was held to be admissible, even though the expert had conducted no testing. He cited other golf carts that included features similar to what he proposed,¹¹⁴ and his opinions were not based on “alternative designs that would require enhanced technology or a complete overhaul of the hip restraint.” While they might “impede on a passenger’s ability to enter and exit the vehicle with ease, a jury could readily find that such an imposition would be insignificant compared to the increased safety users would enjoy by the alternative design.”¹¹⁵ Likewise, in *Cruz v. Kumho Tire Co., Inc.*,¹¹⁶ the expert had not physically tested her proposed alternative design, and could not identify any manufacturer that used it, but her testimony was admissible as she “utilized accepted engineering calculations and risk-utility analysis in developing her design, which draws support from relevant industry studies.”¹¹⁷

Unlike the “did a defect cause the event” cases discussed above, the “is the alternative reasonable” cases almost all require consideration of how engineers

at *4 (N.D. Ga. Feb. 1, 2006) (expert conceded he had done no testing of alternative design, and court held that “testing is particularly important in alternative design cases . . . where it is necessary to show that an alternative design is actually feasible”); *Peck v. Bridgeport Mach., Inc.*, 237 F.3d 614, 618 (6th Cir. 2002) (testimony inadequate where expert said he would have designed a lathe differently, with a “safer” lever shift mechanism, but “had never fabricated such a design and, in fact, had never seen his proposed design used on a lathe anywhere”). *Cf. Crawford v. ITW Food Equip. Grp., LLC*, 977 F.3d 1331, 1340 (11th Cir. 2020) (expert testimony admissible where he built and demonstrated the alternative design he proposed for a meat saw).

July 30, 2014) (Expert allowed to testify about alternative design for artificial hip based on his education and experience, which “underpinned his opinion that [defendant’s acquisition of designs for similar products] provided [defendant] with an available and reasonable alternative design [for the product at issue].”); *Thierfelder v. Virco, Inc.*, 502 F. Supp. 2d 1025, 1030–31 (W.D. Mo. 2007) (admitting opinions of expert with years of experience “in the design of wheels and the dimensions of wheelbases for various kinds of mobile furniture” in case involving injury caused by a cart used for folding chairs; expert did no computer modeling or calculations, but did observe the cart and explained proposed changes to protect the feet of users). *Cf. Thomas v. FCA US LLC*, 242 F. Supp. 3d 819, 831 (S.D. Iowa 2017) (in a case involving allegedly defective airbag, experts did not have to design an alternative airbag because, in their view, defendant already had viable alternatives); *Nicholson v. Biomet, Inc.*, 537 F. Supp. 3d 990, 1010 (N.D. Iowa 2021) (existing products could serve as reasonable alternative design); *Borsack v. Ford Motor Co.*, No. 04 Civ. 3255(PAC), 2007 WL 2142070, at *9 (S.D.N.Y. July 26, 2007) (expert opined there were three alternative door latch designs without citing any testing, though the court did not address whether they were all already in use).

actually go about creating and evaluating designs. Based on that standard, testing is not an absolute requirement, nor is it necessary in many cases. Prototypes are not always required before executing a design, and while moving from design to manufacture of a product may require testing of certain components, that does not mean establishing reasonable feasibility requires such testing. The result in the *Lara* case (exclusion of expert testimony on alternative design for a power saw) might well have been different had the expert fully explained how the proposed alternative design could feasibly have been executed.

Manufacturing Defects

In manufacturing defect cases, the problem with the product is often quite evident, and close gatekeeping scrutiny is not required. For example, in *Schmude v. Tricam Industries, Inc.*,¹¹⁸ the parties agreed a ladder was defective because of an improperly installed rivet, but the defendant nonetheless challenged the plaintiff's expert based on a lack of testing and peer review. The court held that the "defect, by its very nature, did not lend itself to the kind of empirical testing *Daubert* envisioned for opinions that are based on cutting edge science. . . . Once [the ladder] failed, there was nothing to test. . . . Other than carefully examining the failed rivet, including the portion embedded in the backing plate, there seemed little else for an expert to do."¹¹⁹

Other cases have subjected engineering experts to closer scrutiny, especially when testing is reasonably possible and would provide important information. In *Myrick v. U.S. Saws Inc.*,¹²⁰ the plaintiff was injured when a power saw blade manufactured by the defendant broke apart. The plaintiff's expert attempted to eliminate all possible causes except for a manufacturing defect, and eventually concluded the failure had occurred because of a defective weld. The court rejected this approach,

118. 550 F. Supp. 2d 846 (E.D. Wis. 2008).

119. *Id.* at 852. See also *Martin v. Apex Tool Grp., LLC*, 961 F. Supp. 2d 954, 960–61 (N.D. Iowa 2013) (expert's opinion that flaws in pry bar caused it to fail held admissible based on detailed examination of the bar—which led him to conclude failure originated at location of flaw—size of flaw, location of flaw, the way bar was used, and absence of evidence of misuse; court cited *Kumho Tire* for proposition that "an expert might draw a conclusion from a set of observations based on extensive and specialized experience"); *McCloud v. Terex Telelect Inc.*, No. Civ–08–433–D, 2010 WL 3259823, at *3 (W.D. Okla. Aug. 17, 2010) (expert engineering testimony on manufacturing defect in step on rear of a truck admitted because expert "testified in his deposition . . . that he employed a recognized method of engineering analysis in reaching his conclusions"); *Engler v. MTD Prods., Inc.*, No. 13–CV–575 (CFH), 2015 WL 900126 at *2 (N.D.N.Y. Mar. 2, 2015) (plaintiff was thrown off a virtually new riding mower after the brakes failed because of excessive wear; engineer's testimony—that brakes likely had not been adjusted right when the mower was sold—was admitted even though he did not know what had caused the brakes to come out of adjustment or why they were prematurely worn).

120. No. C11–1837Z, 2013 WL 766192 (W.D. Wash. Feb. 28, 2013).

holding that the expert's testimony was not reliable. Expert "was aware of multiple destructive and non-destructive tests available that could have been done in this case, but [he] conducted no tests on the weld or blade at issue."¹²¹

*Pugh v. Louisville Ladder, Inc.*¹²² provides an excellent example of how courts sometimes consider both empirical testing and analytical explanation in assessing engineering testimony on a manufacturing defect. The plaintiff, injured when he fell from a ladder, attributed the accident to manufacturing defects that caused the ladder to fail. In particular, he claimed "microscopic cracks at the ladder's rivets . . . [had] propagated into larger cracks causing catastrophic failure/buckling that resulted in [his] fall."¹²³ The defendant ladder manufacturer maintained that the buckling occurred when the plaintiff slipped and fell on top of the ladder.¹²⁴ In other words, the case came down to whether cracks and buckling caused the fall or whether the fall caused the buckling. The jury returned a plaintiff's verdict, and the defendant appealed, arguing, among other things, that the trial court had abused its discretion in admitting testimony from the plaintiff's engineering experts. The Fourth Circuit affirmed after rejecting the defendant's claim that "principles of physics would disprove [plaintiff's] experts' theory."¹²⁵ The plaintiff's experts initially had concluded the ladder failed based solely on a visual inspection, but thereafter they "performed several tests to support their initial assessment."¹²⁶ Based on this testing and their experience, they "determined that their structural failure theory was scientifically supported by the facts of this case and the most likely cause of the accident."¹²⁷ They also performed "testing and analysis to disprove the opposing theory [of] impact damage."¹²⁸

In many cases, design defect and manufacturing defect claims are alleged together, and the distinction sometimes gets blurred in the admissibility analysis. In *Tillman v. C.R. Bard, Inc.*,¹²⁹ for example, the plaintiff claimed that a defective filter had been implanted in one of her veins to keep blood clots from migrating

121. *Id.* at *5. See also *Easterling v. Ford Motor Co.*, 303 F. Supp. 3d 1211, 1222–23 (N.D. Ala. 2018). Plaintiff claimed a seat belt had come unlatched in the course of an accident as a result of a manufacturing defect. His expert engineer's testimony was excluded because expert admitted he did not know why the buckle had come undone, nor had he done any testing.

123. *Id.* at 450.

124. *Id.*

125. *Id.* at 453.

126. *Id.* at 455.

127. *Id.*

128. *Id.* While very well reasoned, the court's opinion did conflate engineering with science, probably because that is how the parties argued the case. For example, the court noted that the plaintiff's experts "determined that their structural failure theory was scientifically supported by the facts of this case and the most likely cause of the accident." 361 Fed. App'x at 455. The court cited *Kumho Tire* once and *Daubert* 24 times.

129. 96 F. Supp. 3d 1307 (M.D. Fla. 2015).

to where they could cause serious harm. Her doctor planned to remove the device when her clotting risk subsided, but could not do so because it had tilted and become stuck in the vein. Although it had not failed, she claimed that owing to design and/or manufacturing defects it was prone to failure, and that she'd suffered harm because she would be forced to endure monitoring to avoid a failure-related injury. The plaintiff proffered five experts, ranging from an epidemiologist to several engineers, and while the court excluded some of them, all the engineering testimony on manufacturing defects was admitted, even though none of the experts could examine or test the plaintiff's filter because it remained implanted in her vein.¹³⁰ Whether the design or a manufacturing defect caused this conundrum was not really addressed.¹³¹ The court ultimately denied a motion for summary judgment on the design and manufacturing defect claims simply "because there are issues of fact as to whether the filter's risks are unreasonable as a result of its arguably defective design or manufacture."¹³²

Just as courts sometimes do not require distinctly different testimony on design versus manufacturing defect, they also sometimes do not require an expert to specify the exact nature of the defect that caused an injury. In *Rudd v. General Motors Corp.*,¹³³ the plaintiff was injured while tuning a pickup truck engine. As he leaned over the motor to turn the distributor housing, a blade came off the fan and struck him.¹³⁴ His expert could not pinpoint the cause of the failure, other than to say he thought "the fan blade had to have some small defect for the fatigue failure to start."¹³⁵ He said that, based on what he had encountered in his experience, there were three possible explanations, but also said there could be others.¹³⁶ He could rule out catastrophic or abnormal use, however, as well as the development of lesser damage that might have occurred post-manufacture.¹³⁷ "Although . . . he did not find direct evidence of a manufacturing defect, such as a microscopic grind mark or inclusion near the fatigue-fracture origin, his testimony [was] replete with circumstantial evidence that—through a process of eliminating alternative explanations—might support a finding of a manufacturing defect."¹³⁸

Warning Defects

Experts on warnings often have engineering degrees, but their expertise more typically relates to fields like human factors, ergonomics, or communications. Although both human factors and ergonomics might be considered engineering specialties, separate experts are often used for warning defects.¹³⁹ Importantly, the issue of admissibility rarely if ever implicates the creation or analysis of designs, which is the focus of this reference guide. Indeed, some courts have held that no expert testimony is required on the adequacy of a warning.¹⁴⁰

That said, some courts do allow warnings testimony from design experts, especially when the expert has experience with warning issues. In *Thierfelder v. Virco, Inc.*,¹⁴¹ the plaintiff was injured when a cart designed for moving folding chairs rolled over her foot. Her expert was a mechanical engineer with over thirty years' experience in the furniture industry, and he had worked on wheel placement on moveable furniture.¹⁴² He opined that the defendant could have made several changes to improve the safety of the cart in question.¹⁴³ He also opined

139. Proceeding on both design defect and warning defect claims can create something of an evidentiary conundrum, especially if the plaintiff suggests a reasonable alternative design. If one witness says there's a serious design defect for which a safer alternative exists, and another says "yes, yes, but the defendant should have warned against the problems caused by the defective design," the testimony is not completely consistent. *Bullock v. Volkswagen Group of America, Inc.*, 107 F. Supp. 3d 1305 (M.D. Ga. 2015), is an extreme example of the logical problems potentially created by asserting both a defect claim and a warning claim. The court held that even without a warnings expert the plaintiffs could assert a failure-to-warn claim because the defendant knew a defective turbo-charger might cause unexpected acceleration. *Id.* at 1316. Just what good such a warning might do went completely unexplained. The plaintiff did have two experts on the nature of the defect, and apparently neither of them provided an opinion about how a warning might ameliorate it. On the other hand, when a defect can, in fact, be remedied with a warning, the two kinds of defect claims don't conflict, and in some circumstances the warning claim can proceed on its own. *See, e.g.*, *Lara v. Delta Int'l Mach. Corp.*, 174 F. Supp. 3d 719 (E.D.N.Y. 2016) (in which the court excluded the plaintiff's design defect expert, but allowed the warning expert to testify).

140. *See In re FEMA Trailer Formaldehyde Prod. Liab. Litig.*, No. MDL 07-1873, 2009 WL 3247967, at *2 (E.D. La. Oct. 6, 2009) (court held there was no need for expert testimony on "the issue of the adequacy of a particular warning" because such a conclusion "involves a common sense assessment 'within the realm of the average juror's knowledge and experience'"); *McSwain v. Sunrise Med., Inc.*, Civ. Action No. 2:08cv136KS-MTP, 2010 WL 200004, at *8 (S.D. Miss. Jan. 14, 2010) (plaintiff proffered expert testimony that based on expert's experience, he knew "that a warning affixed to a product is more effective than a warning inside a manual"; court excluded the testimony because it was "well within the grasp of jurors who have undoubtedly experienced both types of warnings in their daily lives"). *Cf. Bradley v. Ameristep, Inc.*, 800 F.3d 205, 213 (6th Cir. 2015) (because consumer-expectations test applied in case about treestand ratchet straps, plaintiff "was entitled to have a jury employ its own sense of whether the relevant warnings provided the ordinary consumer with knowledge of how to effectively avoid or minimize the risks associated with the . . . straps").

141. 502 F. Supp. 2d 1025 (W.D. Mo. 2007).

142. *Id.* at 1027.

143. *Id.* at 1028-29.

that the “warning label was inadequate in color and wording [because it did not specify] the hazard, how to avoid the hazard and the consequences in not avoiding the hazard of the casters rolling over the feet during use.”¹⁴⁴ The court allowed him to testify on both defect and warnings, and on the latter held that he “was not talking ‘off the cuff’ but rather contrasting the existing ‘Notice’ on the cart with the ANSI standard and dozens of warnings he has previously drafted for other furniture himself.”¹⁴⁵

Still other courts allow testimony from engineers on the *need* for a warning, but not on the substance, appearance, or placement of the warning. In *Pineda v. Ford Motor Co.*,¹⁴⁶ for example, the plaintiff was an automotive repair technician who was injured while installing a replacement lift gate on a sport utility vehicle. His only expert, an engineer, testified that the manufacturer’s service manual should have laid out better step-by-step instructions for doing the installation, and that the “manual should have contained an explicit warning [about the need to follow those instructions].”¹⁴⁷ In reversing the trial court’s exclusion of this testimony, the Third Circuit held that while the engineer might not have been the best expert on warnings, his opinions should have been admitted, including testimony about a later warning issued by the defendant, as an example of what kind of language would be acceptable.¹⁴⁸ The court noted that the expert “did not purport to opine on how the warning should be worded or how it should appear in order to effectively convey its message to an automobile technician. He only testified that . . . a warning was necessary to alert a technician to the potential problem.”¹⁴⁹ Neither the engineering process nor the scientific method has much bearing on determining the admissibility of warning testimony in a case like *Pineda*.

June 30, 2021) (the court cited *Pineda* and held that an “expert need not ‘opine on how the warning should be worded or how it should appear’ to testify that the instructions might result in failure or that a warning is necessary”); Schaaf v. Caterpillar, Inc., 286 F. Supp. 2d 1070, 1074 (D.N.D. 2003) (expert allowed to testify about lack of warnings but not about “the appropriate size, shape, color, content or location of any such warning signs”); Furry v. Bielomatik, Inc., 32 Fed. App’x 882, 883 (9th Cir. 2002) (safety engineer could give both design and warning opinions at conceptual level, without details).

Causation

Proof of defect and proof of causation are often bound together in products liability cases. A plaintiff who proves (or fails to prove) one element almost automatically proves (or fails to prove) the other. In *Lapsley v. Xtek, Inc.*,¹⁵⁰ for example, the defendant did not dispute that a spurt of grease caused the plaintiff's injury. The question was whether a design defect caused the grease jet. The plaintiff's successful proof of the defect necessarily included proof of the cause.¹⁵¹ By way of contrast, in *Nease v. Ford Motor Co.*,¹⁵² the court rejected the plaintiffs' claim that a pickup truck crash occurred because a defectively designed accelerator cable had stuck and prevented the throttle from closing. Their expert hypothesized that dirt had entered the cable housing and caused the cable to bind, but he conceded it worked properly when he examined it, and that he'd conducted no tests to corroborate his hypothesis.¹⁵³ Failure to prove the cause necessarily entailed failure to prove the defect.¹⁵⁴

Although evidence of defect and cause are intertwined, the emphasis is on defect in most cases involving engineering experts, and the causation question is addressed secondarily or by implication. In cases about pharmaceutical products, medical devices, or exposure to allegedly toxic chemicals, the emphasis often reverses, and causation becomes the primary focus, but the experts typically are scientists or physicians rather than engineers. *Daubert*, which involved the drug Bendectin, is perhaps the most famous pharmaceutical example.

When a plaintiff attempts to use an engineering expert to establish medical causation in a medical products case, courts generally exclude the testimony. For example, in *Bayes v. Biomet, Inc.*,¹⁵⁵ the court admitted testimony from the plaintiffs' biomechanical engineering expert on what caused wear in a hip implant,¹⁵⁶

150. 689 F.3d 802 (7th Cir. 2012).

151. The reverse, however, was not true. Proof of the cause did not establish a defect because without showing there was a reasonable alternative design, the plaintiff would have lost. In fact, his expert explained that a design actually used by the defendant both before and after the accident would have prevented the spurting grease, or at least reduced its velocity (*Lapsley*, 689 F.3d at 807), which is why the plaintiff prevailed. *See also* *Williams v. Tristar Prods., Inc.*, 418 F. Supp. 3d 1212 (M.D. Ga. 2019) (pressure cooker lid popped off); *Bullock v. Volkswagen Grp. of Am., Inc.*, 107 F. Supp. 3d 1305 (M.D. Ga. 2015) (defective turbocharger caused uncontrollable acceleration). *Cf.* *Lara v. Delta Int'l Mach. Corp.*, 174 F. Supp. 3d 719 (E.D.N.Y. 2016) (injury clearly caused by saw; court rejected design defect expert but admitted testimony from failure-to-warn expert).

152. 848 F.3d 219 (4th Cir. 2017).

but her medical causation opinions were excluded because she was not a medical doctor.¹⁵⁷

Occasionally, the mix of engineering and medical experts occurs in the context of a non-medical product case. *Campbell v. Fawber*,¹⁵⁸ which involved injuries allegedly caused when the roof of an SUV crushed in an accident, provides an outstanding example of how engineers can address complex causation questions in the context of products liability litigation. The first of three engineering experts in *Campbell* had a degree in physics, but taught engineering at the National Crash Analysis Center at George Washington University.¹⁵⁹ He was allowed to testify about both the defective design of the SUV and how the structural failure of the roof caused the plaintiff's injuries.¹⁶⁰ The second expert had a Ph.D. in applied mechanics and had "taught courses on engineering physics and mechanics, and strength of materials, and limit analysis of structures."¹⁶¹ He offered an opinion on the strength of the SUV's roof, and the vehicle's propensity to roll over.¹⁶² The third engineering expert was a biomedical engineer who had "taught courses in the areas of applied mechanics, materials science, biomechanics, biomaterials, ergonomics, occupational health and safety, strength of materials, and orthopaedic engineering."¹⁶³ He testified that the manufacturer could have designed the roof so the amount of collapse would have been greatly reduced, and that a poorly designed seat belt may also have contributed to the plaintiff's injuries.¹⁶⁴

In explaining its decision to admit the testimony of all three engineers, the *Campbell* court went to some length to distinguish their work from that done by experts in other cases who were excluded. The first engineering expert "uses established systems analysis techniques to form his opinion, evaluating 'crash statistics, vehicle dynamics, occupant kinematics, injury susceptibility and mechanism, crashworthiness, and occupant protection.' He examines a number of materials, including those published in peer-reviewed journals. Most importantly, however, [he] relies on [information about other vehicles with a roof structure similar to the SUV, and with alternative designs]."¹⁶⁵ The second expert reviewed extensive information and concluded that "the roof intrusion over [the plaintiff's] seat would have subjected her to as much as twice [the] dynamic deflection as her body could withstand."¹⁶⁶ Similarly, the third expert "observed the crash location,

and took measurements in order to reconstruct the accident scene [and explained that the SUV had a higher-than-acceptable propensity to roll over].”¹⁶⁷

The defendant argued that no expert had conducted a test of a modified SUV to show that remedying the supposed defects would have prevented the plaintiff’s injuries. The court rejected this rote invocation of testing. To require such tests would make plaintiffs “prove their case twice.”¹⁶⁸ The court also noted that the factors listed in *Daubert* do not constitute a definitive checklist or test for admissibility.¹⁶⁹ Thus, *Campbell* is another example of how engineering design evaluation rather than scientific testing of hypotheses can be the basis for admissible causation testimony.

There are cases, however, in which causation testimony from an engineering expert is properly analyzed based on hypothesis testing criteria. Many fire investigation cases fall into this category. *Werth v. Hill-Rom, Inc.*¹⁷⁰ is an excellent example that also involved products liability. The plaintiff was a newborn infant who required oxygen therapy. He was placed under an oxygen hood in a bassinet with a baby warmer over him.¹⁷¹ When a fire erupted in the bassinet, the hospital and his parents blamed it on “a hot particle [that] had broken from the baby warmer and fallen into the bassinet, igniting the flammable materials (blankets and the like) below,”¹⁷² but the court excluded expert testimony on this theory of causation. Citing a publication from the National Fire Protection Association, it found that “once an investigator has developed a hypothesis about a fire’s cause, [a key step] is *testing* that hypothesis. Yet, nothing in the Report or the Supplemental Report indicates that the team tested its hypothesis at all. Indeed, as [one investigator] candidly acknowledged in his deposition, it never did.”¹⁷³

Duty of Care

In products liability cases based on the legal theory of negligence rather than strict liability or warranty, a plaintiff has to establish that the defendant breached a duty of care, and engineers sometimes testify about the duty of care as well as product defect or causation. In *Crawford v. ITW Food Equipment Group, LLC*,¹⁷⁴ the plaintiff lost an arm “when it came into contact with the unguarded blade of one of [the defendant’s] commercial meat saws.”¹⁷⁵ His engineering expert testified about

alternative designs of which the defendant should have known, and this testimony sufficed to establish negligent design.¹⁷⁶ Obviously, testimony about what the defendant should have known is a matter of engineering knowledge, and *Daubert*'s admissibility criteria for scientific evidence would not apply.

Non-Products Liability Cases

Contract and Construction Litigation Cases

Engineers are often called as experts when disputes arise about contract compliance, especially in the context of construction contracts.¹⁷⁷ For example, *Waste Management of Louisiana, L.L.C. v. Jefferson Parish*¹⁷⁸ involved a complex dispute between Jefferson Parish, Louisiana, and Waste Management, the company that operated, managed, and maintained the parish's sanitary landfill.¹⁷⁹ The core issues in the case related to (1) what work the plaintiff, Waste Management, and its subcontractor and counterclaim plaintiff, T & K Construction, were supposed to do, (2) when it was to be done, and (3) how the parish might have interfered with that work. The parish retained a civil engineer to serve as an expert on these issues, and the two plaintiffs moved to exclude his testimony.

The plaintiffs did not challenge the expert's methodology or theories, or the data he considered, "except to the extent that they challenge his interpretations of provisions of the [contract with Waste Management]."¹⁸⁰ Though the court recited the *Daubert* factors, it made no real attempt to apply them, and ultimately held that the expert had "explained his methodology, which involved a careful review of all of the relevant pleadings and documents provided by the parties, as well as an interview with the Landfill engineer and a visit to the Landfill. [His] expert report reveals that he has more than 30 years of engineering experience across the fields of sewerage systems, site engineering, land surveying and structural engineering, among others, albeit not seemingly focusing on landfills. [Though he] may lack expertise on certain questions of landfill construction, . . . his overall experience suggests that Waste Management and T & K have failed to set forth that any such failing disqualifies [his] expert report in its entirety."¹⁸¹

The court was concerned, however, that the expert had strayed from engineering testimony into contract interpretation. "The Court agrees that [the]

181. *Id.*

expert report is rife with legal conclusions and contractual interpretations. . . . However, the Court finds that although many of the opinions offered in [the] expert report are inadmissible, [the expert] . . . may testify that “[a]s a national landfill operator, Waste Management should have been aware of the problems that gas could cause in capping work and should have made provisions for it in the plans they developed.”¹⁸²

Waste Management is a prime example of how the *Daubert* factors do not properly apply to some engineering testimony, and other contract cases further illustrate this point. In *First Assembly of God Church v. Fondren*,¹⁸³ the issues were whether a construction company had complied with drawings and specifications, and whether failure to comply had resulted in the collapse of a church’s roof. The defendant raised about every argument possible in unsuccessfully challenging the plaintiff’s engineering expert.¹⁸⁴ On the facts of the case, however, the broadside attack on the expert verged on the frivolous. The expert was “a registered public engineer in nine states . . . and [had] actively practiced engineering for [about 29 years].”¹⁸⁵ He had “previously conducted investigations into numerous other building design and construction defects as well as building collapses,” co-authored articles, and “testified in numerous cases.”¹⁸⁶ Here, the expert opined that “[b]ased on my knowledge of the behavior of rigid frame metal buildings, I determined that braces should have been installed at the knee joints and that braces would have precluded the observed failure.”¹⁸⁷ The defendant did not raise “any specific objections to the methodology used by [the expert] . . . [and made] no argument as to why additional calculations on the bending strength of the steel frame [were] necessary.”¹⁸⁸

188. *Id.* See also *United States ex rel. Poong Lim/Pert Joint Venture v. Dick Pac./Ghemm Joint Venture*, 2006 WL 5230015, at *3 (D. Alaska Mar. 2, 2006) (in a dispute between a contractor and subcontractor, the court rejected the plaintiff’s motion to exclude the defense experts, holding that in “cases where the subject of the expert testimony is non-scientific, as the case at bar, education,

Waste Management and *First Assembly of God* do not establish a blanket rule for experts in construction cases. Generally, it does take more than educational background and experience for engineering testimony to be admissible. The exclusion of two architecture experts in *Cross Creek Multifamily, LLC v. ICI Construction, Inc.*¹⁸⁹ illustrates all too well that there has to be some rational basis for an expert's opinion. The issue before the court was how to apportion responsibility for construction defect damages among a project's architect, general contractor, and several subcontractors. When asked at his deposition how he had come to assign 64% responsibility to the architect and engineers, the expert for one defendant essentially answered that he had used his "training, education, and experience, [and] look[ed] at all the documentation. . . . That's how I saw it, and that's how I distributed it."¹⁹⁰ Upon further questioning, he admitted there was no "exact formula by [the American Institute of Architects] or anyone that works in these situations."¹⁹¹ He also testified that he'd never done such an apportionment before, that it was "a very unusual and difficult situation," and that there existed no "specific book or reference or industry material . . . that tells an architect how to do [it]."¹⁹² The expert for another defendant fared no better. He admitted that he did not have all the relevant information when he initially opined, and when provided additional information during his deposition, he said he *probably* would change his apportionment.¹⁹³

Intellectual Property Cases

Engineers in copyright cases

Engineering testimony does not figure in most copyright cases, but there are exceptions. In *Vargas v. Transeau*,¹⁹⁴ the plaintiffs claimed the defendants had copied from their sound recording and then digitally manipulated the sound to create a new and infringing recording.¹⁹⁵ To make their case, however, they had to explain why the two recordings were not identical. Thus, they sought to introduce testimony from "a purported sound engineer and sampling expert . . . who asserts that [one of the defendants] created [his recording] by importing drum

training and experience, not necessarily methodology or theory, are more appropriate benchmarks for determining reliability"); *Ferguson v. Erie Ins. Prop. & Cas. Co.*, Civ. Action No. 3:19-0810, 2021 WL 4392040, at *3 (S.D. W. Va. Sept. 24, 2021) (in dispute about what caused walls to crack, expert allowed to testify "as to his own personal observations and experience as an engineer").

beats from [the allegedly infringed recording].”¹⁹⁶ The court granted summary judgment after finding that the expert had failed “to substantiate his opinion. . . . He offers no explanation for what the tools [for sound manipulation] are; provides no significant detail regarding how they alter sound; and provides no demonstration of how a sound from [plaintiff’s recording] would be manipulated to achieve one of the sounds in [the other recording].”¹⁹⁷ The engineering issue in cases like *Vargas* would be how engineers develop and use tests to determine similarity of recordings.¹⁹⁸

Engineers in trademark cases

Engineers sometimes appear in trademark cases, though the experts more typically are people who conduct surveys to see if one party’s use of a logo or the like has caused confusion with another party’s logo or the like. In *Malletier v. Dooney & Bourke, Inc.*,¹⁹⁹ one issue was whether the defendant’s use of certain colors caused confusion about multicolor handbag logos.²⁰⁰ The court denied a motion to exclude an expert on colorimetry who was “a principal engineer in color technology, and a professor at Boston University, researching and teaching issues pertinent to vision and color.”²⁰¹ Again, the engineering issue would be the development and use of tests.

Engineers in patent cases

Most engineering expert testimony on intellectual property issues occurs in patent litigation. In the United States, patents are issued by the U.S. Patent and Trademark Office (USPTO) after an extensive application and examination process.²⁰² There are three kinds of patent. A utility patent “may be granted to anyone who invents or discovers a new and useful process, machine, article of manufacture, or composition of matter, or any new and useful improvements of

these.”²⁰³ A utility patent may cover a business method.²⁰⁴ A design patent may be granted to “anyone who has invented a new, original ornamental design for an article of manufacture.”²⁰⁵ A plant patent may be granted to “anyone inventing or discovering and asexually reproducing any distinct and new variety of plant.”²⁰⁶ Utility patents far and away constitute the majority of patents granted,²⁰⁷ and they are the primary focus here.

Every patent includes a specification that describes the patented invention and concludes with what are called claims. Claims “are commonly analogized to the ‘metes and bounds’ of a property deed and serve the same purpose: to delineate the scope of the asset which, in the patent context, is an invention.”²⁰⁸ Importantly, a patent does not give the holder the right to make or sell anything. Rather, each “claim represents the legal right to *exclude others* from making, using, selling, offering to sell, importing, or offering to import the claimed process, machine, manufacture, or composition of matter.”²⁰⁹ “A patent may, and often does, contain many claims, which usually become increasingly specific” as they progress from first claim to last.²¹⁰

A simple hypothetical illustrates how claims work and what rights they confer if the USPTO grants a patent. Suppose Inventor A has a patent with two claims: (1) a drink container comprising a cylinder closed at one end and open at the other, and (2) a drink container as in Claim One wherein the closed end cylinder is made of ceramic material. Claim One, which would be considered an independent claim, would cover, or “read on” almost any drinking glass, except, for example, a non-cylindrical glass that’s wider at the top than at the bottom. Claim Two, which would be called a dependent claim, would only read on a drinking “glass” made of ceramic material.²¹¹

Now suppose Inventor B comes up with a new idea that would make it easier to use one of the cylindrical drink containers for hot beverages, like coffee.

210. Menell, Patent Case Management Judicial Guide, at 14–8.

211. Note that in patent law, the term “comprising” simply means having *at least* the elements in the claim. See *CIAS, Inc. v. Alliance Gaming Corp.*, 504 F.3d 1356, 1360 (Fed. Cir. 2007) (“In the patent claim context the term ‘comprising’ is well understood to mean ‘including but not limited to.’”), cited in *In re Skvorecz*, 580 F.3d 1262, 1267 (Fed. Cir. 2009). *Cf.* *Guardant Health, Inc. v. Foundation Medicine, Inc.*, Civ. Action No. 17-1623-LPS-CJB, 2019 WL 5677748 at *15 (D. Del. Nov. 1, 2019) (making clear that an independent claim must be construed to include a dependent claim).

Inventor B obtains a patent with a single claim: a drink container comprising a ceramic cylinder closed at one end and open at the other and a ceramic handle attached to said cylinder. The claim in this patent would read on a coffee mug, at least one cylindrical in shape. Can Inventor B now start making and selling cylindrical coffee mugs with handles? No, because doing so would infringe on the claims in Inventor A's patent. Inventor A, however, could not make or sell the mugs either, because doing so would infringe on Inventor B's patent. Would it then be impossible to make and sell coffee mugs in our hypothetical world? As a practical matter, probably not, because the two patent holders likely would enter into a cross-licensing agreement that would let them both make mugs.²¹²

Patent litigation almost always arises when a patent holder believes a competitor is making or selling something that infringes on the patent, or when the competitor seeks a declaratory judgment that its "accused" process, product, or method does not infringe. Infringement means at least one claim is infringed;²¹³ that is, at least one claim reads on the allegedly infringing process, product, or method. Once litigation has commenced, there are three principal issues on which experts may testify: (1) claim construction, (2) infringement or non-infringement, and (3) validity or invalidity.

Claim construction Claim construction, or "the process by which courts interpret patent claims, represents one of the most distinctive aspects of patent litigation."²¹⁴ "When patentees seek to enforce their rights in court, the interpretation of patent claim boundaries guides both infringement and validity analysis."²¹⁵ In the coffee mug hypothetical, for example, the manufacturer of an accused cup that tapered from a wide opening at the top to a smaller diameter at the bottom might seek construction of the claim in Inventor B's patent as covering only cylindrical cups. In such a case, the claim construction likely would be dispositive, and under the U.S. Supreme Court's 1996 decision in *Markman v. Westview Instruments*,²¹⁶ the judge, rather than the jury, does the analysis of any claims at issue.

Justice Breyer's opinion in *Markman* recognized that because a trial court has to consider at least some evidence in addition to the language of the claims, interpretation of a claim is not the kind of purely legal question typically addressed by a trial judge rather than the jury. Construing "a term of art following receipt of

216. 517 U.S. 370, 384–88 (1996).

evidence” was termed a “mongrel practice.”²¹⁷ Nonetheless, taking into account precedents in prior cases and “the relative interpretive skills of judges and juries and the statutory policies that ought to be furthered by the allocation [between judge and jury],”²¹⁸ the Court held “there is sufficient reason to treat construction of terms of art like many other responsibilities that we cede to a judge in the normal course of trial, notwithstanding its evidentiary underpinnings.”²¹⁹

Only a few months after *Markman*, the Federal Circuit, in *Vitronics Corp. v. Conceptronic, Inc.*,²²⁰ held that a trial judge had erred in relying on expert testimony in interpreting a claim. The Federal Circuit distinguished between intrinsic evidence (the patent file and history) and extrinsic evidence (e.g., expert testimony, inventor testimony, dictionaries, and technical treatises and articles).²²¹ “[E]xtrinsic evidence in general, and expert testimony in particular, may be used only to help the court come to the proper understanding of the claims; it may not be used to vary or contradict the claim language.”²²² Given this rule, expert testimony during the claim construction stage of a litigated case is less frequent than during the trial, when experts often testify about infringement and validity.²²³

Moreover, when experts do testify on claim construction, their opinions typically derive from their experience, and not from any engineering analysis or scientific hypothesis testing. Thus, challenges to the admissibility of their testimony focus mostly on their education, training, and experience. *Pentair Water Pool and Spa, Inc. v. Hayward Industries, Inc.*²²⁴ is a good example of how courts evaluate such testimony. The case involved heaters for swimming pools and spas. During the *Markman* hearing, the defendant tried to introduce testimony from a materials engineering professor. The court held the professor’s testimony largely inadmissible because the expert was not someone with adequate “skill in the

221. *Id.* at 1584.

222. *Id.*

223. The allocation of claim construction to the judge quickly led to the practice of holding pretrial “*Markman* hearings.” Such hearings promote settlement and provide a basis for summary judgment. J. Jonas Anderson & Peter S. Menell, *Informal Deference: A Historical, Empirical, and Normative Analysis of Patent Claim Construction*, 108 Northwestern Univ. L. Rev. 25 (2014). These hearings also facilitate the development of expert reports on the issues of infringement or validity, because they clarify how the claims in a patent have to be interpreted. *Id.* Because *Markman* hearings occur well before trial, and sometimes even before discovery, they often involve no expert testimony at all. J. Michael Jakes, *Using an Expert at a Markman Hearing: Practical and Tactical Considerations*, IP Litigator, Aug. 2002 at 2 (“Once the primary means for presenting claim-construction issues to juries, expert testimony may or may not be allowed by the courts today.”), available at <https://perma.cc/GLH3-UXVG>.

224. Case No. CV 11-10280-GW(FMOx), 2012 WL 12887686 (C.D. Cal. Dec. 12, 2012).

[relevant] art.”²²⁵ The court found that while he was “clearly a distinguished Professor of Engineering, [he was not] a person of ordinary skill in the art in the field to which the . . . patent pertains. He admitted as much at his deposition where he said ‘I’m not of ordinary skill, but I know who such people are. I teach them and have taught them for years.’”²²⁶

Infringement Unlike during claim construction, expert testimony is allowed once a patent case moves on to a determination of whether infringement (when at least one claim reads on the defendant’s accused product) has occurred. The admissibility review, however, is very different from cases in other areas, where the focus is typically on methodology and testing and/or analysis based on accepted principles and standards. As an initial matter, expert testimony that contradicts a court’s construction of the patent will not be admitted. As the court held in *Exergen Corp. v. Wal-Mart Stores, Inc.*,²²⁷ once “a district court has construed the relevant claim terms, and unless altered by the district court, then that legal determination governs for purposes of trial.”²²⁸

When the actual merits of expert testimony on infringement are addressed, the scrutiny is often less strict than in products liability cases. In *Fontem Ventures, B.V. v. NJOY, Inc.*,²²⁹ a case involving several patents for e-cigarette devices, the plaintiff’s expert on infringement was a mechanical engineer with “40 years’ experience in the design, development, and manufacture of electromechanical devices, both as an employee and as a consultant.”²³⁰ For each allegedly infringing device he “provide[d] photographs of the accused products annotated with numerals in the ‘Infringement Analysis’ and brackets or arrows pointing to portions of the accused products, referencing numerals from [various exhibits].”²³¹ His conclusion was essentially “look at the patent and look at what the defendants have done.” Neither the engineering design process nor the scientific method was involved.

231. *Id.*

In ruling the expert's testimony admissible, the court held that

a patent infringement expert's opinions as to certain uncomplicated elements can be based on a visual inspection and operation of the accused products, as well as the expert's knowledge, skill, experience, and education. The traditional and appropriate means of attacking 'shaky' or simplistic but admissible evidence is by vigorous cross-examination, presentation of contrary evidence, and careful instruction on the burden of proof.²³²

The non-infringement testimony of the defendant's expert was excluded, however, because at his deposition he

repeatedly pointed out that he did not know various details about the accused . . . products, [and explained] that his lack of knowledge stemmed from his opinion that [the plaintiff's expert] report failed to inform him about such facts. While he may rely on the alleged weakness of [the opposing expert's] report in his rebuttal testimony, he must actually have a sufficient grasp of the relevant facts to form non-infringement opinions of his own.²³³

Validity A defendant that has arguably infringed claims in a patent can still escape liability by proving that the relevant claims were invalid. That is, the patent should not have been granted with those claims in the first place. Establishing invalidity is not easy, however. Under 35 U.S.C. § 282, a "patent shall be presumed valid. Each claim of a patent . . . shall be presumed valid independently of the validity of other claims . . ." Moreover, the statute provides that the "burden of establishing invalidity of a patent or any claim thereof shall rest on

232. *Fontem Ventures*, 2015 WL 12743861, at *7. See also *Gatearm Techs., Inc. v. Access Masters, LLC*, Case No. 14-62697-CIV-SCOLA/OTAZO-REYES, 2020 WL 6808670, at *14 (S.D. Fla. Apr. 30, 2020) (defendant's expert testimony on non-infringement admitted based on his comparison of defendant's original infringing product with a new design, which he concluded was very different).

233. *Fontem Ventures*, 2015 WL 12743861, at *8. See also *DataQuill Ltd. v. Handspring, Inc.*, No. 01 C 4635, 2003 WL 737785, at *2-4 (N.D. Ill. Feb. 28, 2003) (in a case involving data entry devices, the court held that "operating and examining the accused devices (assuming it is done against the backdrop of a proper claim construction) is a reliable method of conducting an infringement analysis," but nonetheless excluded expert's testimony because he had not properly construed the claims). Cf. *Fuma Int'l LLC v. R.J. Reynolds Vapor Co.*, 1:19-CV-260, 1:19-CV-660, 2021 WL 4820738, at *2 (M.D.N.C. Oct. 15, 2021) (another case involving e-cigarette devices). In *Fuma*, the court held the plaintiff's expert testimony admissible to the extent it was "based on technical analysis on several different points. He discusses technical design similarities between Fuma's patented e-cigarette design and RJR's Solo and Ciro products, such as a transverse heating element and central airflow passageway. . . . He also uses a technical analysis to explain his opinion that RJR's argument that Fuma's e-cigarette design was different than its own is not valid, and that RJR's portrayal of Fuma's e-cigarette design could not electrically function." But see *Elder v. Tanner*, 205 F.R.D. 190 (E.D. Tex. 2001), in which the court held it "is not sufficient simply to list the resources [experts] utilized and then state an ultimate opinion without some discussion of their thought process." *Id.* at 194.

the party asserting such invalidity,”²³⁴ which requires clear and convincing evidence.²³⁵

There are a number of grounds for invalidity, but a 2012 scientific review paper prepared by the Morgan, Lewis & Bockius law firm on invalidation of patents by the Federal Circuit indicates that anticipation and obviousness are far and away the most common reasons.²³⁶ Anticipation is addressed in 35 U.S.C. § 102,²³⁷ and obviousness in 35 U.S.C. § 103.²³⁸ Anticipation essentially means a single prior patent or publication covered the claims at issue, or the invention was available to the public before the filing date for the patent.²³⁹ Obviousness essentially means that a person skilled in the relevant art could easily have come up with the invention based on available information.²⁴⁰ Note that a claim can be non-obvious yet still anticipated.²⁴¹

When expert testimony is introduced regarding validity, it usually involves only a comparison of the claims in the patent at issue with relevant “prior art.” Thus, admissibility decisions typically come down to the expert’s qualifications.

234. *Id.*

235. *Schumer v. Lab. Computer Sys., Inc.*, 308 F.3d 1304, 1315 (Fed. Cir. 2002) (“Evidence of invalidity must be clear as well as convincing.”).

237. Section 102, 35 U.S.C., provides that a person is not entitled to a patent if “(1) the claimed invention was patented, described in a printed publication, or in public use, on sale, or otherwise available to the public before the effective filing date of the claimed invention; or (2) the claimed invention was described in a patent issued under section 151, or in an application for patent published or deemed published under section 122(b), in which the patent or application, as the case may be, names another inventor and was effectively filed before the effective filing date of the claimed invention.”

238. Section 103, 35 U.S.C., provides that a “patent for a claimed invention may not be obtained, notwithstanding that the claimed invention is not identically disclosed as set forth in section 102, if the differences between the claimed invention and the prior art are such that the claimed invention as a whole would have been obvious before the effective filing date of the claimed invention to a person having ordinary skill in the art to which the claimed invention pertains.”

239. *See Therasense, Inc. v. Becton, Dickinson*, Case Nos. C04-02123 MJJ, C04-03327 MJJ, C04-03732 MJJ, 2007 WL 2028197 at *3 (N.D. Cal. July 10, 2007) (“A claim is anticipated under 35 U.S.C. § 102 only if each and every limitation of the claim is disclosed in a single prior art reference.”).

240. *See Izzo Golf, Inc. v. King Par Golf Inc.*, 561 F. Supp. 2d 334, 338 (W.D.N.Y. 2008) (“A claim is **obvious** if the patented invention would have been **obvious** to a person having ordinary skill in the art to which the subject matter of the patent pertains, at the time the invention was disclosed.”) (emphasis in original).

241. *Cohesive Techs., Inc. v. Waters Corp.*, 543 F.3d 1351, 1364 (Fed. Cir. 2008) (“While it is commonly understood that prior art references that anticipate a claim will usually render that claim obvious, it is not necessarily true that a verdict of nonobviousness forecloses anticipation. The tests for anticipation and obviousness are different. . . . Obviousness can be proven by combining existing prior art references, while anticipation requires all elements of a claim to be disclosed within a single reference. . . . ‘[I]t does not follow that every technically anticipated invention would also have been obvious.’”) citing *In re Fracalossi*, 681 F.2d 792, 796 (CCPA 1982) (Miller, J., concurring).

Mobile Medical International Corp. v. Advanced Mobile Hospital Systems, Inc. illustrates how courts analyze the admissibility of engineering testimony on obviousness.²⁴² The plaintiff company in the case brought a declaratory judgment action to invalidate the defendant's patent for a mobile medical unit. The plaintiff company's expert was a consultant in the field of specialty vehicle engineering, including medical vehicles. The defendant challenged the expert's experience and also argued that his opinion on obviousness was based on "hindsight bias." The court rejected a *Daubert* motion to exclude the expert, holding on the hindsight issue that his testimony about not using post-patent information sufficed.²⁴³ There was nothing about the application of the *Daubert* factors for scientific testimony or about the engineering design process.

*Meridian Manufacturing, Inc. v. C&B Manufacturing, Inc.*²⁴⁴ provides an example of a more detailed analysis of expert testimony on obviousness, but while the court initially discussed *Daubert* at some length,²⁴⁵ the ultimate decision on two challenged engineering experts was based mostly on the engineering analyses they had done. The invention at issue was an agricultural trailer specially designed for the transport of large bags or boxes of seeds to planters in the field.²⁴⁶ The defendant (alleged infringer) claimed the patent was "clearly an obvious combination of well-known elements from other patents."²⁴⁷ The court undertook a point-by-point discussion of each expert, and focused largely on their explanations for how they reached their conclusions. For example, the court found that at the beginning of the report prepared by the defendant's expert, he "discussed generally the geometric considerations and principles of guiding objects onto surfaces that go towards the 'common sense' category of motive to combine. While not determinative, and certainly subject to cross-examination and rebuttal, this [was] sufficient to permit [his] obviousness opinion to be admitted into evidence."²⁴⁸

Engineers in trade secret cases

Engineers also sometimes appear as expert witnesses in trade secret cases. Although the primary fact questions in such cases are usually about who stole or disclosed secret information, defendants sometimes will claim the information wasn't really a secret because anyone could easily have figured it out. In *Raytheon Co. v. Indigo Systems Corp.*,²⁴⁹ the defendant's expert opined that some supposed trade secrets

could have been reverse engineered.²⁵⁰ He also suggested that other alleged trade secrets did not “meaningfully differ from information that is widely known in the industry.”²⁵¹ The court admitted his testimony with no detailed analysis.²⁵²

Environmental/Land Use Cases

The use of experts in cases about environmental or land use claims goes back almost 250 years, to *Folkes v. Chadd*,²⁵³ the English case generally considered the first example of allowing experts to provide opinion testimony. Today, engineers often testify in such cases. For example, in *Adler v. Elk Glenn, LLC*, the court admitted testimony from a geotechnical engineer about the cause of land subsidence under the plaintiff’s property.²⁵⁴ This expert had

consulted mine maps and websites, United States Geological Survey maps, topographic maps, excavated material, and rock strata visible in nearby areas. He also relied on his extensive experience with mine spoil to figure out the likely distribution of materials within the fill beneath the house. . . . He developed this opinion based on his extensive personal experience with mine spoil and his review of scholarly literature finding that mine spoil settlement worsens over time [and he visited the property].²⁵⁵

The fact that he had not performed readily available tests did not make his testimony unreliable because he had “followed the prevailing methods of his profession.”²⁵⁶ *Adler* is another example of how engineering analysis rather than scientific hypothesis testing can suffice to establish causation.

250. *Id.* at 821.

Failure Analysis Cases

The 1981 collapse of a hotel skywalk in Kansas City, discussed above, provides a classic example of both design and failure analysis. Science and hypothesis testing were not at issue.

*Georgia Power Co. v. Sure Flow Equipment, Inc.*²⁵⁷ is a more recent example of a failure analysis case. The plaintiff power company bought strainers from the defendant for use in removing debris from turbine steam cooling systems.²⁵⁸ They “failed in service, broke into pieces, went upstream into two turbine units and caused damage.”²⁵⁹ The central issue was the adequacy of the design.²⁶⁰ But while the court cited *Kumho* once, its analysis was based more on *Daubert* and a number of cases cautioning that the *Daubert* criteria are not absolute requirements. In the end, it admitted the disputed testimony from the plaintiff’s expert in “engineering, metallurgy, design of materials, and failure analysis”²⁶¹ after finding that it was “sufficiently reliable. His report, affidavits, and deposition testimony demonstrate that he has tested his theories, his methodology is supported by peer-reviewed research, and his conclusions are based on sufficient underlying facts and data.”²⁶² While this ruling seems well reasoned and correct, the emphasis on *Daubert* reflects the conflation of engineering and science sometimes seen in other cases.

Testing Cases

In some cases (most typically involving contract compliance), engineers simply testify about test results, where a measurement or some other parameter is at issue. In *Illinois National Insurance Co. v. Ace Stamping and Machine Co., Inc.*, for example, a central question was whether certain washers met hardness and flatness requirements.²⁶³ Testimony from the plaintiff’s expert about testing for these two characteristics was admitted. In *Cedar Petrochemicals, Inc. v. Dongbu Hannong Chemical Co., Ltd.*, the issue was whether phenol sold by the defendant to the plaintiff conformed to contract specifications.²⁶⁴ In particular, the plaintiff claimed the phenol was too dark, and relied on test results that measured the color in

something called Hazen Units. The defendant questioned whether the plaintiff's witnesses were "sufficiently expert in 'chemistry or phenol discoloration.'"²⁶⁵

Occasionally, the validity of a test rather than whether it was properly conducted may be the central issue. A case that involved toxicology testing rather than engineering best illustrates this point. In *Ruffin v. Shaw Industries, Inc.*, the plaintiffs claimed off-gassing from carpets was toxic.²⁶⁶ Their expert had developed her own test to determine toxicity, and the defendant challenged its validity. The trial court excluded her testimony, and the Fourth Circuit affirmed based on an application of the *Daubert* factors. The Environmental Protection Agency had attempted to replicate the test results, but could not do so.²⁶⁷

Conclusion

The two core messages of this reference guide are (1) the way in which engineering differs from science, and (2) the centrality of the design process and the evaluation of designs to the way engineers think and go about their work. Our review of cases in which engineering expert testimony is at issue shows that courts by and large admit testimony based on engineering design and analysis without requiring the kind of hypothesis testing and peer-reviewed publication that is central to the scientific method. When the testimony is more like science than engineering, however, at least some of the *Daubert* criteria for the evaluation of science are often applied; and sometimes admissibility depends primarily on an expert's knowledge and experience rather than either hypothesis testing or engineering analysis. These distinctions are fully in keeping with *Kumho Tire's* admonition that the objective in determining the admissibility of expert testimony is "to make certain that an expert, whether basing testimony upon professional studies or personal experience, employs in the courtroom the same level of intellectual rigor that characterizes the practice of an expert in the relevant field."²⁶⁸

Glossary of Terms

artificial intelligence (AI). The ability of machines to make decisions and exhibit human-like behavior. AI combines mathematics, computer science, and data to augment human abilities.

complexity. The characteristic of a system being large, intricate, involving many parts, and displaying emergent behavior.

constraint. A fundamental or selected specification that limits the range of solutions.

design process. The collection of steps by which an engineer proceeds from a goal to a product, while making tradeoffs that satisfy given constraints.

engineer. A person who designs products, structures, computer algorithms, or the like, and/or oversees or participates in their implementation. Engineers also develop standards and tests for use in their work and do analyses of designs and the failure of designs to function as anticipated. An engineer may or may not have licensed credentials to practice. See professional engineer (PE).

engineering design. The process of devising a system, component, or process to meet desired needs.

error. In reference to statistics, the potential difference between a computed or measured value and the true value; more broadly, the difference between a predicted outcome and what actually occurs.

evidence. Within science and engineering, phenomena or data that tend to corroborate or confirm the validity of a hypothesis or a design or to show a hypothesis is wrong or that a design does not function as intended.

experiment. Testing methodology that involves intentionally manipulating some factor in a system to learn how that affects an outcome.

failure. The inability to perform according to the predicted or designed levels. Failure may be catastrophic if it results in the loss of lives, products, or property.

falsification. The idea that a scientific explanation is always contingent on some phenomenon or occurrence that shows it cannot be correct. Some accounts of how science works make falsification the touchstone of the scientific method, but more recent thinking makes it a less central factor.

hypothesis. Within science, a potential explanation for a specified set of natural phenomena. Note that this term is inconsistently applied outside of science.

licensure. See professional engineer (PE).

machine learning (ML). The subfield within the general artificial intelligence field that uses data and algorithms to learn, identify patterns, provide models, and make decisions with little or no human intervention.

model. Within engineering, usually, a mathematical representation of mechanisms and interactions within a system that can be used to investigate the impact of parameter changes on predicted system outcomes; or in some cases a physical device or structure used to approximate a design and facilitate its analysis.

prediction. Potential outcome of a scientific test or experiment that is arrived at by logically reasoning about what we would expect to observe if a hypothesis were true or false.

product. The ultimate outcome of an engineering design process.

professional engineer (PE). Designation earned after a graduate of an accredited engineering bachelor's degree program passes two tests and then obtains a state license.

science. A body of knowledge regarding the natural world and the process for building that knowledge based on evidence acquired through observation, experiment, and simulation.

scientific method. This method proceeds in a logical sequence from a statement of a question about why certain phenomena occur to communicating an explanation resulting from scientific inquiry. It is not a rigid lockstep process, but instead is dependent on publication, debate, and eventual consensus always subject to rejection or modification in light of new evidence.

structure. In the context of systems level models, something arranged in a definite pattern of organization.

systems engineering. An interdisciplinary field of engineering and engineering management that focuses on how to design, integrate, and manage complex systems over their life cycles. At its core, systems engineering utilizes systems thinking principles to organize this body of knowledge.

testing. The step in an engineering design or in a scientific pursuit where a product or a hypothesis is subjected to realistic operational conditions, whether in a laboratory setting or in its ultimate field of application.

theory. Within science, a concise, coherent, and predictive explanation for a broad range of natural phenomena that integrates and makes sense of many hypotheses. This term is inconsistently applied, and its use is more or less common in different disciplines and at different points in history. Hypothesis and theory are often used interchangeably, but a theory is more properly an explanation that has been accepted as correct, subject to modification or falsification.

tradeoffs. In the engineering design context, choices that necessitate striking a balance between two or more desirable but often competing criteria.

uncertainty. The idea that calculations or problems may not be precise, and that what actually occurs often can be predicted only within a defined range.

Introduction

Computers have become inescapable. Virtually every adult and teen carries and uses a computer in the form of a smartphone holding incredible amounts of information about the user. Computers are present as wearable devices that monitor our health or are present in our buildings as fixtures that monitor and control our environment. Cars and critical infrastructure no longer work without them. We commonly use computers to communicate, seek and find information, navigate, and supplement our memory—and evidence of our actions often remains. Companies store massive amounts of data electronically about their activities and, where applicable, those of their customers. Accordingly, our everyday movements, communications, and actions often result in critical evidence that is relevant to both criminal and civil disputes. Court cases often depend on a forensic analysis of this stored digital evidence of the computational activity that has occurred or been recorded, particularly in the realm of emails and other communications. Computers will be part of many legal cases, in some aspect, for the foreseeable future.

In this reference guide, we provide a brief overview of how computers operate and communicate; the basics of algorithms, software, and cryptography; how computers communicate over networks like the internet; computer security goals and the process of meeting them; and what digital forensic evidence can be collected to support or refute some legal theories. Given the wide scope of topics, we are necessarily brief in our treatment of these topics, but we hope this reference guide provides a basis for understanding the technology that is involved in many legal issues. Standard textbooks are available that cover many of these topics in greater detail, such as from Kurose and Ross,¹ Anderson,² Bishop,³ and Kernighan.⁴ See also Darrell⁵ and Kerr⁶ for legal textbooks concerned with technology and computers.

Computer Organization

We begin with a general overview of computer organization, including hardware, file systems, databases, and virtual machines. Computer networking is covered in a later section of this guide.

6. Orin Kerr, *Computer Crime Law* (5th ed. 2022).

Overview of Computer Hardware

A computer is a tool that processes information at blazing speeds. It performs this feat by encoding the information as electrical signals that can be processed as billions of operations per second, stored in huge quantities, or sent over a network. The hardware of a computer is designed to process data quickly through simple mathematical operations. It is the combination of computational power with functionality provided by programs that makes it incredibly useful. We describe programs and how they are created in “Algorithms, Programs, and Software.”

Binary Encoding, Bits, and Bytes

Every computer performs computations using a series of high and low voltages that represent a series of 1 or 0 values, each value being called a bit. All information on the computer, including programs or data files, is a series of bits, with the series representing some numeric value that has meaning in a particular context. This representation is called binary encoding. Each added bit in a series doubles the number of possible values that can be represented. A single bit can represent two values; two bits can represent four values; three bits eight values, and so on. The most common unit of data is 8 bits combined; this unit is named a byte, and it can represent 256 possible values and often represents one character of text. Most data are measured in terms of bytes, and it is common for measurements of bits to be represented with a lowercase b and bytes with an uppercase B. Units of a thousand bytes are called a kilobyte, abbreviated KB; units of a million are a megabyte, or MB; units of a billion bytes are gigabytes, or GB; and units of a trillion bytes are terabytes, or TB.

Buses and Controllers

Almost all computers have a similar physical structure. Typically, there is a motherboard that provides a base for other components and for communication between them, using electrical connections called buses. The buses connect components called controllers that handle receiving data from the user, from storage, or from the network and sending that data to the central processing unit (CPU). A typical motherboard will have a variety of buses, some that are very high speed to access random access memory (RAM) or to other components like graphical processing units (GPUs), and others that are lower speed and connect devices like Universal Serial Bus (USB) mice and keyboards.

Central Processing Units (CPUs)

The primary computational component that is mounted on the motherboard is the central processing unit (CPU), which is often the single most expensive component. Older computers most often had one CPU that contained one computational core whose speed was governed by a clock that generated electrical signals to keep computations internally synchronized. Some higher-power computers had more than one CPU mounted on the motherboard and could perform multiple computations at the same time with one set of computations in each CPU.

Advances in computational speed initially came from increasing the tick speed of the internal clock. However, this approach reached physical limits, mostly in terms of power consumption and related heat generation. More recently, designers started adding additional computational cores to a single CPU so that each CPU could perform multiple computations simultaneously. Now a single physical CPU typically has many computational cores, which enable new uses like hosting virtual machines, as discussed below. The number of cores varies depending on design and cost of the CPU; low-cost CPUs might have 1 to 4 cores, while high-end CPUs might have 64 cores or more, with a range in between. With mobile computing becoming widespread, designers often work to decrease the power required for computation so that mobile devices, like phones and laptops, can last longer while running on battery power.

Graphics Processing Units (GPUs)

The other component that is increasingly used for computation is the graphics processing unit, or GPU. The GPU was originally used to increase the speed of on-screen video, particularly for games, but over time other uses have become popular. GPUs are excellent for machine learning and cryptocurrencies, and they have become essential to those areas.⁷

GPUs differ from CPUs in that they have many more computational cores than a CPU, though each core is more specialized and limited in what it can do. Whereas a CPU might have between 4 and 32 cores, a GPU might have thousands of less-powerful cores. In addition, GPUs execute tasks delegated by the CPU during the execution of a program, and they do not run programs on their own.

7. For a detailed discussion of machine learning, see James E. Baker and Laurie N. Hobart, *Reference Guide on Artificial Intelligence*, “What is Machine Learning?” section, in this manual.

Random Access Memory (RAM)

The CPU stores some working data in its own circuitry, but such storage is expensive and displaces circuitry that could be used for computation. Each CPU has several caches of memory: the high speed but smaller level 1 cache, and one or more other levels of caches, each larger and slower than the prior level. More storage is supplied off the CPU in random access memory (or RAM). RAM is a large bank of hardware memory that can be accessed relatively quickly by the CPU when it needs data. RAM is often connected to the CPU on a dedicated, high-speed bus so there is no conflict with other data coming from other devices. GPUs have less cache, instead having high-bandwidth connections to the RAM to supply the data needed.

RAM is volatile memory, meaning it requires continuous power to store data. For desktop computers this means that data can be lost when power is lost. For laptops and some battery-powered devices there is usually a mechanism to store the contents of RAM in longer-term storage when it appears the battery will become exhausted; other devices have a memory-preserving sleep mode.

Data Storage

Flash Memory, SSDs, and USB Drives

Most computers now use flash memory for internal data storage. Flash memory is a type of hardware-based storage similar to RAM, except that it is nonvolatile. When power is removed from flash memory the data is not lost. Flash is not a replacement for RAM in part because it is much slower and in part because flash has a characteristic that the memory cells can only be written to a limited number of times. Flash memory is commonly used for solid state drives (SSDs). These drives are an improvement over hard drives that are based on spinning magnetic platters, described below. SSDs have faster access speeds and lower power usage, but they can be more expensive for the same amount of storage.

Flash is also commonly used in portable storage. It is incorporated into a huge range of cards, sticks, and keys, which sport a variety of connectors. Perhaps the most common type of portable storage is the USB drive—often referred to as a “USB key fob” or “USB key”—which connects via a computer’s USB port. Card readers that support a variety of formats are available, and some laptops include built-in readers.

Hard Drives

Non-SSD hard drives use an older mechanical technology based on magnetism to store bits of data on a rotating platter. While these drives are less common in laptops and PCs, they are still used in many server applications for bulk data storage. The size of the platter has been getting smaller over time, though the density of information written on the platter continues to increase. Desktop drives commonly use 3.5-inch platters, while laptops use 2.5-inch platters, and embedded devices and the smallest laptops use drives with 1.5-inch platters.

Other Media

While SSDs and hard drives are most common, there are other types of media still in use. Optical media, such as compact discs (CDs), digital video discs (DVDs), and Blu-ray discs, encode data in a way that they are readable by laser light. Current technologies store data on discs by encoding bits as tiny pits that change the reflectivity in reflective media and can be read as bits by a laser. Tape is sometimes used as a backup media. It is a long, magnetic, ribbon-like material that is stored on spools that are often inside a cartridge. Tape provides sequential access to data instead of random access. The tape must be read from front to back. Tape can provide significant amounts of storage inexpensively, though the access rate is slow.

General System Diagram

Figure 1 shows the basic layout of the devices in a computer. The high-speed bus and low-speed bus are separate components on older computers, but some or all of that functionality might be incorporated directly into modern CPUs.

Operating Systems

The hardware of a computer is shared across all the programs using it. Operating systems (OS) are a common and specialized type of software that mediates between the system hardware and the software that wants to use it. Operating systems provide a number of useful functions. They manage resources shared between programs, such as access to devices like storage and input/output devices and allocating memory. They provide a common interface to hardware so that programmers don't need to be aware of specific differences between individual hardware brands or components by providing an interface for drivers, which specify how the OS can interact with hardware. They provide a user interface so that users can start

Figure 1. The components of a computer system.

and stop programs and access files and other information. Computer programs written for one operating system are generally not compatible and will not work with others. Some OS are designed for desktop and laptop use, like Microsoft Windows and Apple's macOS. Others are used for mobile devices, like Google's Android or Apple's iOS. Still others are most commonly used for servers, like Linux.

File Systems, File Metadata, and Databases

Computer storage media provide the ability to store information, but they do not inherently organize it; they come as large blank storage areas. Computer operating systems format storage media with a file system that provides a structure for storing and retrieving directories and files. Operating systems typically protect

files that are critical for the OS to function and isolate user-generated files between users. The file system also keeps accounting information about each file. This is generally referred to as the MAC times, which are the times a file was last modified, when it was last accessed, or when it was created. These times may or may not be entirely accurate, depending on the operating system being used, if the system clock is accurately set, and the circumstances of the file creation; they also might be manually changed. They are not inherently reliable. These data are a type of metadata, which is data about or related to other data.

File metadata can be instrumental in litigation as it can reveal many facts relevant to key issues in litigation, such as the location and the date and time files were created, accessed, or modified. Often the most important role of file metadata is to support or attack the credibility of evidence—both testimonial evidence and document evidence. For example, in a contract dispute metadata revealed the creation date of a key document was almost one year later than the defendant had represented. Of note, the creation date shown by the file's metadata was in fact just two days prior to the document being disclosed to the court. While metadata still requires authentication to be introduced as evidence of the true creation date, it provided sufficient grounds to challenge the credibility of the defendant's prior assertions regarding the existence of the document.⁸ A court may deem metadata to be self-authenticating if the opposing party shows no reason to doubt the authenticity of the metadata.⁹ Metadata regarding the time a file is created, accessed, or modified can also be relevant in medical malpractice cases where electronic medical record systems are utilized. In today's world of electronic files, metadata can be relevant in any case where the creation and access times for key files are important to pending litigation.

When a file is written to storage by a program, it is itself formatted in a very specific way according to the design of the program and the information the program needs to store. The internal format of the file depends on the program being used, but many files include additional useful information about the file that may not be visible to the user without special tools or without using program features to access it. For example, one image file format is the exchangeable image file format (EXIF) standard, which can include the time and date the photo was taken, a GPS location, as well as details on the camera that took the image. Similarly, Microsoft Office documents contain metadata about the creation of the document, often including the author and the amount of time spent editing the document and changes made, among many other things. Any file under the control of a user can be altered. Thus, just like the images themselves, EXIF data could be easily altered by the owner of a file, meaning the authenticity of the metadata should be confirmed before accepting it as evidence.

8. *SPV-LS v. Transamerica Life Ins. Co.*, 912 F.3d 1106, 1114 (8th Cir. 2019).

9. *Tamares Las Vegas Props., LLC v. Travelers Indemnity Co.*, 586 F. Supp. 2d 1022 (D. Nev. 2022), *cited by* *CNA Ins. Co. Ltd. v. Expeditors Int'l of Wash.*, 2023 WL 6892565 (W.D. Wash.).

EXIF data can become critical evidence in criminal cases. For example, an image of child sexual abuse material (otherwise known as child pornography) containing EXIF data revealing the GPS location where the image was taken with an iPhone 4 was posted to a website. This EXIF data led the FBI to the owner of the iPhone who admitted to taking the image. During the resulting prosecution, the defendant filed a suppression motion arguing the EXIF data was protected by the Fourth Amendment because it was not visible to anyone viewing the image on the website. The court denied the motion holding there is no Fourth Amendment protection for the EXIF data as it was publicly accessible when the image was publicly posted.¹⁰

It is also important to note that the internal format of the data may not translate directly to what is shown on the screen. Additional information may be recoverable from careful analysis. For example, a portable document format (PDF) file is used to format and display documents for printing. Making a PDF file is often the final step in releasing documents in public settings. Information that was intended to be redacted from PDF documents is sometimes recoverable with special tools or simple mechanisms. For example, if the redaction involves covering text with a black rectangle, the redacted text may still be stored within the file and recoverable using the right tools.

A database is an alternative way of organizing a collection of information. Instead of files, the database has entries stored in tables. Most often, all items in a table are related information. For example, one table might consist of a set of names; another table might consist of a set of addresses. Internal identifiers are used to relate items across tables. Databases use a different interface than file systems. Most often, there is a computer language that can issue queries to the database so that it can retrieve items that match the queries. (For example, a query may be issued to identify all rows in a table related to a specific city.) In contrast, files are most often accessed by the file name and perhaps what directory the file is in; while some operating systems support searching files by content, it is not the primary means of accessing data.

Virtual Machines

Computers exist in the physical world, each taking up some space and requiring cabling for power and networking—which can be inconvenient for those who need an additional computer, for example, to run different operating systems or for those who want their own isolated server for security reasons. Providing these individual devices—real, physical devices—can be cumbersome and expensive.

10. *United States v. Post*, 997 F. Supp. 2d 602 (S.D. Tex. 2014).

Virtual machines (VMs) have become a commonplace solution to this problem. A virtual machine is a software program that pretends to be computer hardware while running on a host's real hardware. A virtual machine makes use of one or more of the host computer's CPUs or computational cores like any other program running on the host. The VM is allocated storage on the host computer, and it provides network access through the host computer. Within the environment provided by the VM, it is then possible to install the same or a different operating system as the host and then run programs on the VM. Programs operating in a virtual machine most often run the same way they do on a physical machine; some malicious software will attempt to detect if it is in a virtual machine and change its operation as a result, but few if any benign programs do so. Virtual machines are designed to be completely separate from each other and to isolate operations in the virtual machine from the host systems and other VMs.

Virtual machines have several uses. The most common is internet server hosting. Instead of paying to have an expensive physical server placed in a secure co-location facility, users and companies can instead rent virtual machines from services such as Amazon Web Services, Google Cloud, or Microsoft Azure, among many others. The use of rented servers is often called cloud computing or a serverless architecture (see section titled "Cloud Computing and Serverless Systems" below) and represents a multibillion-dollar market, although not all such services are provided through virtual machines. VMs are also commonly used to increase security. Untrusted software can be run in isolation on a VM in case the software acts maliciously. If it does, the impact is isolated, and the virtual machine can be easily discarded. Finally, individual users might run virtual machines to experiment with different operating systems. Rather than having a computer for each, one computer can host many different operating systems that can run different software.

Algorithms, Programs, and Software

The operation of programs is central to understanding other topics surrounding computing. Here, we provide an overview of how programs are developed and turned into software products, which is relevant to legal issues that address what software does and how it was developed.

An algorithm is a series of ordered steps used to complete a task.¹¹ We use algorithms in many aspects of our daily life: a recipe to cook a certain dish or the diagnosis and repair of an item are both common examples of algorithms that

11. Algorithms (and in particular complex algorithms) are discussed in detail in James E. Baker and Laurie N. Hobart, *Reference Guide on Artificial Intelligence*, in this manual. See, e.g., sections titled "Complex Algorithms," "The Heart of AI Is the Algorithm," "Forms of Algorithmic Bias," and "Algorithms that Predict Human Behavior."

humans follow. An algorithm must be specified in terms that the person following it can understand and complete; you couldn't give a child direction on how to drive somewhere as they don't know how to drive, for example. It is also possible to define an algorithm as a combination of many smaller algorithms. For example, one might follow one algorithm to diagnose the cause of an item's malfunction, and then repair the item following an algorithm determined by the diagnosis.

Programs and Programming Languages

A computer program is an algorithm that a computer can run to solve a computational problem or task. An application is a program that a user interacts with directly. When a program is in a format that the computer's hardware can execute directly, it is called an executable. Because this executable format is difficult for humans to edit, programs are instead created by programmers who determine what the algorithm should do and then write source code that specifies the steps of the algorithm in a human-understandable programming language.

Some programming languages are called interpreted languages; sometimes these are called scripting languages, or scripts. In these languages there exists an executable called an interpreter that takes the source code and executes the algorithm one step at a time, essentially performing the interpretation and execution concurrently. Other languages are compiled languages. Programs in these languages are translated into executable form using a program called a compiler. This resulting executable can then be distributed and run independently of the source code. For compiled languages, translation to an executable occurs entirely ahead of the execution of the program. In general, compiled programs have better performance than interpreted programs but require more programmer time to develop and are closely tied to the system where they are expected to run; they often cannot run on other systems without changes or special support. To be able to run on many different types of hardware, some languages are designed to use an intermediate format that is independent of the hardware being used and which gets translated as needed to run on a local processor. For example, Java is designed to run on a Java virtual machine (JVM) or equivalent. Instead of recompiling the Java source code for each computer platform, the JVM only is recompiled. To execute a compiled Java program, the JVM translates from the program's instructions to the actual hardware instructions; performance is better than purely interpreted code.

There are many different programming languages, each of which is generally used to solve some class of problems. Some languages are most convenient to use for the web, with some on the web server (such as Ruby and PHP) and some in the web browser (like JavaScript); some for data analysis (like Python, R, and Julia); others for games (commonly C++ and C#); others for computational infrastructure (like C and Rust); and still others for mobile application

development (like Swift and Java). There is a significant overlap between languages, and most can be used for multiple purposes.

It is also possible to partially reverse the compilation process, which is called decompilation. It is not straightforward to decompile code. For example, decompilation typically does not produce the exact source code used to create the executable because information of use only to human programmers, like names or labels indicating what a value means, is often removed as a step in the compilation process.

Computer programmers often split programs into smaller pieces for a variety of reasons, including to reuse algorithms and to allow many programmers to work on the same program at once. Because of this, code is often written in a modular form where smaller sub-algorithms can be assembled to form the larger overall algorithm. Within a program, these sub-algorithms might be called functions, methods, or procedures interchangeably. Often, so that such functions can be shared among many programs, they are placed into libraries. These libraries might natively be part of the ecosystem of the programming language; they might be libraries that are freely available for download; they might be libraries that are commercially available for license; or they might be part of the computer's installed operating system, as described above. The term software refers to any or all of these various executable portions of code, from applications to libraries to the operating system.

Software Engineering

Programming is just one aspect of the larger topic of software engineering. Software engineering is a process that also involves design, testing, documentation, and maintenance of software. Many factors affect the complexity of the process, including the number of users of the software, the complexity of the software, the longevity of the software, the level of reliability needed, and the number of programmers coordinating simultaneously or longitudinally over time. A critical aspect of software engineering is communicating and documenting the requirements of a project.¹²

A variety of tools are commonly used to manage these processes. For example, splitting software into modules helps with the development of larger projects. Different teams of programmers can work on and test each module separately,

12. For a general discussion of the engineering design process, see Chaouki T. Abdallah et al., *Reference Guide on Engineering*, “The Engineering Design Process” section, in this manual. The role of computers and the implications of their use in design and complex systems is discussed in the *Reference Guide on Engineering* in the “Complex Systems” and “Computers, Artificial Intelligence, and Machine Learning” sections.

then combine them into a larger program. This approach leads to a model where most programs are layered. Each layer is independent and presents an interface known as the application programming interface (API) that defines how the software in that layer can be accessed. Each layer can then be changed or replaced without major modifications overall as long as the layer maintains a consistent API. APIs can be an important part of commercial products. For example, services like Amazon Web Services, Google Cloud, and Microsoft Azure provide computational services for rent that can be accessed through an API.

Software projects can vary significantly in size. Software size is often measured in lines of code, which is what it seems: a count of how long the programming language portion is. This metric is not easily comparable between languages and is a rough approximation of effort at best.

A small module or program might be only a few tens or hundreds of lines of code. A large project, like the source code for a computer operating system, might contain thousands of smaller modules and be many millions of lines long. It is thought that the code for Microsoft Windows totals over 50 million lines; the Linux operating system has about 28 million lines of code as of the time of this writing.

Code is typically stored in a source code repository. This is a specialized database, often called version control software, that can track changes made by different programmers to the code, which can help programmers and forensic investigators alike understand when and where code was added. A repository is helpful in merging new code with existing code, including new code in a program for testing, and submitting code for managerial or peer review before final inclusion. It also allows for different code versions and reverting source code changes should there be errors. Common tools for source code management include git, CVS, svn, and Visual SourceSafe. These can be useful sources that can show how software was developed over time.

Many kinds of testing methodologies are involved in verifying the correct operation of software. For example, unit tests ensure that the smallest components of a code base function as expected. Regression tests ensure that as new features are added or as repairs are made the current level of performance of a software system is not reduced or new errors added. Integration tests ensure that distinct subsystems interoperate as expected. Often software systems involve a continuous integration continuous delivery (CI/CD) pipeline where new changes are tested against a battery of tests before they are accepted into the main code base; this testing often occurs overnight. The goal of CI/CD is that software is always available in a state that is operational and correct, so that it can be delivered to the customer at any time. As a code base is expanded, developers add to the battery of tests to keep the CI/CD pipeline current. Finally, many larger projects will involve a team of quality assurance (QA) tests that test for bugs, rate performance, and ensure a high-quality user experience before software is released.

Source Code Distribution and Software Licensing

Most commercial programs that are developed by companies do not disclose source code, and the program's source code is not shared with others. This closed-source approach helps protect trade secrets and avoids aiding competitors. In contrast, some programs are developed openly, and the source code is publicly available. For example, Microsoft's GitHub.com platform hosts many open-source projects.

Software is commonly licensed, rather than being sold outright. Licensing allows the software vendor to impose conditions on its use, including prohibitions on copying, distribution, and reverse engineering. Many commercial programs are licensed under proprietary End User License Agreements (EULAs) that users must accept to acquire or use the software, and copyright is retained by the company.

Open-source software is often distributed under what are commonly called Free and Open Source (FOSS) licenses and are sometimes referred to less accurately as "free software." There are a variety of open-source licenses; most allow use, copying, and modifications of the program. They vary on whether the code can be sold, redistributed, or sublicensed. Some licenses, most notably the GNU Public License (GPL), allow modification and private use but require that any such modifications that are sold or distributed are also licensed under the GPL, ensuring that source code improvements become available and that software will be improved over time by interested parties but remain available to all. As this approach is quite different from usual copyright, this license is referred to as copyleft.

Other open-source licenses allow sale and modification without requiring source code distribution; the BSD license, for example, allows use of and modification of code if the original license is included in future distributions. Similar licenses exist for other material, such as writing and photographs. A common one is called the Creative Commons license.

Source Code Review

In many situations, parties in a legal proceeding disagree about what software does, making source code review a key part of the discovery process so that both parties can assess essential evidence. This scenario arises in cases involving product liability, trade secrets, and patent infringement and is sought by defendants in criminal cases where key evidence was collected through software. Source code review intrudes on information protected as proprietary, trade secret, or law-enforcement sensitive information and therefore should only be used when the threshold has been met to overcome these software protections. Source code

review occurs when the software code is the central evidence to the case, such as in the seminal software copyright case of *Google, L.L.C. v. Oracle America, Inc.* Source code review was also used by plaintiffs in a key Toyota product liability case to argue that the software governing the electronic throttle control system was defective, causing sudden acceleration events that resulted in numerous deaths and injuries.¹³

However, protections for trade secret, proprietary, and law enforcement sensitive information should prevent disclosure of source code when the software is not the central evidence of the case itself. For example, in a patent infringement case involving wireless communication technology, a U.S. district court denied the plaintiff the opportunity to review a third party's source code, holding that the third party's concerns regarding the security of the source code could not be ignored despite the protective order. The court stated that the entity owning the source code was not a party to the lawsuit nor were they accused of patent infringement. Furthermore, the court held that the relevant information could be obtained from deposing a company engineer rather than from reviewing the source code.¹⁴ Similarly, software used in criminal investigations becomes essential when it is used to collect evidence in the prosecution's case-in-chief. For example, in *United States v. Budziak*, the Ninth Circuit held that the source code was material to the defense's case relying on the fact that the evidence presented at trial to support the distribution of child pornography charge was devoted to the government's investigative software (called eP2P) and the evidence that was collected by its use. No court has held the investigative source code was material to the defense when the prosecution's case-in-chief does not include evidence collected through the software.¹⁵

The demand for source code review in civil cases has resulted in an industry of source code review companies offering experts who can conduct code reviews and testify in court proceedings. Often the code being reviewed is proprietary and may contain information like trade secrets, so the source code is made available only on a secure machine, disconnected from any network, sometimes at one of the parties' representatives' offices. The parties often agree to provide the same set of tools to be used in the code review that the programmers used to develop it, or sometimes an even more minimal subset of similar tools is chosen by the legal representatives without expert guidance.

Programmers need to change code, however, to create new features and then turn those into a working, executable program. Source code reviewers usually

13. *Bookout et al. v. Toyota Motor Sales USA Inc. et al.*, No. CJ-2008-7969, *verdict returned* (Okla. Dist. Ct., Okla. Cty. Oct. 25, 2013).

14. *Realtime Data L.L.C. v. MetroPCS Tex. LLC*, No. 12cv1048-BTM (MDD) (S.D. Cal. May 25, 2012).

15. See *United States v. Pirosko*, 787 F.3d 358 (6th Cir. 2015); *United States v. Hoeffener*, 950 F.3d 1037 (8th Cir. 2020); *United States v. Arumugam*, 2020 WL 949937 (W.D. Wash.); *United States v. Feldman*, 2015 WL 248006 (E.D. Wis.).

have different needs, as their goal most often is not to create or redesign code. Instead, the focus is on being able to read existing code easily to understand the underlying algorithm, to search the code for features, and to print code for reference in a way that allows ease of reference in legal discussions. This goal requires a different set of tools that focus on reading and searching code. For example, *doxygen* is a tool that converts source code to non-editable local files that can be opened as web pages that include the file name and line numbers for easy reference to the original source, and *dnngrep* is a free tool that can conduct fast searches.

It is worth noting that the term “source code” might refer to different things depending on context. To a computer scientist, the term typically refers to the programmatic source code that is compiled or interpreted to produce a program. In a legal context, however, the term commonly applies to all files that are produced as part of discovery, which can include many other related files. These often include the following: build system configurations files or scripts, which are used to compile and link together the many modules that make up a large program; code that conducts testing of the program to detect errors; and other files, such as design documents, notes about the code, or histories of when files were added during development. These additional files often provide useful context to a source code reviewer.

Reverse Engineering

Aspects of hardware and code that are protected as a trade secret are subject to reverse engineering, in which others attempt to discover the secrets through independent discovery. *Kewanee Oil Co. v. Bicron Corp.*¹⁶ established that trade secrets do not receive patent protection and that it is legal to reverse engineer items in the public domain.

Reverse engineering is also used as an innovative tool for chip design. In 1985, Congress passed the Semiconductor Chip Protection Act (SCPA),¹⁷ which protects semiconductor design while providing a reverse engineering provision that allows copying of the entire chip design. The law does not distinguish between the protectable and nonprotectable portions of the chip as long as the copying is for the purpose of teaching, evaluating, or analyzing the chip. The law was written to specifically protect industry practice and encourage innovation. In intellectual property litigation where chips appeared to be similar, Congress assumed that admitting expert testimony to assist in determining whether subtle changes in a chip layout (called a “mask work”) were significant would resolve the problem of distinguishing a copy from a legitimate reverse-engineering attempt in most cases.¹⁸

16. 416 U.S. 470, 94 S. Ct. 1879 (1974).

17. 17 U.S.C. §§ 901–904 (1984).

18. *Altera Corp. v. Clear Logic, Inc.*, 424 F.3d 1079 (9th Cir. 2005).

Reverse engineering of software is often prohibited. License agreements and non disclosure agreements can limit the right to work with software to determine its function. A copyright owner can disallow making copies of a work for reverse-engineering purposes. The Digital Millennium Copyright Act (DMCA) prohibits “circumvention of ‘technological protection measures’ that ‘effectively control access’ to copyrighted works.” In some cases, however, it has been found legal to reverse engineer software in particular circumstances, primarily to provide interoperability between systems.¹⁹

Overview of Cryptography

With a basic background of computing hardware and software complete, we move toward a brief description of the cryptographic mechanisms that have become essential tools for securing information stored on computers and transmitted across networks. These algorithms are fundamental to many areas of computer science as they relate to legal issues. We introduce concepts here that appear in later sections.

Encryption is used to maintain the secrecy of information. Encryption can be a legal issue when, for example, critical evidence is held inaccessible within an encrypted file. Cryptographic hashing algorithms are widely used to preserve the integrity of data and to recognize known content accurately and easily. Cryptocurrencies are complex networked systems that can allow transfers over the internet of funds that have public value without the involvement of financial institutions; their rise has enabled new types of criminal activity and new ways to launder money.

Encryption

The most common way to ensure the confidentiality of data is to encrypt it. The net effect of encryption is to take a large secret (the data being encrypted) and reduce it to a small secret (the key used for encryption). This approach makes handling sensitive information easier, as data can be stored and transported securely on the open internet in an encrypted form. In general, if the data is obtained by others, it will remain confidential as long as the key remains a secret. The keys are transported by a separate, more secure mechanism, which is easier because they remain small regardless of the size of the data. The terms passwords and keys are similar concepts but often used differently. The term password most often refers to a collection of characters that can be entered with a keyboard (letters, numbers, and punctuation) and are human-readable. A key is a more general term as the collection can contain additional values that cannot be entered

19. *Sega Enters. v. Accolade, Inc.*, 977 F.2d 1510 (9th Cir. 1992); *Sony Computer Ent. v. Connectix*, 203 F.3d 596 (9th Cir. 2000).

with a keyboard, or perhaps a collection of values that is too long for a human to reasonably enter. In other words, the set of possible keys is much larger than the set of possible passwords. Keys are best chosen randomly, but they can be derived from passwords when needed so a human can remember them more easily.

When we encrypt data, we are altering data so that it no longer has any visible structure. The process of alteration is governed by the encryption algorithm and the encryption key chosen. Taking the original bits, referred to as the plaintext, and running them through the encryption algorithm with a given key produces the ciphertext. A good encryption algorithm produces a ciphertext that appears to have been generated completely at random. When we later want to recover the plaintext, we decrypt it by running the ciphertext through the encryption algorithm with the correct key.

If the algorithm works correctly, the secrecy of the data lies entirely with the key. For proven encryption algorithms the operations are publicly available and the best-known attack is to painstakingly attempt every possible key. We say that information is secure if an adversary cannot possibly attempt all keys in any reasonable amount of time given the resources (i.e., time and money) they have available or before the information loses its value. The number of possible keys for modern algorithms is so large that it is impossible in practice to search through all of them for the correct one, as we discuss below.

Shared Key Encryption

Algorithms that use the same key for encryption and decryption are called shared key or symmetric key algorithms. The standard shared key algorithm today is the Advanced Encryption Standard (AES), which is commonly implemented in hardware on many modern computer CPUs to increase performance.

While shared key encryption is common and efficient, it does have its drawbacks. The primary one is that if you want to have secure communication with many independent people, you need to share a different key with each individual separately. A simpler approach to this key management problem is to use public key encryption, as we describe below. The advantage of shared key encryption algorithms is that they are generally much faster than public key algorithms.

Public Key Encryption

Public key encryption algorithms use a linked pair of keys: anything encrypted with one key can only be decrypted using the other key. It is called public key encryption because one of these keys—the public key—is not kept secret. The other key is the private key and is kept secret by the owner. The advantage of this approach is that everyone who wants to send a confidential message to a recipient can

use the recipient's public key for encryption; pairwise keys between individuals are not required as they are in shared key algorithms. All messages can be decrypted by the recipient using their private key.

Public key algorithms are based on the fact that mathematically there are problems that are difficult to solve but very easy to check if a solution is correct. By analogy, it is easy to see that a jigsaw puzzle has been solved; but it takes effort to complete a puzzle given a bag of pieces. A real cryptographic example is that given two large prime numbers it is easy to multiply them together to determine if their product is equal to a third value. But given a large number alone, it is difficult to factor out the original prime numbers. One of the original public-key algorithms, called RSA after the initials of its inventors, was based on this factoring challenge. Other algorithms are based on similar mathematical problems that are easy to solve for the person who has the private key but essentially impossible to solve without it.

Because these algorithms work differently than shared key algorithms, the key size is not an accurate indicator as to how long it would take to search for and find an unknown key, and because of the mathematical operations that need to be performed, public key encryption is often much slower than shared key encryption. It is also possible that some breakthrough in mathematics or computer science will render a previously difficult to solve problem suddenly easy to solve, making any algorithm based on that problem immediately breakable. Common public-key algorithms include RSA, elliptic curves, and El Gamal.

Cryptographic signatures

Public key encryption can also provide proof of who sent a particular message, called a digital signature. The basic idea is that if someone encrypts some data with their private key, decrypting it with the known public key verifies it was encrypted by the private key owner. Proving it was encrypted with the private key is therefore equivalent to the private key holder signing it (under the assumption that the private key would never be disclosed by the owner). For convenience and speed, some digital signatures do not encrypt the entire document. Instead, a cryptographic summary of the document is computed (called a hash, as described below), and that is encrypted. The hash is small and unique to the document being signed. Not all cryptographic digital signatures operate this way, but it's a good high-level model for understanding how digital signatures are computed.

Certificates

One problem with public key cryptography, however, is verifying who owns a particular key. This verification must be managed by computers, be performed

in milliseconds, and be mathematically based. The common solution to this is the use of cryptographic certificates, which make use of digital signatures to verify public key ownership; certificates provide much of the cryptographic foundation of the internet. Individual operating systems or software, such as web browsers, are preloaded with root certificates. These certificates are, in short, the public key of trusted organizations that serve to verify other certificates. In this hierarchical system of trust, a shopping website would create a public key to include it in a certificate of its own, and then pay one of the root certificate organizations to sign it. Consumers are trusting the root certificate organizations to sign with integrity.

For example, when a secure connection is made over the internet to shop using a web browser, the shopping website presents its own certificate to the browser. As described above, this certificate contains the public key for the shopping website and a digital signature from one of the root certificate organizations. The browser uses one of the preloaded root certificates to verify the trusted organization's signature on the shopping website certificate. When the browser finds that the shopping site certificate is correctly signed, it then trusts that the shopping site certificate belongs to the shopping site (and not some impostor) and that it is safe to conduct transactions. The site public key is then used to exchange a shared key used during only this session for encrypting the transactions between the user's browser and the shopping website. The actual process has a few more steps, including some intermediate certificates and keys, but conceptually the result is the same.

Cryptographic Key Sizes and Attacking Encryption

Cryptographic operations depend on the fact that the number of possible keys and hashes are so large that they represent values far outside human experience. Each key or hash is a series of individual bits, each a single 1 or 0 value, often hundreds of bits long. Each time a bit is added, the number of possible combinations for the series doubles. By the time the length of the series is 128 bits, the number of possible combinations is 2^{128} which is about 10^{38} (or 1 followed by 38 zeros). To put this in perspective, some estimates put the number of grains of sand on the earth at about 10^{24} . In other words, there are about 100 trillion times as many possible values for a 128-bit sequence than grains of sand on earth. Moving to 256 bits or 512 bits produces combinatorial sizes that are even less comprehensible. A sequence of 256 bits produces about 10^{77} possibilities; for 512 bits the set of possibilities becomes about 10^{154} .

Breaking encryption for these size sequences by trying all keys is impossible; there is not enough computational power to do so nor is it possible to create

enough computational power to do so. If keys or hashes are random then they are incredibly unlikely to be broken this way.

Attacking Encryption

It is impossible to try every possible key to attempt to decrypt something encrypted; there are too many keys to try as bounded by the laws of physics. For that reason, when users let their computers pick their keys or passwords randomly then decryption through automated guessing will not work. On the other hand, people are frequently not random when picking their own passwords, and they are often poor at securing the storage of those passwords. For example, passwords might be based on pets and birthdays and be written down in a notebook, or on a scrap of paper, or recoverable from a computer memory or disk. In these cases, there might be some hope that the password might be recovered. It is also possible to try and brute force passwords by repeated guessing. Humans often use statistically predictable patterns, and software exists that will work through trillions of combinations of statistically probable passwords to see if they create a key that can be used for decryption; this approach can be very effective for poorly chosen passwords, and very ineffective for randomly created ones.

In cases where the password is not recovered, it might be possible to get it from the user.²⁰ Some courts have reached a variety of conclusions whether a court can issue an order to compel disclosure of a password or even compel someone to unlock a device. Some courts hold there is no Fifth Amendment violation to compel a password's disclosure if the ownership of the device is a foregone conclusion.²¹ Other courts have explicitly refused to apply the foregone conclusion doctrine and denied orders to compel disclosure of passwords.²²

21. See, e.g., *United States v. Apple Mac Pro Comput.*, 949 F.3d 102 (3d Cir. 2020) (court upheld court order under the All Writs Act compelling disclosure of password under the foregone conclusion exception to the Fifth Amendment); *State v. Andrews*, 234 A.3d 1254 (N.J. 2020), *cert. denied*, 141 S. Ct. 2623 (2021) (the foregone conclusion exception allows the defendant to be compelled to communicate his memorized passcodes to the government); *Commonwealth v. Jones*, 481 Mass. 540 (Mass. 2019).

22. See *Seo v. State*, 148 N.E.3d 952 (Ind. 2020) (discussing concerns with extending the foregone conclusion exception to the Fifth Amendment in the context of compelling production of an unlocked smartphone); *Commonwealth v. Davis*, 220 A.3d 534 (Penn. 2019) (foregone conclusion exception to the Fifth Amendment is inapplicable to compel the disclosure of a defendant's password to assist the government to gaining access to a computer).

Cryptographic Hash Functions

A cryptographic hash is a mathematical function that takes any digital content as input of any length and produces a short unique numeric signature as output, typically 512 bits or fewer. This reduced number of bits, which is often referred to as the hash, is like a digital summary or identifier of the content that was input. Changing any single bit in the input changes the output hash significantly and unpredictably. We can therefore use hash functions to verify the integrity of large amounts of data, at any input size, at a level of granularity involving single bits. Good hash functions have the following properties that ensure the hash is secure:

- First, given a hash, it is not possible to recover the original data. This means that you can share the hash with anyone, and they cannot tell what was used to create it. If you give them the original data, though, it is easy to run those through the hash function to ensure that they are the same. Hashing is a one-way function.
- Second, given a hash, it is virtually impossible to find any other content that produces the same hash when run through the hash function. This property is related to the size of the hash output in bits: increasing the length of the hash output increases the difficulty of finding other content.
- Third, it is very difficult to create two different digital objects that have the same hash. This task isn't as hard as the second property, as we describe below, but it is still very hard for good hash functions. (By "hard" and "difficult" we mean that an adversary cannot acquire sufficient computing resources to achieve the desired result with even the smallest probability of success.)

Cryptographic hashes have myriad uses, the most common as digital summaries. To detect changes to a file, the hash of a file or other digital object is taken and recorded separately from the object itself. Later, the hash can be recomputed from the object or a copy of it. If the object has changed, then the hash will have changed. Similarly, no two objects will have the same hash value, as described above.

Accordingly, hash values are an important tool used in e-discovery as they provide a guarantee for the authenticity of an original data set and can be used as a digital equivalent of the Bates stamp used in paper document production.²³ Amendments to Federal Rule of Evidence 902 provide a procedure to authenticate electronic documents without calling the testimony of a witness. Committee notes to the 2017 amendment specifically point to the use of hash values to self-authenticate, relying only on a certification by a qualified person that they checked the hash value of the proffered item and that it was identical to the original.

23. Managing Discovery of Electronic Information 52 (Federal Judicial Center Pocket Guide, 3d ed. 2017).

Attacking Cryptographic Hashes

There are a variety of commonly used hash functions. Some older ones, particularly MD5 and SHA-1, have been shown to be weak or broken in ways that newer hashes such as SHA-256 are not. Specifically, attackers can violate the third property above and produce multiple data files that have the same cryptographic hash.

In contrast, for cryptographic hash algorithms that have no known weakness, the chance of generating a second file that has the same hash as a given, fixed first file is vanishingly small. For example, given a file with a particular cryptographic hash value that is n bits long and violating the second principle above, one would expect to have to generate 2^n candidate files before finding a match. For example, when using SHA-256, which produces a 256-bit output, one would have to generate 2^{256} (roughly 10^{76}) candidate files before expecting to find a match, which is essentially impossible in practice.

The process of creating hashes is subject to the so-called *birthday attack*, however, which violates the third property above. This attack is so named because while the chance of any one specific person having a set birthday is $1/365$ (ignoring leap years), the chances that some two people in a group of 23 having the same birthday is about 50%. In the first case, we have fixed on a single birthday date; in the second case, any matching birthday date achieves success. These are analogous to principles one and two above. Producing a large set of random digital objects will produce two objects that have the same hash more often than when fixing a file to match against. Specifically, one would expect to generate $2^{n/2}$ candidate files to find any pair that match from among all generated candidates. In the case of SHA-256, finding a matching pair requires generating 2^{128} (roughly 10^{38}) candidate files in expectation, which is still impractical.

Hash values are also used by electronic service providers to detect images of apparent child pornography. They typically configure their systems to watch for such images being transmitted or stored across their networks by computing hashes of the images and comparing them against hashes known to be illegal.²⁴ It is, however, easily possible to make alterations to the image that will not be visible but would change the hash.

Cryptocurrency

Cryptocurrencies have become the de facto standard form of conducting online payments for many illegal activities; in addition, there seems to be a growing

24. See *United States v. Miller*, 982 F.3d 412 (6th Cir. 2020) (analyzing Fourth Amendment concerns when Google used hash values to identify images of apparent child pornography transmitting across their network).

number of financial fraud cases involving cryptocurrency companies. In this subsection, we provide a very brief overview of how Bitcoin, the original cryptocurrency, works. There are many different cryptocurrencies that are based on a variety of cryptographic principles, but others are often similar in their design.

The fact that many cryptocurrencies have “coin” in their name is misleading. Instead of tracking individual currency units, most cryptocurrencies instead operate on the concept of a shared ledger. On this ledger there are a series of identifiers called addresses (analogous to a bank account number) that are each associated with an amount of cryptocurrency; the ledger is essentially a shared database that maps addresses to the cryptocurrency balance. This approach is as if a bank kept track of how much money is in an account without recording the serial numbers of any cash deposited and without attaching a name to the account.

Transactions cause some portion of a balance to be transferred from one address to another and recorded on the ledger. This ledger is called the blockchain and contains a history of every transaction that has ever happened in Bitcoin (or other cryptocurrency). By processing through the list of transactions listed on the blockchain, anyone can determine the balance associated with any address. In Bitcoin, each address is a public cryptographic key. Only the person who knows the corresponding private key may create transactions with that identity. Transactions are analogous to bank checks: they transfer currency controlled by one private key to the control of a different private key. One person might have control of any number of addresses. Transactions, however, are not anonymous in that they are inseparable from the addresses listed in the ledger. It is often possible to associate these Bitcoin addresses to real-world persons by finding Bitcoin transactions that are associated with real-world financial actions, like purchasing Bitcoin using a bank account or using Bitcoin to order physical items mailed to a postal address.

The major innovation of Bitcoin was to establish a mechanism by which a large group of computers could come to a consensus, without a central organizing authority, on which transactions become part of the blockchain despite some minority of participants attempting to cheat or otherwise influence the outcome. This mechanism, called mining, also creates new Bitcoin, and it incentivizes participation in the Bitcoin protocol, which helps make it resilient against attack.

The value people see in Bitcoin is that it is exceedingly difficult to alter the blockchain; to do so would require a very significant amount of computational power, in general roughly more than about half the computer power already performing mining on a chain; for the more popular cryptocurrencies it's most often an amount out of reach of any single entity. As long as a majority of participants, as rated by computational power, behave consistently then changing the blockchain should be quite challenging and therefore secure.

For some cryptocurrencies it is possible to anonymize the relationship between currency deposited in an address and later expenditures from that address. This process is often called mixing. Because the blockchain is a public ledger, it can be used by criminal investigators to follow illegal transactions. Blockchain

analytics can become key evidence in criminal activity involving virtual currency. For example, IRS investigators analyzed the blockchain and de-anonymized Bitcoin transactions allowing for identification of hackers compromising celebrities' Twitter accounts. The affidavit supporting the criminal complaint steps through the blockchain analysis leading to the identification of several co-conspirators.²⁵

Networking

The internet's core feature is the connections it creates among the world's people, computers, and devices. The internet is supported by an enormous amount of infrastructure, including: equipment commonly used in homes and offices, such as Wi-Fi access points and cable modems; equipment deployed by internet service providers (ISP) that have home and business customers; and the connections among ISPs that connect the world together. The internet is further extended by cellular network providers, including mobile phones, radio towers, and connecting infrastructure.

It has become commonplace for people to carry mobile phones and devices at all times, and for almost all communications to be based on the internet and modern cellular infrastructure. For this reason, a great deal of evidence and legal issues are based on network communications and services. To understand modern networks and the legal issues surrounding them, it's helpful to learn a number of fundamental concepts that we explain here.

Networking Layers

The connection of the world's cellular carriers, ISPs, and *end users* as one massive system is made possible by a collection of standards called the internet protocol (IP) suite. All computers that speak IP can communicate with each other regardless of the developer and manufacturer responsible for the software or hardware. These protocols are organized as several layers. At the top layer are the applications, such as email and the web. And at the bottom are the wires and cables that carry data. In between are a series of layers that handle reliability, routing, and access control, which are all terms that we define below.

An important aspect of this design is that each layer has its own naming and addressing scheme. An address is a place on the internet that data can go to, while a name is an identifier unique to that address. For example, an email "address" is actually composed of a name (like *alice*) connected by an @ symbol to an address (like *alice@umass.edu*).

To help understand the purpose and relationship among these layers, we can make an extended analogy to the postal service. Figure 2 illustrates the five IP

25. *United States v. Sheppard*, 3:20-mj-70996 (N.D. Cal. 2020), <https://perma.cc/5NSR-7QD3>.

layers. At the top is the application layer, which consists of protocols that operate between two instances of the same application running on different desktops, laptops, or smart phones. These different devices at the edge of the internet are often called end-hosts. Email clients, web browsers, messaging programs, social media applications, and online multiplayer games and other applications each send data across the network in their own way. Application-level content very rarely is examined or modified by devices on the network. One of the reasons the internet has been able to grow to a world-wide system is that what happens on these end-hosts is largely separate from the core infrastructure. In our postal service analogy, the application layer is like letters and magazines that are mailed: although the content is important to the sender and receiver, the actions taken by the postal system are not affected by the specific words, images, or other content within the letters, and the postal system generally does not examine the content.

Figure 2. The IP network architecture is divided into several distinct layers, each providing services that build on the layers below.

Application — email, web, gaming, instant messaging
Transport — ensuring reliable data delivery
Network — providing routing of data across the network and other services
Link — managing sharing of wireless and wired connections between computers
Physical — wires and wireless

Below is the transport layer, which also operates across the network between the two end hosts. The transport layer corrects problems and errors that are caused by the layers below so that applications see a consistent stream of data. The specific transport-layer protocol that performs these functions is called the Transport Control Protocol (TCP). In our analogy, TCP is like one of the special services that can be purchased from the post office, such as a delivery acknowledgment. For an important letter, you might make a copy of the letter and then send the original. If you don't receive a delivery acknowledgment after a time, you'll send a new copy of the letter and reset your timeout for the delivery acknowledgment; at its core, the algorithm providing reliable delivery of data operates the same way.

Next, going downward, is the network layer, which is the first layer that operates on the core devices that form the internet. Whenever information leaves an end host, it is handed off to a router. Just like desktops, routers are computers. The only difference is that they are not computers that are used to run just any program; they are specialized to operate programs that route data from one end host to another end host across a building or across the world. The entire internet is composed of routers that communicate in an unbroken mesh.

Most routers have more than one or two neighboring routers, and so just like roads that intersect with other roads, routers have to be navigated from a starting end host to a destination end host. A series of protocols determine for routers which of its neighbors most quickly leads to a destination. In our analogy, routers are like post offices. When a letter leaves a home, it travels from one post office to the next, until it reaches a final post office that delivers the mail to the destination home. The network layer is responsible for assigning an IP address, and it is often critical to attributing evidence in an investigation.

The link layer manages the connections between routers (and between hosts and routers). For example, the link between a host and its wireless access point can be managed by a Wi-Fi protocol. Stretching our analogy to almost its breaking point, links are like the postal workers that are the conduits for managing the many letters at a time that go from a home to the neighborhood post office, as well as transfers along a sequence of post offices on route to the destination.

Finally, at the bottom, physical layer protocols allow hosts to send data via some physical medium, including wireless, optical fiber, or coax wire. To complete our analogy, the vans, trucks, trains, and airplanes used by the post office are the physical objects that move mail from one point to another.

IP Network and Link Layer Addresses

The two most important computer addresses that are used to move a user's data across the internet are a computer's IP address and the address of a computer's network interface.

IP addresses are assigned by the local network administrator at an internet service provider (ISP). Before data can be transferred by a computer, it must obtain an IP address. They can be assigned once and remain static for the lifetime that the computer uses the ISP. Or, more typically, IP addresses are assigned dynamically by the internet service provider using the Dynamic Host Configuration Protocol (DHCP).

Network interface addresses are assigned at the factory that manufactured the radio card or Ethernet card, and they are typically 48 bits long. They are often written as colon-separated hexadecimal strings: e.g., 00:17:F2:40:F9:B2. The first 24 bits are a prefix that should identify the manufacturer; the second half should uniquely identify the hardware across the world. This value is easily

changed by the user, as we explain below. The link-layer protocols that make use of network interface addresses are called medium access control (MAC) protocols, and so most often the 48-bit values are called MAC addresses.

A person can take their laptop from one ISP to another. For example, a laptop may move from a person's home ISP to their work ISP, and then to an internet café afterwards, all in the space of one day. Each move will cause the computer to be assigned a new IP address—however, the MAC address will stay the same throughout. A computer's MAC address is never sent farther than a router or host one hop away, to the neighboring link-connected computers. Across the internet, it will be impossible to learn that one MAC address is behind all three IP addresses at different times.

Typically, a DHCP IP address assignment is logged, including the date and time, network interface address, and assigned IP address. The Communications Assistance for Law Enforcement Act (CALEA) asks ISPs to keep DHCP logs for 90 days, but this is not a requirement under the law. Some ISPs keep information for hours, some for longer than 90 days. Many law enforcement investigations involving a network are led by a search for the computer (and home) that has been assigned an IP address that was observed online. The ISP that assigned the computer needs to be found first, so that the DHCP logs can be requested via legal process.

Sometimes an IP address is not a completely unique identifier. There are only 3.7 billion of the shorter (version 4) IP addresses for the entire world, and they are assigned in large blocks by Internet Assigned Numbers Authority (IANA). Given the number of computers in the world, addresses are scarce. Some organizations have tens of computers yet are assigned only one address by their ISP. To get around this problem, many organizations (and home routers) make use of network address translation (NAT) boxes, which allow many computers inside a network to share a single external IP address. Figure 3 illustrates this operation.

Figure 3. Network address translation box hides a larger network behind it from the rest of the internet.

Cloud Computing and Serverless Systems

The term cloud computing refers to a popular approach to supporting online computer services. When the web and online services first started gaining popularity, it was common for businesses to operate a computer to serve online customers on their own premises. As the customer base grows, the business would not only require more powerful computing hardware, but investments in air conditioning, physical security, electrical power, redundant hardware, and more. Further, for some businesses, demand might be extraordinarily high for one day and not most of the year; it can be challenging to expand infrastructure for that one day.

Cloud computing addresses these issues for businesses. Cloud providers build large data centers that provide power, network access, and cooling for many thousands of computers. Typically, there are staff onsite to provide security and help deal with hardware problems. The computers used in these centers are different than laptops and desktops. Called rack servers, they are shaped more like elongated pizza boxes so they can stack neatly, as shown in Figure 4. They often include remote management interfaces so that they can be configured and operated across the network without a human needing to be present, but humans are required to address hardware problems.

Figure 4. Racks of computers or “rack” servers in a data center.

Source: Provided by the U.S. Department of Energy’s National Energy Technology Laboratory, <https://perma.cc/VGR4-URGD>.

When the notion of cloud computing was introduced, it was common to lease a complete virtual machine above, and this is still done. More recently, cloud providers realized that they could charge for hosting a specific program. For example, the program might accept a photographic image as input and return the text that appears in the image as output. This approach, called serverless computing, allows the cloud customer to avoid paying for an idle virtual machine. Instead, they pay for each execution of their program. The cloud provider ensures that as demand ebbs and flows, the execution of the program remains performant and reliable. Large providers of such services include Amazon Web Services, Google Cloud, and Microsoft Azure. Businesses can lease computing power from the provider and scale up or down quickly as demand for their product changes.

Cloud services are a good example of what is defined as a remote computing service (RCS) in federal law.²⁶

Wireless Networking and Mobile Devices

Wireless networking is commonly of two primary types. Cellular networks support long-range communication between a user's mobile device (e.g., a smart phone) and radio towers that can be miles away. Wi-Fi networks support short-range communication between a user's mobile device and access points (AP) that can be hundreds of feet away. Bluetooth networks are similar to Wi-Fi but typically operate over an even shorter range. There are many other types of wireless networks, including satellite-based communication, that we do not discuss here.

Wireless communications are typically broadcast in nature and based on radio waves. The physics of the radio frequencies involved and the expense of the equipment determines whether the signals can permeate walls or travel long distances. For example, cellular networks are based on very large antennas situated on very large towers. Wi-Fi networks are based on small antennas affixed to boxes placed on shelves in homes. The difference explains the large geographical ranges that cellular networks can traverse compared to Wi-Fi networks. Given that wireless signals will be received by anyone within range, cryptography is typically used to keep communications confidential between the two parties communicating over the wireless channel.

26. See the definition of remote computing service, 18 U.S.C. § 2711(2).

Cellular Networks

Cellular networks are deployed across large geographic areas to allow for a user to be mobile and stay connected. Originally, cellular networks were deployed to support voice phone calls. Over time, the networks have evolved to support the data connections required by internet-enabled apps and services common on smart phones.

To enable cellular service, towers or other installations with antennas are connected to the provider's network over backhaul connections that go over cable, fiber optic, or microwave links. Each tower that a cellular provider deploys covers a geographic cell in which users have connectivity. The towers are often called cell sites. The towers are connected to a complex set of systems that route data to users and ensure that only paying, authenticated customers have access. Commonly, a subscriber identity module (SIM) card is issued by the cellular provider and inserted into the user's mobile device. The SIM card uses cryptography to authenticate the user's subscription. Records held by the cellular provider link the user's identity and billing information to the SIM card. The mobile device has an International Mobile Equipment Identity (IMEI) assigned to it.

As cellular networks have advanced in terms of range and available bandwidth, they have changed names, including 2G, 3G, LTE, and 5G. These names represent a combination of changing technical specifications and marketing efforts. The basics have remained the same even if internally the industry has changed its terminology continually. Therefore, we will describe these basics in high-level terms.

When a user powers on a mobile device, the device seeks out a nearby cell site. Using the credentials held in the SIM card and via a well-defined signaling protocol, the device authenticates to the cellular provider. As the user moves, the device will associate to a new tower with a stronger wireless signal. Voice calls and data are routed to the tower the device is associated with. Typically, the provider stores a record of these associations called cell site location information (CSLI). If a device is in range of three or more towers, the device's geographic position can be estimated from the signal strengths. This estimation can be performed after the fact if the signal strengths are recorded, or it can be performed in the moment and the estimation stored in a record. Alternatively, if the mobile device contains Global Positioning System (GPS) functionality, it can tell the cellular provider of its location. Geographic location is not required to provide wireless communications; it is required to assist with calls to emergency 911 services.

The internet includes mobile devices attached to cellular networks. These devices typically are assigned an IP address via the cellular provider's NAT gateway. Some cellular providers keep records of these NAT assignments; some do not. The amount of time these records are kept by providers also varies.

Wi-Fi

Wi-Fi is a commercial term for a series of industry standards for short-range wireless communication among computers and mobile devices. Wi-Fi networks are inexpensive for consumers to deploy to cover part of a living area with one central access point (AP). With several coordinated APs, a large home can be covered. The same technology can be scaled up to cover a large building or campus. Typically, the Wi-Fi AP includes NAT and security functionality.

Many consumer devices are available that serve a single purpose and are designed to connect to the user's Wi-Fi network. These so-called internet of things (IOT) devices include services such as monitoring and adjusting temperature and lighting, controlling door locks and entryway cameras, and managing smoke alarms and other sensors. Some IOT devices connect to each other, smartphones, and desktop computers via Bluetooth wireless technology. Bluetooth was designed to allow for very short-range connections between devices, replacing short cables. Bluetooth operates very differently than Wi-Fi internally, but it includes the same concepts, such as a MAC address and broadcast radio waves.

Network Architectures

The classic architecture used for coordinating the communication of a large set of computers over a network is called client-server. A single server acts as the single point of coordination of all communication, and the multiple clients never transmit data to one another. The burden of work is on the server, which must be a machine that is provisioned with significant network bandwidth, disk storage, and processing. However, the reliance on a single point of coordination results in a system that is easier to control and manage, i.e., there is little complexity to the clients' operation and design. Figure 5 illustrates this architecture.

Peer-to-peer (p2p) network systems are possible because home computers have sufficient resources, having access to high-bandwidth home internet connections. Peer-to-peer systems allow a group of clients to pool their resources and offer a networked service to each other, even though no single client has sufficient resources to act as a server. The disadvantage of peer-to-peer is an increase in complexity at each peer: each plays the role of a client and a server. The details of how a particular peer-to-peer network operates can be complex for that reason. Figure 6 shows a possible p2p architecture.

Peer-to-peer applications are a popular way of sharing content with other users without relying strongly on a centralized server. Because there often appears to be no central computer in charge, many users of p2p applications believe that they have relative anonymity. While it is more difficult for investigators to examine these systems, they are not anonymous, as the efforts of the recording

Figure 5. A client-server network architecture. Dotted lines represent connections across the internet.

Figure 6. A peer-to-peer network architecture. Dotted lines represent connections across the internet.

industry have shown.²⁷ We discuss applications specifically designed to provide anonymity on the internet, including Tor, below.

Peer-to-peer applications are widely instrumental for the sharing and distribution of files containing copyrighted music, videos, and software, as well as child sexual abuse material (CSAM). BitTorrent is the primary p2p file-sharing

27. A&M Records, Inc. v. Napster, Inc., 239 F.3d 1004 (9th Cir. 2001).

application in use on the internet today. Others include eMule (also called eDonkey), Ares, and Gnutella.

Anonymity and Obfuscation

Whenever a computer uses the internet to directly connect to another computer, its IP address is revealed. To obfuscate their address, one of the senders could use a third party. For example, Alice may communicate to Carol with the help of her friend Bob as an intermediary. In this subsection, we explain the most prominent methods used for obfuscating IP address information.

Open-Access Wi-Fi

The simplest method of obfuscating one's real IP address is to make use of open-access internet connections, such as free Wi-Fi offered by cafés and other businesses, or by libraries and other municipal services. Free Wi-Fi is almost always provided using network address translation (NAT); see section titled “Network Address Translation,” above. An inexpensive Wi-Fi access point providing the connection and the NAT service that might be used by a small business or home typically do not have logs of the device that was provided service. For someone seeking obfuscation from free Wi-Fi, the disadvantage compared to other mechanisms is that they must be in physical proximity of the Wi-Fi. Their image or their vehicle's image may have been caught on security cameras. And some Wi-Fi services require registration via an email address, which can be a lead to start an investigation of illegal activity.

Virtual Private Networking (VPN)

Virtual Private Networking (VPN) services work similarly to hide IP addresses. In this example, we describe how entities can communicate while hiding their IP address. We do this in a manner common to computer science, where entities referred to as “Alice” and “Bob” and others participate in communications.

Alice can hide her IP address from Carol's computer if she sends her communications through Bob's VPN service. Alice's computer connects to the VPN endpoint (also called a VPN concentrator) administered by Bob, and all traffic she sends is encrypted so that it cannot be read or altered by others. Many businesses make use of VPN connections to allow their employees to work remotely. In these scenarios, “Bob” is the company that “Alice” works for. A VPN connection from an employee's home computer to systems administered by the business ensures the communications over the internet are confidential. Furthermore,

such connections can involve credentials that are issued only to the employees, ensuring the connections are authorized.

In other scenarios, “Bob” is a company that sells VPN services as a proxy that offers privacy to users like “Alice” who pay for the service. When Bob’s VPN endpoint receives Alice’s communications, he sends it to Carol’s computer with his own IP address as the sender. Thus, Carol learns the IP address of Bob and not Alice. In these scenarios, Alice trusts Bob with the knowledge that she is communicating with Carol. While Alice has an active communication with Carol, Bob’s VPN endpoint has to keep track of the connection so that return traffic from Carol can be routed to Alice. Once the communication is over—for example, after a single web page is retrieved—the record of the connection can be disposed of. Many commercial VPN service providers advertise a “no logs policy,” which means that the record of past communications is not kept by the VPN service provider. Bob is providing a more secure service for Alice by erasing logs that might be discovered by third parties that seek to monitor Alice’s communications. If Alice’s interest in Bob’s services is to obfuscate her illegal activities, then a no logs policy is similarly advantageous. For example, VPN services are known to be hurdles for investigations into child exploitation.

Anonymous Communication Systems

Several services on the internet were designed to provide stronger obfuscation than free Wi-Fi and VPN services. The Tor Project has created software that is used by volunteers on thousands of computers worldwide. Each computer is called a relay. This peer-to-peer network of relays is called the Tor Network and supports two systems for anonymous communication. The first is Tor Browser,²⁸ which is by far the most prominent system that can be used to browse internet websites without revealing the client’s IP address. The second is Tor onion services, and it is used to prevent disclosure of a server’s IP address. A variation of the approach used by the Tor Project is employed by the Invisible Internet Project (i2p), though it is less popular than the Tor Project. The i2p system comprises a set of relay computers that are distinct from the Tor Project. Freenet is another lesser-used obfuscation service that operates differently from the Tor and i2p systems.

The term “darknet” or “dark web” is often used by popular media to describe services that obfuscate a user’s IP address, but it is a poor word choice.²⁹ The term

28. Roger Dingledine, Nick Mathewson, & Paul Syverson. *Tor: The second-generation onion router*, in Proc. Conf. on USENIX Security Symposium, 2004.

29. This text based in part on “Increasing the Efficacy of Investigations of Online Child Sexual Exploitation: Report to Congress,” Brian Levine, May 2022. NCJ Number 301590, <https://perma.cc/WA8J-SURQ>.

darknet originally referred to the fact that the content made available by these services is not indexed and made searchable by sites such as Google and Bing, hence the content is “dark” and not easily found. It is more instructive to consider the purpose and structure of the services. The Tor Network is designed to thwart the ability to attribute the content of traffic from the user. VPNs, which we describe above, are single-proxy systems for obfuscation. Tor and Freenet are multi-proxy anonymous systems for IP address obfuscation (anonymous systems, for short). Tor and Freenet are peer-to-peer networks, and they are possible because volunteers operate internet-connected computers running the software. Software for Tor and Freenet is free and does not require users to register or identify themselves with a central authority. Consider that in contrast to using a VPN where users typically register with a VPN service provider, likely submitting a form of payment such as a credit card number.

Tor Browser is similar in function to a single-proxy VPN service in that a remote web server can be contacted without revealing the IP address of the Tor user’s computer, as illustrated in Figure 7. Unlike a VPN service, Tor Browser uses three Tor relays in sequence. Communication is encrypted in layers so that each relay knows only the previous and next steps in the chain. The clear internet destination of the communication is known to only the last relay, called an exit node while the exit node does not know the IP address associated with the initial sender. The destination web server is unable to learn the IP address of the user. The guard node does not know the destination’s IP address; the exit node does not know the user’s IP address; the guard and exit are separated by the middle node. Tor relays do not keep logs about the connections formed, and because the service is operated by volunteers it is free. Tor Browser provides anonymous internet connectivity in that it hides the IP address of the user’s computer but does not modify the content sent.

Figure 7. Tor Browser connects a user to a website in a multi-proxy setting.

Tor onion services, previously called “hidden services,” allow for a website (or any server) to hide its IP address from users that communicate with it. The site is behind three relays, awaiting web requests. As illustrated in Figure 8, the requests can come from Tor Browser users only. (A version of onion services is present in i2p, and they are referred to as eepsites.)

Figure 8. Tor onion services connect a user to a website in a multi-proxy setting. Unlike Tor Browser, the IP address of the website is unknown to the user.

Freenet³⁰ is much less popular than Tor, but it is used daily by thousands of users. Freenet provides an anonymous service where users can publish and retrieve files. It cannot be used like Tor Browser or a VPN service to connect to the clear internet. Freenet can only retrieve content that has been previously inserted in Freenet's system by other users, and in that sense, it is akin to Tor onion services. Freenet attempts to prevent attribution of downloads using an approach that is different from Tor; we do not detail its operation here.

Network Identifiers and Third-Party Data Collection

All told, a tremendous number of layered mechanisms allow for the internet, mobile communications, and modern apps and websites to work seamlessly and reliably. Each layer typically makes use of various network names and addresses that uniquely identify a device or its user. The IP address of a device is the most obvious example, but many more are present and often contribute to the evidence in a case. Below we provide a glossary of the more common identifiers.

IP addresses used on the public internet are attributable to a particular internet service provider (ISP) via public records. ISPs are given a contiguous range of addresses in a block, which they can assign to their customers. As described above, it's possible that one address can be shared among many users as part of a NAT setup, whether within a home or business. Often IP addresses are associated

30. Ian Clarke et al., *Freenet: A distributed anonymous information storage and retrieval system*, in *Designing Privacy Enhancing Technologies*, pp. 46–66, 2001, https://doi.org/10.1007/3-540-44702-4_4.

with a billing record that has a street address and credit card information. Logs of the assignment of an address to a customer usually exist, but no law requires that they be stored or retained. For example, many VPN providers do not keep records.

Email addresses are one of the oldest identifiers on the internet. Typically, email addresses are secured by an email provider with a password, and logs of access to the account often exist. It is a challenge to authenticate the true sender of a received email from the email alone. A log of the sending of the email or a copy on the sender's computer is stronger evidence.

Cellular phones have a series of identifiers. These include the following: unique phone numbers, which are assigned by the provider; International Mobile Equipment Identity (IMEI) that uniquely tag a hardware device; and the International Mobile Subscriber Identity (IMSI) that uniquely tags a particular SIM, which is a small card containing tamper-proof electronics issued by the cellular provider and inserted in the mobile device. Typically, providers keep track of all three values (and more) and the calls and connections to cell tower base stations for each device.

Almost all computers are connected to the internet via a shared network at the link layer (see section titled "Networking Layers," above). Wi-Fi and cellular connections are almost always shared with other computers. Wired Ethernet connections are also typically shared. In all these cases, each device on the shared wireless or wired medium is identified by a unique medium access control (MAC) address. While usually globally unique, a MAC address can be changed quite easily by the user and is often not shared beyond the local network.

As users browse the web, the websites they visit store small amounts of information within their browsers. Generally, this information is called a cookie, and more broadly there are many ways for a website to store data on a user's device. The stored information can be useful for the website to reidentify visitors and store preferences. Some mobile phones and some desktop devices are assigned unique advertising IDs (AdIDs) and other identifiers that identify the user's devices across different apps. These values can be cleared easily by the user, but many users do not.³¹

Within some systems, there may be other identifiers that are stored internally to track user activity. For example, web-based systems that require users to log in typically assign each user an internal identifier. The identifier is often a number that is used to look up the user's information in a database. Each action the user takes, which can vary by system, is linked to this identifier. For example, posts in social media systems will be linked to this identifier. The identifier is typically logged each time users perform an activity, from creating the account

31. Keen Sung et al., *Re-identification of mobile devices using real-time bidding advertising networks*, in Proc. ACM International Conference on Mobile Computing and Networking, September 2020, <https://doi.org/10.1145/3372224.3419205>.

to each time they log in, and each post or comment they make. Given some information about the user, a site administrator should be able to retrieve the business information they have collected on the user. The resulting data will vary by what each site has determined to collect and keep.

Most of the identifiers above are assigned or stored by third parties (e.g., advertisers and app platforms), as their purpose is to globally distinguish the user or their device. Thus, it can often be key information in both civil and criminal cases. It is common for these values to be both stored on a device and with a third party. The legal process required to obtain the information of course depends on many factors, including who holds the information sought, whether the information is provided in real time during transit or if it is stored prior to disclosure, and how the information is categorized by law (e.g., content, subscriber information, or other records). Several statutes may come into play here, including the Stored Records Act (18 U.S.C. §§ 2701–2710); Pen Register and Trap & Trace statute (18 U.S.C. §§ 3121–3126); and the federal wiretap act known as Title III (18 U.S.C. §§ 2510–2522). The Department of Justice’s Guide to Searching and Seizing Computers³² is a good resource to step through the application of these laws to obtain the various forms of identifying information discussed here.

Geographic information is a part of many networking systems and apps at various levels of granularity. Global Positioning System (GPS) information is the most accurate type of information. GPS coordinates are determined by devices based on signals received from orbiting satellites. The accuracy of a position can be within tens of feet under perfect conditions. However, tall buildings and other occlusions can reduce the accuracy.

Not to be confused with GPS is the concept of IP address geolocation, which is a method by which the geographic location of a device is estimated by its IP address. Geolocation accuracy varies widely depending on many factors. It can be accurate for IP addresses assigned for a long duration of time to places with a fixed location, for example the IP address assigned by an ISP to a home. IP address geolocation can be inaccurate and misleading if used incorrectly,³³ and it is inherently inaccurate for devices on cellular networks or connected to a VPN service.

The geographic location of a mobile device might be discovered via cell site records kept by cellular providers. As devices roam the cellular network, they attach to radio towers (also called cell sites) that have the strongest signals. Since the towers are in fixed locations, knowing the tower a device was attached to provides information about the device’s location. If several towers are within range of a device, then it is possible to estimate the location more accurately. Specifically, a device’s location can be triangulated among three or more towers. To do

32. Available at <https://www.justice.gov/criminal-ccips/ccips-documents-and-reports>.

33. Cyrus Farivar, Kansas couple sues IP mapping firm for turning their life into a “digital hell,” *Ars Technica*, Aug. 10, 2016, <https://perma.cc/MUZ4-YMFM>.

so requires the signal strength information from the towers, either in real time or as part of a stored log.

It can be instructive to consider the context of each of these identifiers and other information that is a part of typical computer use and internet communications. Dialing, routing, addressing, and signaling information is abundant in network communications. When real-time dialing, routing, addressing, and signaling information is collected, the Pen Register and Trap and Trace Statute may be implicated. *See* 18 U.S.C. §§ 3121–3126. While IP addresses may be considered routing information, many identifiers addressed here are not.

Putting It All Together

A short example can illuminate how many of the technologies detailed above fit together to leave a trail of evidence about a user's actions.

Alice begins her day by checking her mobile phone. She unlocks her phone with a biometric (such as her face scan or fingerprint). She realizes that her phone is disconnected from her home's Wi-Fi and her cellular provider. She connects to her home Wi-Fi (but not her cellular provider) and immediately several apps are active. Her email client retrieves new email messages sent overnight. Other apps send and receive notifications related to social media messages, sales, and promotions. A device worn on her wrist has already synchronized information about her sleep duration with her mobile phone via Bluetooth. From these actions, several companies around the world may have stored records that associate her user accounts with activity from her home's IP address at a specific time. Notably, Alice's home ISP has not changed her IP address in many months.

Before she leaves home, she browses social media and reads the news. Advertisements make note of the device's AdID and IP address. She has allowed her weather app access to her geographical location and both her location and AdID are relayed to hundreds of third parties who bid to show her an advertisement.

As she leaves home to go to the store, she realizes that she needs to connect to her cellular provider and turns on the cellular connection, possibly by turning off airplane mode, which disables the cellular connection for flights. A record now exists of her device's association with a specific cell site. As she drives to work, the series of cell sites that her mobile device connects to is recorded by her provider. Her navigation app shows her more advertisements; the AdID is the same as when she was home even though her IP address has changed.

She enters a store, and her phone connects to the Wi-Fi. She purchases some items on credit cards stored on her phone and Bluetooth.

During this short excursion, she was captured in videos taken by her own front door camera and the store's cameras. A neighbor down the street has a camera that captures her car drive by. Her financial transactions are stored on her phone, at the store, and with the credit card company. She has sent text messages

on several apps providing some context to her trip; these messages are on her phone, stored in the cloud, and on friends' phones. A fitness device captures aspects of her movements.

Because she shares access to her mobile device with no one, there is reason to believe the messages are truly authored by her, and that other aspects of the records are accurate. The fact that the records are stored by many third parties also speaks to their accuracy and integrity.

Investigating Network Traffic

Investigators can acquire evidence relevant to civil or criminal litigation by examination of network traffic. In some cases, investigators can, with permission from a court, directly monitor the traffic being sent over a wire or a radio link and capture a recording. In others, they participate in ongoing network communications and, as participants, receive the network traffic shared among all participants.

Network engineers and administrators sometimes need to observe network traffic to help understand and debug network issues. For this, they use one of many tools that can read, record, and interpret all traffic coming across some communications link. One such tool is named Wireshark, which is freely available and commonly used. Wireshark can collect packets traversing a link, record them in a commonly used format known as a packet capture (or pcap) file, then analyze the traffic contained in the file. This collection provides a complete record of what was sent and received, including the participant addresses and data within the packets.

Investigators gathering information on network communications can use the same tools and methods to record and analyze network traffic. Given access to a network link, investigators can record the network traffic and then analyze it to determine what communications took place during the observation period. This can reveal the addresses of the parties that were using the link for communication and the data that were being sent between them. Such collection may be lawfully done when an investigator is a party to the communication. In such cases the investigator can record all network communications sent to their device, as they are one of the intended recipients. This is known as consensual monitoring.³⁴ Another relevant exception to the federal wiretap statute that authorizes the collection of network traffic without a wiretap order is known as the computer trespasser exception, which authorizes law enforcement to collect the communications of a computer trespasser transmitted to, through, or from the protected computer if the owner or operator of the protected computer authorizes the collection.³⁵

35. *Id.* § 2511(2)(i).

Investigating Peer-to-Peer File-Sharing Systems

As described above, investigators can gather evidence from public activity conducted on peer-to-peer networks. Different p2p networks have different utility to users; some, for example, exist to share files between users, others to facilitate cryptocurrency operations. In general, anyone can choose to join a p2p network, and the network makes use of their computer's computational power and network bandwidth and includes it in the operation of the network. As part of the network, each computer processes data voluntarily sent by other computers in the network. Often, the data can include evidence of illegal activity.

For example, p2p file sharing networks allow users to exchange copies of files; in some cases, they support searching for particular files as well. Well-known p2p file sharing networks include BitTorrent and Gnutella. Commonly, the files being shared are subject to copyright. In other cases, the files being shared can contain child sexual abuse material.

Civil or criminal investigations on these networks are aided by the fact that normal operation of the p2p network results in peers sharing information voluntarily with other peers. Any investigator who connects to a p2p network as a user will thus be able to see some of the activity that is happening on the network. For example, peers often publicly advertise the files they are sharing or seeking to obtain. Often files are identified on file sharing networks by the hash value associated with the file. The file sharing network is designed to allow a user to then download the shared file. When an investigator has joined the file sharing network as a user, they can then download that file directly from a particular peer to confirm possession and sharing of that file. As part of that download, the investigator's computer will see the network address information, which can be used to later identify the user.

All this activity occurs publicly as part of the normal operation of the network. No special access is required by the investigator. Courts considering civil or criminal cases involving p2p networks have consistently held that the information shared on the p2p network is publicly available, including but not limited to the user's IP address and shared files.³⁶

Investigating Anonymous Communication Systems

Anonymous systems were designed with the intention of providing privacy for persons who are vulnerable and require protection, such as journalists. However, for decades, anonymous systems have been heavily leveraged by those who

36. See, e.g., *United States v. Borowy*, 595 F.3d 1045 (9th Cir. 2010).

commit crimes such as child sexual exploitation,³⁷ creating malware botnets,³⁸ and selling illegal drugs.³⁹ Investigations of anonymous systems make use of a variety of techniques that are tailored to the operational details of each system.

Users associated with criminal Tor onion services have been identified by law enforcement when the criminal sites and information contained on those sites were seized by law enforcement. For example, in 2015, the FBI obtained a search warrant to install computer code on the seized child exploitation onion service named “Playpen.” When users visited the site, the computer code inserted and executed code on the visitor’s computer, which then conducted a remote search of the user’s computer then sent the true IP address of the user to the FBI (see section titled “Legally Authorized Intrusions,” below).⁴⁰ In 2017, the Dutch National Police obtained judicial authority to seize and take control of the “Hansa marketplace,” an onion service operating as a marketplace for illicit goods and services including drugs, firearms, and cybercrime malware. While operating the online marketplace, law enforcement was authorized to monitor the criminal activity occurring there, which led to the collection of information on high-value targets and delivery addresses for tens of thousands of orders.

Investigations of users of the Freenet anonymous network are based on the network traffic that travels between neighboring Freenet peers.⁴¹ As described in the section titled “Network Architectures,” above, Network Architectures, users of the Freenet system can retrieve content that has been previously uploaded by others into the network. Users direct their Freenet software to request a desired file from neighboring peers, one piece at a time. Neighbors of the original requesters either provide the requested file piece, or they relay the request to one of their neighboring peers. The relayed request contains information about

what is being requested along with other distinct signaling information necessary to operate the network as designed. Careful statistical analysis can be done to distinguish whether a neighboring peer requesting content is the peer that made the original request or merely a relayer.⁴² When law enforcement joins the Freenet network, it receives requests for illicit material just as any other user of the Freenet network would. (Notably, as the investigator is the intended recipient of all information used in the analysis, the investigation is not similar to the techniques and legal authorizations relevant to the Playpen cases described above.) Using statistical analysis, law enforcement can then calculate the probability the neighboring peer sending the request for illicit material is the original requester and can move forward with an investigation.

Computer and Network Security

In this section, we provide an overview of computer and network security principles to help judges understand the nature and extent of cybercrime, including hacking, malware, and other types of cyberattacks. We provide an overview of privacy issues to aid judges in determining whether data breaches are the result of insufficient security measures and, if so, whether they constitute a violation of data privacy laws. These principles might also arise in intellectual property cases when considering the theft of trade secrets or other work, or in national security matters to understand how attacks on critical infrastructure can threaten the nation.

The classic definition of security has three aspects: confidentiality, integrity, and availability. Confidentiality refers to preventing access to information by those who are not allowed to see it or know it. Integrity refers to the reliability of data. In some cases, this refers to ensuring that the accuracy of data is maintained; it can also refer to digital data not being altered by those who are not allowed to do so. Availability means that we can access systems and data when required and that data cannot be destroyed by those not allowed to do so.

Each of these fundamental aspects relates to some policy that defines who is allowed to perform some action, like accessing, changing, or deleting data. An important aspect of digital security is therefore being able to prove who you are so that access to the appropriate actions can be granted. This is called authentication. Additionally, the idea of nonrepudiation means that users cannot deny their actions and that they can be held accountable for them.

It is worthwhile to note that the desired security aspects depend on the situation. For example, the government would like classified intelligence documents to remain confidential, unaltered, and available. Confidentiality is not required, though, for public governmental websites, though it would be desirable for them

42. *Id.*

to remain accurate and available. Some instant messaging programs, notably Snapchat and Signal, have messages that are automatically deleted after some period and thereby gain confidentiality at the cost of integrity and availability.

It is common to approach assurance as a cycle with at least three steps (though more detailed models exist): systems are *protected*; mechanisms then attempt to *detect* when protections have failed; and then people *respond* to the event. The response can include upgrading protections, thus completing the cycle. This cycle is common in many security situations. For example, we protect our homes with locks and fences; detect when those have been bypassed by cameras, barking dogs, or alarm systems; and then recover from incidents by summoning the police, relying on insurance, or getting better locks.

It is important to be aware that detection, like protection, is an imperfect process. Most people are familiar with this in the context of car alarm systems. Almost no one responds to car alarms because most often it is a false alarm; the alarm sounds even though no one is breaking in. This is called a false positive. Similarly, sometimes cars get stolen without the alarm going off, which is called a false negative. All detection systems have some rate of false positive and false negatives.

In addition, detection systems suffer from the base rate fallacy, which occurs when the thing a system is trying to detect is very rare compared to the number of events. An example might be a system to differentiate terrorists from normal passengers on airline flights. Assume there might be 1,000 terrorists who fly every year, and we have a system that can detect them with 99% accuracy. This system can also identify normal travelers with 99.9% accuracy, and in the United States there are about 400 million travelers a year. (We note that these are exceptionally accurate systems; it would be quite difficult to reach these numbers in practice.) This system would correctly identify 990 travelling terrorists a year ($1000 * 0.99$), but it would also falsely identify 400,000 normal passengers as terrorists ($400,000,000 * (1 - 0.999)$). The problem is that only about 0.25% ($990 / (400,000 + 990)$) of the resulting alerts are correct; the sheer number of misidentifications of normal travelers dominates the alerts.

The resulting low positive predictive rate, which represents what part of alarms are useful, might not be a problem depending on the circumstance; it might be this initial screen is fast and inexpensive and that a more costly test is used on the positive results. A risk, however, is that humans who monitor the alerts will become habituated to the large number of false alarms and miss correct ones.

Privacy

Privacy online differs from security because privacy is concerned with what information about you others might possess and share; security is primarily concerned with protection of your own data. The advent of online discourse and commerce has allowed a variety of entities to collect, store, and share information about users

that visit their sites. Advertisers and others are able to trace an individual across multiple sites and build a profile of that user and their preferences and interests. They can then use this profile for many purposes, including trying to identify items to promote for sale, or influencing political views and activities. There are many technical ways to identify users across sites; even sophisticated users who try not to be tracked can fail.

Online privacy is addressed in numerous laws and regulations; however, individuals often agree to the disclosure of their data to others by agreeing to the terms of use before using software, websites, or apps. Class actions have arisen when companies are accused of disclosing data in violation of their terms of use agreed upon by the users. For example, in 2022, Facebook's parent company, Meta, agreed to pay \$725 million to settle a class action privacy lawsuit where plaintiffs alleged in part that Facebook shared user data with business partners without disclosing such sharing and failed to restrict and monitor third parties' use of Facebook users' sensitive information.⁴³ In addition, a company's computer systems may be hacked, resulting in the release of private information that users never expected nor agreed to have released.

Sometimes poor cybersecurity can lead to violations of privacy laws. For example, in 2017, Equifax experienced a breach that resulted in the loss of personal and financial information for nearly 150 million people owing to its failure to fix a vulnerability in software associated with one of its databases. The Federal Trade Commission (FTC) filed suit against Equifax alleging violations of the FTC Act, 15 U.S.C. § 45, and the Safeguards Rule codified at 16 C.F.R. Part 314 issued pursuant to the Gramm-Leach-Bliley Act (GLB Act) by failing to reasonably secure the sensitive consumer personal information held in their computer networks. The parties reached an agreement resulting in a stipulated order for a permanent injunction and monetary judgment. The injunction prevented Equifax from making misrepresentations regarding the protections of personal information, ordered the creation of an information security program and third-party assessments of the information security program, and ordered prompt reporting of any future unauthorized access to a consumer's information. The monetary judgment totaled \$575 million, with the majority of this judgment used to provide direct relief to consumers by compensating for related harms and providing extensive free credit monitoring.

Authentication

An important part of computer security is accurately identifying a user so that the correct security policy can be applied to their actions. In particular, evidence

43. Facebook, Inc. Consumer Privacy User Profile Litig, 3:18-md-02843-V (N.D. Cal.).

of user actions might be stronger or weaker depending on what form of authentication was used. A password or device might be stolen and reused; biometric data might show a person was present.

What You Know (Passwords)

The most common and least expensive form of authentication is something you know, in the form of a password that is shared between the user and system. Passwords have many vulnerabilities, however. Anyone who knows a password can use it. An attacker can use an automated process to try likely passwords to gain access to accounts—and in fact do so commonly. Users also often reuse passwords across accounts. If one account is compromised and the password stolen, the same password can be tried at other sites to see if it works there. Such password reuse attacks are also common.

Some organizations use a password recovery process that has the user answer questions about themselves when the account is created. These questions are often used as an alternative to a forgotten password. The information used in questions is sometimes guessable, and an attacker with time to research their subject can often answer them. Compromising less-secure systems by guessing passwords or using such password recovery systems to gain access to a computer without authorization can amount to a crime under the Computer Fraud and Abuse Act codified in 18 U.S.C. § 1030. In 2008, a hacker used the password recovery system to gain unauthorized access to the personal email account of then-Vice Presidential candidate Sarah Palin. He was charged and convicted of violating 18 U.S.C. § 1030(a)(2).⁴⁴

Passwords are also vulnerable when an attacker compromises a site and obtains the database of user passwords. In the worst case, those passwords are not encrypted and can be read directly. In other cases, the passwords are protected by hashing, hiding the original password. An attacker who acquires the hashes can try computing the hash of many different possible passwords to see if they match any of the stolen hashes; if they match, the attacker then knows the password. Using a number of graphics processing units, attackers can create billions or trillions of guesses per second. Passwords that are not sufficiently complex are thus easily obtained. There is also an attack against hashed passwords and other forms of encryption called rainbow tables. This is a method of pre computing many possible passwords or keys, which are stored in a table, reducing the time required to break passwords using brute force at the expense of the storage and pre computation.

Security experts recommend the use of a password manager. This is software that creates unique and complex passwords for every account. A user can create

44. Press Release, U.S. Dept. of Justice, Tennessee Man Sentenced for Illegally Accessing Former Governor Sarah Palin's E-Mail Account and Obstruction of Justice (Nov. 12, 2010), <https://perma.cc/XPH7-EBH3>.

and remember one complex password and use that to access all the stored passwords.

What You Have (Physical Tokens)

Possession of a unique item can also identify a user. Most often, these are used in conjunction with a password so that a stolen item alone is not sufficient for identification. Common mechanisms require the device owner to provide a response to some challenge, to provide a limited-time token to log in, or to perform a computation with a cryptographic key.

Mobile phones often are used for challenge response authentication. When logging into a site, the user might be sent a text message and be required to enter the code that it contains to prove possession of the device. There are similar programs, such as Google Authenticator, that run on a phone that provide a time-based code that changes frequently; before mobile phones were common, employers often provided small, dedicated devices that displayed this changing code on a small screen to provide the same functionality. Other devices include those that contain a cryptographic key. These include USB devices or smart cards that are inserted into a computer and that perform operations on the key embedded in the device.

What You Are (Biometrics)

Users can be identified by their physical characteristics. This is called biometric identification. There are a wide variety of measurements and observations about a person that can be made to determine if they are someone who has been seen by the system before and uniquely identified on that basis. The most common methods are facial recognition and fingerprints, but many others can be used as well, including retinal or iris scans, voice recognition, and hand shape. Some systems include a liveness check to ensure that the user is alive; this limits the ability of an attacker to murder the user or steal a body part for authentication, or to use a photo or fake finger to enter the system.

Biometrics is a detection problem. The system is trying to determine if a particular user is someone known to the system. As such, it does have a false positive and false negative rate, though modern systems can be very accurate. Biometrics also have additional error rates, known as failure to capture and failure to enroll. In the first, the sensor sometimes does not obtain adequate information to make a determination. In the second, it is possible that some users may be unable to use the system. As an example, it is not rare that some people are unable to use fingerprint recognition. People who have no easily measurable fingerprint ridges either owing to physiology, accident, or manual labor can fail to register on the system.

Requiring subjects to unlock devices using biometric security is considered distinct from requiring disclosure of passwords. Courts have generally allowed law enforcement to require individuals to provide biometric identifiers such as fingerprints or facial recognition to unlock a device, as they are considered physical evidence rather than testimonial evidence.⁴⁵

How Intrusions Happen

It is unfortunately common for computer security systems to be compromised and data to be accessed, modified, or stolen. A variety of actors take part in this process, each with their own motivations, goals, and abilities that affect how a breach occurs.

Types of Attackers

In the simplest case, security breaches happen because of mistakes by well-meaning but perhaps ignorant users or workers. They do not intend to create a problem, but sometimes can be enticed to do so by an attacker who uses social engineering. This is a technique that exploits human interaction to get a user to provide access to systems or information through fraud. Technical attackers have more sophisticated tools. One aspect of computer intrusion is that an expert can determine how to exploit a flaw in software and write a program to do so; one doesn't need to be an expert to run that program. The experts who are able to write tools to exploit flaws are often referred to as system crackers or hackers. This activity is not inherently illegal unless those tools are used to commit crimes. A black hat hacker typically has malicious intent and wants to break into systems to steal information or resources, or to extort the system owner, and may be involved with organized crime. Conversely, a white hat hacker finds exploits but notifies the software developer and does not exploit them; many companies have a bug bounty that pays rewards for these exploits so they can be fixed before they are a problem. In between these is a gray hat hacker who might not always act ethically; they might sell an exploit to others to use though they do not do so themselves. There is a large market for exploits. At the time of writing, a remotely exploitable but undetectable attack on an iPhone that gave the highest level of access was worth over \$1.5 million; it is unlikely that a bug bounty from Apple would prove as lucrative.

While companies like Google have dedicated white-hat teams, many of the best resourced attackers are those that are part of nation-states. Most large nations

45. *State v. Diamond*, 905 N.W.2d 870 (Minn. 2018).

have their own well-funded intelligence services that seek to penetrate other nations' systems for intelligence gathering.⁴⁶ These services have capabilities beyond any commercial organization, and they can exploit a variety of attacks against hardware and software in coordinated and sophisticated ways. Often, they gain access to computers and networks and can keep a presence in there even if they are discovered; these are referred to as advanced persistent threats. Smaller nations turn to commercial suppliers of online intelligence tools; these tools are still often very effective, particularly against citizens being surveilled. More recently, tech companies have started suing these companies.⁴⁷

The most damaging attackers might be insiders. These are users who are given some trust within an organization and who have access to some or all internal systems, then abuse that trust to conduct attacks. Sometimes they do so after being recruited by other nations; other times they do so for financial gain or because they are disgruntled.

Types of Intrusions

There are a wide variety of ways to intrude on a computer system, most of which are outside the scope of this guide. As a general overview, though, most attacks occur through stolen authentication credentials or technical flaws in systems or software.

Attackers gain access to user credentials in a variety of ways. The easiest is to trick the user into providing credentials by getting them to visit a fake website that will capture what the user enters; hence the large volume of phishing emails and texts that are sent every day. At other times, attackers are able to find leaked user passwords that are posted online and then try them at other websites. Sometimes other credentials, such as for cloud computing services, end up stored online but without proper confidentiality settings and are later discovered and abused.

Attackers are also able to gain access to systems by exploiting flaws in the running code. A general approach for this is for the attacker to find a flaw in the system in which attacker input gets interpreted as computer code and executed, or to find input that causes an unanticipated effect. The techniques for this vary depending on what kind of software is running and what input the attacker can provide.

Locating and identifying attackers who conduct remote attacks over the internet can be challenging or impossible. These attackers can try to hide their

46. U.S. Dept. of Justice, "Two Chinese Hackers Working with the Ministry of State Security Charged with Global Computer Intrusion Campaign Targeting Intellectual Property and Confidential Business Information, Including COVID-19 Research" (Off. of Pub. Affs., Nov. 27, 2023), <https://perma.cc/MJS6-QMD7>.

47. Apple Inc. v. NSO Grp. Techs. Ltd., 5:21-cv-9078.

location. They might use an anonymous network service like Tor, or they might intrude on other computers and use those to direct attack traffic through; the eventual victim only sees traffic coming from these intermediate computers and not from the computer originating the attack. Botnets, described in the malware section below, are used to facilitate this.

Legally Authorized Intrusions

Not all computer intrusions are illegal. The law criminalizing unauthorized access to a protected computer includes an exception for authorized law enforcement activity (*see* 18 U.S.C. § 1030(f)). However, this statutory exception does not address Fourth Amendment protections. Thus, when law enforcement seeks to gain access to a computer in this manner to collect information protected by the Fourth Amendment, they often obtain a search warrant. When executing this type of search warrant, law enforcement might overcome the computer's security using techniques similar to those a hacker might use, just as when law enforcement executes a court-authorized search of a home utilizing lock-picking tools similar to those used by a thief. Law enforcement might identify a technical flaw to which the systems are vulnerable; create or purchase an exploit that can take advantage of the vulnerability; deploy the exploit to gain access to the systems; then deploy a payload that will gather the authorized evidence; and collect that evidence at a law enforcement-controlled computer elsewhere on the internet.

When the location of the target computer is concealed through technological means, such as through obfuscation provided by an anonymous network, Federal Rule of Criminal Procedure 41 provides a court in the district where activities related to the crime may have occurred the jurisdiction to issue a warrant authorizing law enforcement to remotely search a computer located outside the court's district. Criminal Rule 41(6)(A) was added to the federal rule governing search warrants in 2016 and eliminates the jurisdictional challenges that occurred across the nation when the FBI obtained a single search warrant in the Eastern District of Virginia for the deployment of code from a seized child exploitation website called "Playpen" operating on the Tor network. Under this search warrant, the code was deployed from the government-controlled "Playpen" website to the computers visiting the site. This code conducted a limited search and forced the user's computer to reveal its true IP address to the FBI. Prior to this remote search provision in Rule 41, it was unsettled which court had the appropriate jurisdiction to issue such a search warrant. This question is now clearly resolved by this remote access provision to Rule 41.⁴⁸

48. Some of the federal cases addressing this jurisdictional question include *United States v. Henderson*, 906 F.3d 1109 (9th Cir. 2018); *United States v. Horton*, 863 F.3d 1041 (8th Cir. 2017);

Malware

Malware is malicious software that is designed to operate without the knowledge or consent of the computer user. It is often useful to differentiate how malware gets spread or placed on a computer from what it does once it is there. There are a wide variety of mechanisms used to get malware installed, and malware can have a variety of effects, including targeted ones that are specific to a victim. For descriptions of various types and components of malware, see the Glossary of Terms.

It is worthwhile to note that there is a market for access to computers infected with malware. Attackers will create a botnet by infecting many computers with malware that allows continuing access—these infected computers are called bots—and then install other malware on behalf of others who pay for access to the compromised computers. For example, in one case a Russian-born cybercriminal claimed on online forums that he could control up to 500,000 infected computers at one time.⁴⁹ When the threat is large and difficult for individuals to mitigate, courts have approved government efforts to enter compromised machines and remove the malware that was part of the botnet.⁵⁰

It is common for computer users who are accused of a computer-related crime to claim that they are innocent of it, and that any evidence is a result of malware installed by some outside actor. This is not an impossible occurrence, especially for a nontechnical user targeted by someone more technically sophisticated. In these cases, however, a forensic examiner should be able to determine if this is likely to have occurred by looking for evidence of malware or correlating user activity with evidence about the time of the alleged criminal activity. Often, this defense is undermined by robust evidence of user interaction with the computer or evidence during the time in question.

A failure to implement reasonable security measures to protect against a foreseeable risk can lead to civil liability under a claim of negligence.⁵¹ For a plaintiff's suit to survive a motion to dismiss, the court must consider if the complaint failed to establish one or more of the elements of a negligence claim, including causation between the defendants.⁵² If the complaint is found insufficient, courts will often grant leave to amend the complaint.

Forensics and Digital Evidence

As stated in the Introduction, many legal issues involve facts and evidence related to software, computers, networks, and digital information, all of which have become ubiquitous in our personal lives, as well as in commercial and government processes, products, and services. For example, digital evidence is an aspect of almost every criminal investigation.⁵³

Forensics is the scientific investigation and formal presentation of evidence that supports or refutes an investigative hypothesis that explains an event of interest. When the investigator follows a repeatable, structured process for gathering evidence and uses strong inductive reasoning, forensics is a science rather than merely a set of techniques that recover data. A successful hypothesis has supporting evidence that explains allegations as a series of actions, events, identities, or intentions, and does not have strong countervailing evidence. Digital forensics is focused on evidence related to computer and network systems.

Evidence should be gathered following standard techniques that are defined ahead of the crime and accepted by the scientific community. The investigator attempts to identify sources of possible digital data, copy such data, and preserve its integrity; extract relevant evidence from the collected data; and report the results of the investigation.⁵⁴ These stages transform identified artifacts into evidence that speaks to facts, or that link data to a scene or person through individualization or can speak to the intentionality of a person.

Recovery of Digital Evidence

A computer comprises many systems: file systems, databases, networking, and more. Each system is designed to present a simple view of a complex set of interactions.

For example, the networking system hides a large amount of work that goes into presenting a web page. Similarly, the file system presents your files to you without the details of how files are actually managed. The operations that are hidden from the user by each system are designed to operate efficiently, and often efficiency means leaving artifacts behind.

This is particularly true when files are deleted, because the quickest mechanism for the file system is to simply mark the file as deleted, then to later

54. Keith Inman & Norah Rudin, *The origin of evidence*, 126 *Forensic Sci. Int'l* 11–16 (Mar. 2002), [https://doi.org/10.1016/s0379-0738\(02\)00031-2](https://doi.org/10.1016/s0379-0738(02)00031-2).

overwrite the file when space is needed. This process is similar to writing with a pen. It is easier to cross out mistakes from sentences in a letter than it is to re-copy the entire letter’s text onto a new sheet of paper, but the old writing might still be legible.

The file system presents to the user a simplified logical view of the file system that doesn’t include all the information available to the file system itself. In fact, the goal of every system is to present a complex service as something simpler via an interface. One analogy to this process is dining at a restaurant. The menu and the waiter presented to the customer are an interface that can be used to order food from the kitchen. Most kitchens are chaotic and messy, yet the plates that arrive at the table don’t show it. It is the goal of the waiter to present such an illusion, and any computer interface is no different.

Figure 9 illustrates the user’s view of the file system. The interface allows the user to create files, and storage space is allocated accordingly. The user can issue a command to delete the file, and storage space is then unallocated. File modifications can occur through overwriting the same storage space with new data, finding space for additional data, or deleting the existing file and then creating a new file with the same name. Users have no information or influence regarding where a file is stored on the storage medium—that is a complication handled by the file system.

Figure 9. Left: A user’s view of the file system interface. Right: The true life cycle of data and files in a file system.

For forensic investigators, the life of data in storage is not so simple. Figure 9 illustrates the internal life cycle of files, data, and storage on a file system, beginning with data given to the file system by some application, such as a word processor. In Step 1, a file is written to a specific allocated block *x*, and we say that it contains active data. When the user or application issues the command to delete the data, the process moves to Step 2, where the storage block is unallocated. The data remains present in storage, but we say it is expired; that is, the data cannot be recovered through the file system's interface to the user, but it is retrievable by an investigator with direct access to the disk. Finally, once the same block is allocated to new data, the overwritten portions of the old data are removed and unavailable to the investigator. For decades, forensic experts have identified and examined many other types of digital evidence available from computer systems, including desktops and laptops, smartphones, wearables, IOT devices, cloud systems, and more. The same principles as above apply: data are stored on these devices because the data's presence increases usability, performance, and security; data are often copied between and stored on multiple systems because of interactions among parties; and such data often remain available for recovery even after deletion.

Relatedly, it is notable that courts have serious concerns when digital evidence is intentionally destroyed. For example, in *Burris v. JP Morgan Chase & Co.*,⁵⁵ a whistleblower protection case was dismissed with prejudice because of a plaintiff's systematic destruction of electronically stored information (ESI). The court appointed a computer forensic examiner who reviewed the plaintiff's electronic devices and discovered evidence that ESI had been systematically deleted. In addition, two software tools that advertised their ability to overwrite free space, making it impossible to recover deleted data, were found on plaintiff's electronic devices.

Computer Science from the Perspective of Federal Rule of Evidence 702

When considering experts for testifying on computer science matters, the factors elucidated by the Supreme Court in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*⁵⁶ and its related cases⁵⁷ apply well. As the Supreme Court explained, a trial court's evaluation of the underlying reasoning supporting an expert's testimony and the validity of the scientific methodology they use should be "flexible . . . and its focus

55. 566 F. Supp. 3d 995 (D. Ariz. 2021).

56. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993).

57. See also *General Electric Co. v. Joiner*, 522 U.S. 136 (1997); *Kumho Tire Co., Ltd. v. Carmichael*, 526 U.S. 137 (1999).

must be solely on principles and methodology, not on the conclusions that they generate.” The factors established in *Daubert* to be used in a court’s inquiry should be inclusive of:

- “*whether the theory or technique in question can be (and has been) tested.*” If a method is testable, then there are demonstrable, controlled scenarios where the test can result in positive and negative results.
- “*whether it has been subjected to peer review and publication.*” Peer review is the process by which a paper is evaluated by qualified scientists working in the same field as the subject of a submitted paper. In many fields outside of computer science, journals are peer reviewed and conferences are not. However, in computer science, not only are conferences almost always peer reviewed, but they are also often considered the most prestigious venues for publishing (implying a paper’s results have been more carefully evaluated by the reviewers).
- “*its known or potential error rate and the existence and maintenance of standards controlling its operation.*” Ideally the methodology supporting testimony has a quantified error rate based on data independent of the case in front of the court. Notably, there is no requirement that the error rate be at a specific level, only that it be known to the court.
- “*whether it has attracted widespread acceptance within a relevant scientific community.*” Methodologies are often based on known approaches that already appear in textbooks, previous peer-reviewed publications, or reports on best practices from established organizations. Evidence and facts should be based on the results of practices and protocols that are written down in lab manuals ahead of an investigation. This approach often has the advantage of avoiding the appearance of bias. The training and methodologies used by practitioners and examiners should have been developed by experts who have applied a scientific methodology.

In computer science, two international societies stand out as having a strong track record of overseeing high-quality conferences and journals: the Association for Computing Machinery (ACM) and the Institute of Electrical and Electronics Engineers (IEEE). Other high-quality publication venues and societies certainly exist.

These factors were codified in a series of amendments to Federal Rule of Evidence 702 in an effort to clarify their application.⁵⁸ Assessment of admissibility of computer science evidence follows an analysis that includes the *Daubert* questions discussed above: Are the methods testable and have they been tested? Has peer review been employed? What is the quantified error rate? Has there been

58. For a discussion of Federal Rule of Evidence 702, see Liesa L. Richter and Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual.

widespread acceptance? Whether a particular witness is qualified per the expert's scientific, technical, or other specialized knowledge—codified as Federal Rule of Evidence 702(a)—is discussed presently.

Experts in Computer Science

Overall, determining if an expert is qualified should be based on criteria specific to the case at hand. For cases involving computers and computer science, an appropriate expert is one who has experience and training relevant to the particular aspect of computer science involved. By analogy, consider a case that involves accusations of malpractice related to heart surgery—surely a podiatrist is the wrong choice to serve as an expert witness. Like medicine, computer science is a broad field and experts have specialties. These specialties are myriad: networking, security, machine learning, databases, algorithms, to name a few. Moreover, the field is both a science and an applied discipline. A person with years of research experience may not necessarily be able to speak to the complexities of a deployed production system; and likewise, years of applied experience does not necessarily imply an understanding of scientific fundamentals, nor a deep and rich understanding of the limits and consequences of applying techniques and methods.

However, speaking broadly, there are many ways to evaluate whether a particular person is a qualified expert in computers or computer science. These include asking if the candidate has academic degrees in computer science or computer engineering from well-known universities and colleges, awards for high-quality papers, advanced member grade status from professional societies (such as being a “Fellow” of the ACM or IEEE), a high count of publications in peer-reviewed conferences and journals, and a high count of citations to those papers (though citation counts vary in magnitude across subfields of computer science). Just as notable is a record of years of experience in a computer science–related role with reputable companies, government agencies, and other institutions.

Trial courts are considered the gatekeepers of expert testimony, per *General Electric v. Joiner*. For example, in *Resnick v. United States*,⁵⁹ the court found there was no right to call a computer expert to rebut the government's expert witness. In that case, the defendant missed the deadline to file notice of an intended computer expert. The court found the defense counsel's questioning of the government computer expert sufficient and not evidence of ineffective assistance of counsel.

59. 7 F.4th 611 (7th Cir. 2021).

The Quality of Forensics and Digital Evidence

Forensic investigations are at their strongest when conclusions are drawn via inductive reasoning. In this type of reasoning, a generalization or model of what is expected to occur is created based on what has been observed in repeated observations. Ideally, these observations have been made independent of the facts of the case. Other aspects related to *Daubert* should also be present, as listed above: the study of observations should make use of well-known methods, and the conclusions should be published in a peer-reviewed scientific venue. The reasoning should involve a falsifiable hypothesis, and the observations should provide for a known, quantified error rate.

Inductive reasoning is strongest when hypotheses are verified by independent parties. Investigators rely heavily on validation studies that perform repeated and precise tests on equipment and software to determine what can be said with assurance about evidence. Validation reports are published by government agencies, such as the National Institute of Standards and Technology (NIST),⁶⁰ by industry and academic researchers in peer-reviewed journals and conference proceedings, and by professionals who engage in testing of their tools.

Direct evidence proves a fact without inference, such as a voluntary confession would provide. Digital artifacts are often circumstantial evidence of an event or fact, but that status should not be viewed pejoratively. Direct evidence from witnesses is not always reliable. People do not have perfect perception or memory. People have personal biases and can be paid or otherwise motivated to give false testimony. Confessions can be coerced in not very subtle ways. In fact, most evidence at a crime scene is indirect evidence. For any crime for which there are not witnesses, the case must be circumstantial.

Digital evidence is typically modifiable.⁶¹ For that reason, one might conclude that digital evidence should not be considered as absolute fact when it is found—but in fact it is no weaker than other types of circumstantial evidence. DNA evidence has a similar problem: it's easy to plant DNA evidence at a scene—a few skin cells will do it.

Further, indirect evidence can be stronger than direct evidence if there is other corroborating evidence—a notion that Locard's Exchange Principle speaks to. For example, let's say that it has been alleged that John committed a crime against Jane, and John claims to not know her at all. Investigators find that John's web browser has a history of pages he has visited recently, including the text and images from those pages. Jane's public webpage is found in that history cache, and it is used as indirect evidence that he knew Jane before the crime took place. John's

60. NIST, Computer Security Resource Center, <https://perma.cc/4UXM-B6E8>.

61. Forensic practitioners record and report cryptographic hashes of collected material to help identify any modified data and as a best practice should take care not to accidentally modify any data.

browser will record when exactly John last visited Jane's page, and such facts can be corroborated by examining the web server that hosts Jane's webpage. Furthermore, other logs at John's internet service provider may be able to confirm indirectly that his computer was connected to the internet at the time the page was viewed. Logs from John's email server may indicate he checked or sent email at the time when the webpage was retrieved; if he admits to keeping his account and password secret from others, then the email server logs indicate he was at the keyboard at the time.

E-Discovery

Digital forensics is often part of an adversarial investigative process in which an investigative hypothesis about a user's actions is confirmed or refuted based on evidence collected from electronic devices. The assumption is that an individual under investigation might try and conceal data about their actions and authorities need to act to collect data before it is lost or destroyed.

E-discovery differs from forensics in that it is part of a civil discovery process. While forensics techniques might be used in some specific circumstances, such as making a preservation request for a particular user's devices to obtain data and metadata from them, in general e-discovery will require parties in a civil action to produce relevant material they already have in an electronic form to allow faster and less expensive review. Normal discovery rules apply; each party is bound to produce material responsive to the case, but each party decides what materials are responsive rather than the other party having access to all data and making that determination, which can clearly be intrusive.

E-discovery allows for faster and cheaper review than paper. Documents can be searched using a text retrieval system that allows searching for terms. Additionally, supplying documents electronically allows the document metadata to be used. This can include dates when documents were created; dates and times for emails and other messages; and other relevant information that can be searched as well.

There are a variety of commercial solutions for uploading, managing, and reviewing documents. The Sedona Conference has published documents to help guide judges through the e-discovery process.⁶²

Glossary of Terms

This section contains definitions of terms from the text and others that might be legally relevant.

access point (AP). A hardware device that provides wireless internet access to nearby devices over Wi-Fi.

advanced encryption standard (AES). The U.S. government standard for shared-key or symmetrical encryption for all except classified information. This protocol replaced DES in 2005. It allows use of keys of 128, 192, and 256 bits, which are large enough to resist brute-force attacks.

advanced persistent threats (APT). A sophisticated and targeted cyberattack carried out by highly skilled and well-resourced attackers who seek to gain unauthorized access to a network or system for an extended period of time.

adware. A term for legitimate software that is supported by advertisers; can also be malware that illicitly serves advertising to computer users. Unscrupulous attackers get paid by an often-unsuspecting advertiser for what appear to be legitimate ad views. Instead, the ads either replace legitimate ads on a webpage, are added to webpages, or are never shown to a user but are charged for.

algorithm. An ordered series of steps used to accomplish a task. A program is a representation of an algorithm that a computer can execute.

application. See program.

authentication. The process of verifying a user's identity in a secure way to provide access to a system.

availability. The security design goal of ensuring that data and systems are available when needed.

backdoor. A mechanism that is installed to allow future access to the computer that bypasses the normal login mechanism. This is used either to access the computer later in case the installed malware is removed, to gain entry to the machine while bypassing the normal logging mechanism, or both.

base rate fallacy. A problem with detection systems in cases where the thing being sought is rare compared to the number of items to examine; it results in most alerts being false positives, degrading the effectiveness of the system.

Big-O or Big-Ω. Terms used by computer scientists to measure the efficiency of an algorithm in terms of the number of computational steps needed to solve a problem given an input of size n , the number of input items. Big-O ("big oh") notation describes the worst-case running time for an algorithm; this is the most steps it will ever take to compute the algorithm. Similarly, Big-Ω ("big omega") notation is the best possible case for the number of steps needed and supplies a lower bound.

binary encoding. The representation of a value (a number or character) in base 2, i.e., using only ones and zeros.

biometric. A measurement of some physical aspect of a person used in authentication processes to determine identity.

birthday attack. This term is a reference to a type of cryptographic attack where a match is found between any two pairs of items in a set. This type of match is easier to find than fixing one item in the set and looking for a match among the remaining items. The reason the birthday attack is easier is that there are more pairs of items in the set than there are remaining items after selecting one; for example, in a set of 10 items, there are 45 pairs; but if we select one item, only 9 remain. The name of the attack refers to the high chance of finding two persons with the same birthday from among a relatively small group.

bit. A single binary digit that is a 1 or 0.

black hat. A computer attacker/hacker who has malicious or criminal intent.

blockchain. A distributed and decentralized digital ledger that records transactions in a secure and tamper-evident way.

boot sector. The first sector of a storage device, such as an SSD, that contains information about the file system including where code to boot the operating system lies.

bots/botnet. Attackers sometimes take over computers to be part of a wider distributed network that participates in a variety of activities; the computers that are forced to participate are known as bots and the entire group a botnet. Botnets are often used for sending spam emails or text messages; they can also be used as part of a distributed denial-of-service attack, where the bots send large amounts of garbage traffic that overwhelms the internet or a targeted computer.

browser hijacker. Software that infects a user's web browser to automatically click on ads or to redirect traffic to particular webpages that contain ads.

bugs. Errors or defects in software code that can cause unexpected or incorrect behavior in a program.

buses. Electronic interconnections in a computer that move data between its components

byte. Eight bits together; typically, the smallest commonly used measure of data. Measuring bytes commonly includes prefixes, like kilo- for 1,000, mega- for 1 million, giga- for 1 billion, and tera- for 1 trillion.

caches. Small but fast repositories of memory used to store data and speed computation in a CPU. (A CPU cache is just one type, and other caches appear elsewhere in a computer system.)

cell site location information (CSLI). A system that can be used to triangulate the location of a cell phone based on receiving a signal at several different cell towers.

central processing unit (CPU). The primary component of a computer that performs the majority of the processing and controls the other components.

certificate. A cryptographic credential used to verify the identity of websites or the creators of software. A root certificate is a credential that comes with or is installed in an operating system or internet browser that is used to verify the ownership of other certificates.

ciphertext. Text that has been encrypted to be unreadable without the appropriate key.

client-server. A computing communications model in which a centralized system, known as a server, interacts with many subordinate clients.

closed-source. A type of source code that is maintained privately by the creator; contrast with open-source.

cloud computing. A large-scale computing model in which programs are run on computers elsewhere in the network; often these computers are rented out by large cloud providers.

code. See source code.

compiler. A computer program that takes human-readable computer source code and translates it into a binary form executable by a computer; this binary form is referred to as having been compiled.

computational core. The portion of a CPU that executes a program; many CPUs now contain multiple cores.

confidentiality. The security goal of keeping information secret from those who are not authorized to access it.

cookie. A small piece of information recorded in a web browser that is set by and shared with individual websites. Used for authorization, advertising, and to track the user's actions across a site.

copyleft. A type of licensing agreement used for software that allows for the free use, modification, and distribution of the work under certain conditions. The copyleft license requires that any modified or derived work from the original must also be licensed under the same terms as the original work.

cores. See computational core.

crackers (or hackers). Technologically sophisticated attackers who are able to breach computer security measures.

crypto jacking. Many cryptocurrencies require that computers called miners participate to allow transactions to proceed; miners occasionally get rewarded for their work. Attackers install malware that acts as a miner on the user's

computer. This is called crypto jacking, and it allows the attacker to earn some cryptocurrency at the user's expense.

cryptographic hash. An algorithm that takes input of any size and produces a fixed-size output that represents a unique fingerprint of the original input. This output is also referred to as a hash value, message digest, or checksum.

cryptographic signature. Data that authenticate both the author and contents of a message in a manner that is mathematically provable to someone who knows the following: the algorithm used to sign the message; the message; and a cryptographic key created by the signing author.

darknets. A type of network that is intentionally hidden and can only be accessed using special software; often access is limited to authorized users.

data center. A physical location that hosts a large number of computers. Typically, these locations provide physical security, electricity, cooling, and network access.

database. A specialized system that stores data in a relational format and offers a method of querying and processing the stored data.

decompilation. A method of transforming a compiled program back into human-readable source code. Often the decompilation process is not perfect, as information is lost during compilation.

decryption. The process of converting ciphertext into plaintext by applying an algorithm and the appropriate key.

denial of service (DOS). An attack against computer or network systems with the intent of making them unusable or unreachable.

dictionary attack. An attack against password systems where the attacker encrypts large numbers of possible passwords to see if they match an unknown encrypted or hashed password.

digital signature. A cryptographic technique that provides authenticity, integrity, and non repudiation to a digital document by encrypting the document or its hash with the signer's private key.

drive-by downloads and **watering hole attacks.** A drive-by download exploits internet web browsers that have errors that allow websites to force installation of software on computers that visit the site. To find victims, attackers can choose sites that are close in name to a real site and hope that users make a typo when entering the address. They might also place ads that carry malware on internet advertising networks. In a watering hole attack, an attacker might create or compromise a website that appeals to some population they want to attack, like systems administrators, so that malware will be more likely to reach that group.

dropper. The most common item installed through malware, a dropper is software that allows the attacker to install other software. There are underground

markets where attackers pay to access computers that are already infected with droppers so they can install additional malware.

electronic communication services (ECS). Any service that provides users the ability to send or receive wire (voice) or electronic communications. *See* 18 U.S.C. § 2510(15). Some examples include email providers, chat sites, websites that provide direct messaging services, and texting apps.

encryption. An algorithm that uses a key to transform data so that it appears random and protects confidentiality.

end user license agreements (EULAs). Legal agreements between software providers and users that outline the terms and conditions of use.

Ethernet. A hardware computer network protocol used to transfer data over wired local area networks (LANs).

executable. An executable file containing binary instructions that can be run directly by a computer's processor.

file system. The portion of the operating system that structures data and organizes files and directories on a computer's storage device.

flash memory. Non volatile computer memory that can be electronically erased and reprogrammed.

free and open source (FOSS). Software that is licensed in a way that allows users to freely use, modify, and distribute the source code.

Freenet. A peer-to-peer network designed to provide secure and anonymous file sharing.

functions (methods, or procedures). Self-contained blocks of code that perform some algorithm and can be called from other parts of a program.

geolocation. The process of determining the physical location of a device or user, often based on IP address; this can be inaccurate.

GNU public license (GPL). A FOSS license that grants users the freedom to use, modify, and distribute software as long as any derivative works are also licensed under the GPL.

graphics processor unit (GPU). A computer component with many weaker processing cores, primarily useful for rendering images and video but also useful for machine learning and cryptocurrency.

hackers. *See* crackers.

hard disk. A storage device used to store and retrieve digital information using magnetic technology.

hash. *See* cryptographic hash.

International Mobile Equipment Identity (IMEI). A unique identifier assigned to mobile phones and other cellular devices.

internet of things (IOT). Physical devices with sensors, software, and network connectivity that exchange data with other devices and systems over the internet.

internet protocol (IP). The portion of the internet software and protocol stack that handles delivery between computers on different networks.

internet service providers (ISP). Companies that provide customers with access to the internet.

interpreted languages. Programming languages that are executed by an interpreter as they run rather than being compiled into machine code, which is run separately.

interpreter. A program that reads and executes code written in an interpreted programming language.

IP address. A numerical identifier assigned to each device connected to the internet; this address may not be unique to a particular system owing to NAT and other mechanisms.

keylogger. A form of spyware that monitors what the user types, and sends it to the attacker or saves it in a file for the attacker to recover later. This can be used to capture passwords, emails, or other things that the user types.

library. A collection of prewritten functions that can be used by a program to perform common tasks.

link layer. The portion of communication software responsible for communication between devices on a local area network (LAN), such as devices on Ethernet or Wi-Fi.

machine learning. An area of artificial intelligence that enables computers to learn from and make decisions based on data without needing a human creating a particular algorithm.

malware. Software intended to cause harm to or violate the security of a computer system.

medium access control (MAC). A portion of the link layer in the networking stack that controls access to the physical medium of a network.

memory (non volatile). Computer memory that retains data even when the power is turned off, such as flash memory or hard disk drives.

memory (random access, volatile). Computer memory that can be accessed randomly and quickly, but loses its data when the power is turned off (such as RAM).

metadata. Data that describes other data, such as the author, date, and file type of a document.

mining. The process of verifying and recording transactions on a cryptocurrency blockchain by solving complex mathematical problems with dedicated computers.

motherboard. The main printed circuitboard in a computer that connects all of the other components and peripherals.

network address translation (NAT). A technique used to remap one IP address space into another by modifying network address information in the IP header of packets while they are in transit across a traffic routing device.

network interface. The physical or virtual connection point between a computer and a network.

network layer. The layer of the networking stack responsible for routing packets between networks.

open source. See free and open source (FOSS).

operating systems. Software that manages computer hardware resources and provides common services for computer programs as well as a user interface.

optical media. Storage media that uses optical technology to read and write data, such as CDs, DVDs, and Blu-ray discs.

packet capture (pcap). A file format used by Wireshark and other programs to capture and store network traffic for analysis and debugging purposes.

phishing and spear phishing. The act of an attacker who wishes to target a specific individual or group by sending an email, text, or other messages that contain a link to malware or to a site that can install it; when sent widely, this is referred to as phishing. Spear phishing is a more targeted technique in which the attacker learns about the victim through social media or web presence and then forges email from someone the victim would trust. Spear phishing is also frequently used in computer fraud—for example, altering an account number where funds are to be transferred during a transaction so that the funds go to the attacker instead of the intended recipient.

physical layer. The lowest layer of a network software stack that handles the physical transmission of data over a communication channel.

port numbers. Numbers in internet connections used to associate a network connection with a particular process that is sending or receiving data.

program. Computer executable instructions that perform a specific task on a computer system.

programming language. A formal language used to write human-readable algorithms that can, through interpretation or compilation, later be executed by a computer to perform a specific task.

public-private key pair. A set of cryptographic keys that are used to encrypt and decrypt messages and to verify the digital signatures of digital certificates.

rainbow tables. A method of pre computing and storing many possible passwords or keys to reduce the time required to break a password or key compared to brute force computation alone.

random access memory (RAM). Circuitry that holds working data while the computer is running. RAM is volatile, meaning it needs power to continue storing information.

ransomware. Malicious software that encrypts user files, then supplies an apparent route to recover them through paying the attacker—this type of software has become a significant risk. Organized criminal gangs have started targeting larger organizations that are dependent on data, such as banks, universities, and hospitals; cryptocurrency has provided a mechanism for criminals to receive their ransom while concealing their identity and location. One method deployed by law enforcement to fight this criminal activity is to gain control over the servers and websites used to communicate and control its victims.

remote access tool. See spyware.

root certificates. A file containing the public key of a trusted authority. The public key is used to digitally sign the public key certificates of its customers, ensuring they are authentic.

root kit. Malware that subverts the normal operating system observability tools in order to hide the existence of the malware.

router. A specialized computer that connects and transfers data among multiple computers. The router is able to make decisions about which of several possible next “hops” the traffic should be sent to, ensuring that the shortest path to the destination is taken.

scareware. Attackers often try to frighten users into sending money with scareware. One form of scareware is software that produces fake antivirus warning messages that request the user pay for a software upgrade to remove a non-existent threat.

serverless computing. See cloud computing.

shared key. See symmetric key.

social engineering. A process by which attackers gain access and information by convincing a user to provide access to systems or information through fraud.

software. A set of instructions that can be executed by a computer.

solid state drive (SSD). A high-capacity, non-volatile storage device to retain data.

source code. The set of files written in a programming language that are used to create a program. Might also refer to a production of these files along with additional files relating to the design and construction of the program.

source code control. A system used by software engineers to track changes made over time to source code. Typically, the source code (and the log of the changes) is said to reside in a repository.

spear phishing. See phishing.

spyware. A general term for software that can monitor user actions and data on a computer. In terms of malware, this might be a remote access tool (or RAT) that provides complete remote control of the computer, including the ability to access files on the system, add files to the system, or activate a camera and/or microphone.

subnet. A smaller network that is part of a larger network.

subscriber identity module (SIM). A small, removable card used in mobile devices to identify and authenticate a subscriber on a cellular network. Newer phones use eSIMS, which are not physical but are stored as information on the phone.

symmetric key. An unguessable value shared as a secret by two participants exchanging encrypted data via a symmetric-key encryption algorithm. The same key is used to encrypt and decrypt.

tape. A data storage medium that uses magnetic tape to store digital information, most often for long-term data storage and backup purposes.

Tor Browser. Free, open-source software from the Tor Project that enables a user to join a network of other users volunteering as network relays. All traffic from the user is sent through the relays such that the website (or other destination) the user is contacting cannot link the received traffic to the user's real IP addresses. Tor Browser provides a service that is similar to a VPN but is more secure in some ways.

transport control protocol. The portion of the internet software and protocol stack that ensures data is delivered in a reliable manner from one computer on the internet to another.

Trojan or Trojan horse. A program that promises, appears to, or really does supply some useful functionality while secretly performing harmful actions.

USB (universal serial bus) drive. A portable storage device that uses flash memory to store data.

user datagram protocol (UDP). A transport layer protocol that provides an unreliable but low-latency network connection.

version control software. A program that serves as a repository for source code and other documents that is able to track and revert changes.

virtual machines (VMs). A software program that pretends to be computer hardware while running on a host's real hardware so that other programs or operating systems can be run while isolated from the host computer.

virtual private network (VPN). An encrypted connection that forwards data across other networks that can only be decrypted and read at the endpoint; this endpoint might forward the received data, making it appear as if the endpoint is where the initial computer resides.

- virus.** A program that can copy itself by inserting its code into other programs. The infected program then finds other programs that it can infect and adds the virus there. It is common for viruses to spread when files and programs are shared. Designers often take steps to obfuscate what the virus is doing. They might repack their code, which keeps the same functionality but changes the appearance of the code. They might encrypt much of the functionality and decrypt it only as needed. Both techniques and others can be used so that the virus is different on each infected system; this is an example of a polymorphic virus. Viruses also attempt to elude detection, possibly by starting before the operating system; boot sector viruses are an example of this approach.
- VPN concentrator.** The device a computer will connect to send data through a VPN.
- watering hole attack.** See drive-by download.
- white hat.** An ethical hacker who works to improve computer security (see also black hat).
- Wi-Fi.** A commercial term for a series of industry standards for short-range wireless communication among computers and mobile devices.
- Wireshark.** A packet capture tool used to monitor, log, and/or debug network traffic.
- worm.** A computer worm is a self-executing program that runs on its own, unlike a virus. A worm spreads across a network by taking advantage of security vulnerabilities on other network-connected systems. A worm can spread shockingly fast in some cases; it might be possible to infect all vulnerable systems worldwide in under 15 seconds in some cases. A major worm spreading is an uncommon and often newsworthy event as it typically causes large network congestion and outages.

Introduction

Artificial Intelligence (AI) now permeates our lives in seen and unseen ways. It informs how we shop, drive, recreate, and work. It guides supply chains and helps with medical diagnoses and documentation. Just as AI is transforming the economy, healthcare, and American society, it will also transform the practice of government and law. Lawyers use AI platforms for discovery, legal research, and drafting. At least seventy-five countries use facial recognition for domestic security and law enforcement purposes.¹ AI is used to determine travel patterns, link suspects with crime scenes, and populate watch lists. Between 2011 and 2019, the FBI used its facial recognition algorithm to search federal and state databases, including some state driver's license databases, over 390,000 times.² Modern militaries and intelligence services are integrating elements of AI into logistics, weapons, and information systems. "Generative AI" can create language loosely in the style of famous writers, simulate paintings reminiscent of those of the masters, imitate voices and generate fake video of real people, perform academic research at varying levels of sophistication and accuracy, and pass professional exams. The National Security Commission on Artificial Intelligence (NSCAI) has predicted that "[t]he development of AI will shape the future of power."³

Many of these uses of AI may find their way into U.S. courts. Some already have. Not only will courts see AI-generated evidence in civil and criminal cases, some state courts and jurisdictions already choose to use various algorithmic risk assessments in bail, parole, and even sentencing decisions.⁴ Judges may need to determine whether to admit AI outputs into evidence or to use AI in judicial decision making. They may also be called upon to adjudicate disputes related to how AI is used in the real world, such as the implications of the use of recommendation algorithms by social media platforms to direct content to particular users, as in the 2023 Supreme Court cases *Twitter v. Taamneh* and *Gonzalez v. Google*.⁵ To address these challenges, judges must understand how AI works, its

4. "Liberty at Risk: Pre-Trial Risk Assessment Tools in the U.S.," Electronic Privacy Information Center 1 (updated Sept. 2020), <https://archive.epic.org/LibertyAtRiskReport.pdf>. As noted below, criminal risk assessments may not or do not all use machine learning but may increasingly do so in the future.

5. *Gonzalez v. Google*, LLC, 2023 U.S. LEXIS 2059 (May 18, 2023); *Twitter v. Taamneh*, 143 S. Ct. 762 (2023).

applications, its implications for the fact-finding process, and its risks. Judges should be able to answer the following four question-sets in context:

- How is the AI model being used (in the real world) or proposed to be used (in court or to inform judicial decisions)? Is that use the purpose for which the model was designed?
- Does the fact finder understand the AI's strengths, limitations, and risks, such as bias?
- Is the AI application authentic, relevant, reliable, and material to the issue at hand, and is its use or admission consistent with the Constitution, statutes, and the Federal Rules of Evidence (or state equivalents)?
- Has an AI algorithm, a human, or some combination of the two made any "judicial decision," and, in all cases, has that decision been documented in an appropriate and transparent manner allowing for judicial review and appeal?

This reference guide addresses these questions by providing technical background judges should possess to address legal issues that may arise surrounding AI-generated evidence, litigation over AI-enabled vehicles and applications, and proposed AI judicial tools.

However, describing AI is a challenge. The field incorporates many different technologies, functions, and uses. Almost any application or tool that uses computers, algorithms, and data might be described as AI or touch upon AI. AI is also a moving target. AI is by design iterative. This reference guide is intended as a foundation with which judges and court staff can more easily identify and assess this rapidly evolving field by presenting core concepts and terms. Specific applications and methodologies, however, will invariably change and change rapidly over time, including, for example, methods to better identify and understand AI-generated outputs (explainability) as well as validate digital imagery and voice patterns using AI-enabled tools. We do not provide legal judgments about the use of different AI applications. In discussing how AI is used today and may be used in the future, we do not endorse that use in any particular context or application—fact-intensive questions. Rather, we identify core technical concepts and legal issues, so that when judges must decide whether to admit AI applications into evidence or to use AI in a judicial determination, they decide wisely and fairly. Making these decisions requires judges and litigators to know enough about AI to ask the right questions, at the right moment, in the right depth.

We conclude this introduction with a caveat and a statement of purpose. AI is a field of technologies that is changing at an exponential pace. Today's cutting-edge application may be commonplace tomorrow, or obsolete. New methods will replace old methods. Therefore, it is not important for judges to understand how the IBM computer Deep Blue defeated world champion Gary Kasparov in chess

in 1997. It is important to know that a machine beat a human, which means that machines can be better than humans at certain tasks for which humans otherwise use human intelligence. Likewise, it is not important for judges to know how to label or code training, validating, or testing data. It is important to know that the quality and qualities of AI datasets can impact AI accuracy because datasets, like humans, possess bias. In a specific litigation context, expert testimony may be required on the subject. The goal of this reference guide is not to make judges scientific experts on AI or specific AI applications or methodologies; the field will change before this reference guide goes to print. Judges do not need to be coders or a technologist to ask good questions; they need to know good questions to ask. That is what judges do. We hope this reference guide provides a helpful background and sound framework for judges to do so.

Roadmap

This reference guide starts with a brief history and overview of the constellation of technologies associated with AI. The entry point to AI will vary for most jurors and judges; this section offers a quick level set. The next sections take a deeper look at the basics of machine learning, the underpinning of what today is generally known as AI. The reference guide then considers the roles judges will play regarding AI, including overseeing discovery, acting as evidentiary gatekeepers, interpreting law's application to AI contexts, translating complex questions of technology and law into case law, and considering whether to use AI tools in judicial decision making. We provide some high-level technological takeaways about AI for judges, then focus on two areas likely to generate adjudication: AI bias, and algorithms that predict human behavior. All of this technical knowledge is a predicate to judges understanding the myriad and complex ways AI will come before courts. Informed by this knowledge, the reference guide concludes by addressing how AI may change the practice of law as well as discovery and evidentiary considerations presented by AI, including AI deepfakes. Throughout, the reference guide identifies with bullet points threshold questions judges should ask about AI in context. They are threshold questions because each in turn should lead to additional contextual questions about specific AI applications. A glossary of terms follows the reference guide narrative.

An Overview of AI

What Is AI?

AI scholars and practitioners use multiple definitions of AI, a fluid and expansive field. The National Security Commission on AI provided one helpful definition:

Reference Guide on Artificial Intelligence

AI is not a single piece of hardware or software, but rather, a constellation of technologies that gives a computer system the ability to solve problems and to perform tasks that would otherwise require human intelligence.⁶

Each of the components constituting a particular AI system may be subject to legal challenge and validation. Moreover, because many AI components like algorithms are iterative, “learning” as they go, the field is constantly evolving and at a rapid pace. Case law will necessarily need to evolve and adapt as well.

A 2017 Belfer Center Study on AI and national security similarly emphasized that the field of AI is composed of multiple methodologies and technologies:

Artificial Intelligence (AI) is a science and a set of computational technologies that are inspired by—but typically operate quite differently from—the ways people use their nervous systems and bodies to sense, learn, reason, and take action.⁷

These definitions emphasize that artificial intelligence, while often analogized to human thinking with terms like “artificial neural network” and “neurons,” is achieved by mathematical computation: AI identifies, collects, aggregates, analyzes, and derives meaning from data, or performs tasks that rely on data. The AI is not “learning” as humans do; it is using mathematical models and other techniques to better perform or optimize tasks it has been programmed and trained to perform. AI learning is generally statistical in nature. However, as noted throughout this reference guide, developing and creating AI is a very human endeavor that reflects human choices and biases. Machines may be programmed to act autonomously, like a chatbot creating its own code and responses, but it is humans who write the source code that enables the bot to work and humans who select and define the data on which the bot is trained, tested, and validated.

Therefore, a single, capacious definition of AI is elusive, and rightly so. Depending on the AI application, a system will contain different technologies and methodologies, train on different data, and encounter different real-world data inputs in the field, all of which means each application will also have different strengths and weaknesses. At present, case law on AI is limited,⁸ but even as it develops, rather than simply relying on precedent, courts will still need to examine each AI system and its real-world application to specific facts and conditions. However, at least three unifying characteristics give machines “AI”: they

8. We have compiled an appendix list of illustrative cases in our longer publication, James Baker, Laurie Hobart, & Matthew Mittelsteadt, *An Introduction to Artificial Intelligence for Federal Judges*, (Federal Judicial Center 2023), <https://perma.cc/7DJT-T9D2>.

have (1) the capacity to “learn” (with the caveats above) and (2) the capacity to act (3) based on seed coding (algorithms) designed by humans.

A Brief History from Turing to Today: Waves of AI Development

Popular and scientific literature identifies several benchmark events in AI development. In 1950, the English computer scientist and Bletchley Park code breaker Alan Turing wrote an article, “Computing Machinery and Intelligence.” He asked, can machines think, and can they learn from experience as a child does? “The Turing Test” was Turing’s thesis advisor’s name for Turing’s experiment testing the capacity of a computer to think and act like a human. A computer would pass the test when it could communicate with a person in an adjacent room without the person realizing they were communicating with a computer.

In 1956, Dartmouth College hosted the first conference to study AI.⁹ The host, Professor John McCarthy, is credited by many with coining the term “Artificial Intelligence.”¹⁰ The funding proposal submitted to the Rockefeller Foundation stated,

We propose that a 2-month, 10-man study of artificial intelligence be carried out. . . . We think that a significant advance can be made in one or more of these problems if a carefully selected group of scientists work on it together.¹¹

Notwithstanding this optimistic start, progress in the field was neither linear nor exponential. It occurred in fits and starts. As a result, AI development went through a series of “AI winters,” periods of low funding and low results. In the past twenty years, however, AI has emerged as one of the transformative technologies of the twenty-first century.

Experts have described three waves of AI development. The first wave of AI machine learning consisted of if-then linear learning, a process that relies on the brute-force computational power of modern computers. With linear learning, a computer is in essence “trained” that if something occurs, then it should take a countervailing or corresponding step. This is how the IBM computer Deep Blue beat Gary Kasparov in chess in 1997, a significant AI milestone. The computer was optimizing its computational capacity to search through possible positions and use decision trees to weigh possible moves in response to Kasparov’s actual and

9. *Artificial Intelligence (AI) Coined at Dartmouth*, Dartmouth College, <https://perma.cc/856H-6NYD> (last visited Jan. 1, 2025).

10. *Id.*

11. Nick Bostrom, *Superintelligence: Paths, Dangers, Strategies* 6 (2014).

potential moves.¹² It did so with the knowledge of all of Kasparov’s prior games, while on the clock in real time. Deep Blue was an impressive demonstration of computational force, a near instantaneous series of if-this-then-that calculations.

We are in (at least) a second wave of machine learning now, the benchmark of which is AlphaGo, the Google computer that beat the world’s best Go player in 2016. The AlphaGo victory was a milestone not just because Go is a more complex, multidimensional game than chess but because AlphaGo won using reinforcement learning: it got better at the game by playing it. AlphaGo improved with experience, adjusting its own decisional weights internally—in the so-called “black box” of internal machine calculation—without training data or other if-this-then-that learning.¹³ Surpassing brute force computational power, this was a machine optimizing its capacity. Was it “thinking”? No. But was it “learning”? Yes.

What changed? Experts point to several factors working synergistically—specifically, the development of complex algorithms, strides in computational speed, the invention of new sensors, an explosion in data, and the advent of cloud computing and machine learning.

Complex Algorithms

Merriam-Webster’s Collegiate Dictionary defines an algorithm most “broadly” as “a step-by-step procedure for solving a problem or accomplishing some end.”¹⁴ A common example is a recipe for a meal. More narrowly, an algorithm is “a procedure for solving a mathematical problem . . . in a finite number of steps that frequently involves repetition of an operation.” In the AI context, algorithms are rigorously defined steps, written in software, to find, sort, and look for patterns in data. Algorithms are “the set of rules a machine (and especially a computer) follows to achieve a particular goal.”¹⁵

Today’s algorithms can be (but are not always) much more complex than simple recipes. The Google enterprise utilizes over two billion lines of code, while the search engine operates with 200,000–300,000 lines of code.¹⁶ The engine itself combines multiple tools and algorithms that web index (internet catalogue and map), embed potentially hundreds of search factors, and rank pages and references.

12. Adam Rogers, *What Deep Blue and AlphaGo Can Teach Us About Explainable AI*, Forbes (May 9, 2019), <https://perma.cc/2EJW-JNBB> (“The 1997 version was capable of searching between 100 and 200 million positions per second, depending on the type of position, as well as a depth of 20 or more pairs of moves.”).

13. David Silver et al., *Mastering the Game of Go Without Human Knowledge*, 550 *Nature* 354 (Oct. 19, 2017), <https://doi.org/10.1038/nature24270>.

14. Merriam-Webster’s Collegiate Dictionary, <https://perma.cc/82FG-EJRD> (last visited Aug. 18, 2022).

15. *Id.*

16. Rachel Potvin, *Why Google Stores Billions of Lines of Code in a Single Repository*, YouTube (Sept. 14, 2015), <https://perma.cc/5S56-5E7Z>.

By some accounts “the algorithm,” meaning the collective algorithms and tools, are adjusted 500–600 times a year.¹⁷ Thus, there is no single, final Google search algorithm. For many AI applications, not just Google, the algorithm one uses today will be different from the algorithm one uses tomorrow.

Computational Speed

The foundational component of a computer is the central processing unit (CPU), which today is composed of billions of electrical components called transistors. The more transistors in a CPU, the more data that can be processed in smaller packages with greater speed.¹⁸ Increased computational power is directly tied to the miniaturization of the transistor. So far, the number of transistors in a CPU has followed a trend called “Moore’s Law,” “the observation that the number of transistors on an integrated circuit will double every two years with minimal rise in cost.”¹⁹ By one estimate, a 1985 Cray Supercomputer, which took up sixteen square feet, would have had to be expanded to 80,000 square feet, or the size of an office building on two acres of land, to have the same processing speed as a 2020 iPhone 12.²⁰ Humans interact and program CPUs with programming languages that are ultimately turned into ones and zeros (the only thing a CPU understands) through different layers of software. One of the defining characteristics of AI is its capacity to perform tasks and process data at “machine speed.” While all machines might be said to operate at “machine speed,” this term is used by many to mean in effect “instantaneous” speed, distinguishing the capacity of machines to process information and make calculations from the capacity of humans performing the same or similar tasks.

Sensors

The development of sensor technology, such as that found in driverless cars, cell phones, and home devices, has resulted in more data and more applications for using that data to inform and influence human behavior. Personal assistants like Siri, Watson, and Alexa all use sensors to collect data.

Data

Data drives the AI revolution. For many though not all types of current AI modeling, the more data one has the easier it is to train a computer system to perform a task or solve a problem, and likely the more accurate the result.²¹ As discussed below, the quality of the data, as well as the metrics selected in designing algorithms, will also affect accuracy and the degree to which different forms of bias will affect accuracy.²²

Cloud Computing

The advent of cloud computing allows more data to be stored on a permanent and centralized, and thus retrievable, basis. As the Supreme Court encountered in *Carpenter v. United States*, where a criminal prosecution relied on historical cell phone location records that provided “a comprehensive chronicle of the user’s past movements,”²³ data can persist for years, even forever, if not purposefully deleted as a matter of law or policy. (The lifespan of data might also be limited by the expense of storing it and the possibility that future software or computer systems might not be able to read its format or encoding.)

Machine Learning

A critical technological advancement has been the development of machine learning, which refers to different methodologies to program software-driven machines to learn on their own and thus improve and optimize their functions. After the Dartmouth conference in 1956, the AI field “split into two camps: one focused on symbolic systems, problem solving, psychology, performance, and serial architectures, and the other focused on continuous systems, pattern recognition, neuroscience, learning, and parallel architectures.”²⁴ That second camp, or AI subfield, was machine learning. Much machine learning research is

21. Large language models, discussed below, rely on vast quantities of data, but experts are also developing models that do not depend on large quantities of data. For example, an AI “information lattice” model that helps humans without a musical background compose music was trained on a set of 370 Bach compositions. See Michael O’Boyle, *(Re)discovering Music Theory: AI Algorithm Learns the Rules of Musical Composition and Provides a Framework for Knowledge Discovery*, U. of Ill. Urbana-Champaign News (Jan. 27, 2023), <https://perma.cc/BA62-KK46>.

predicated on trying to mimic the human brain (literally, in the case of efforts to replicate the brain using 3D printers) or with neurological metaphors such as “artificial neural networks.” While AI may mimic, and in some cases outperform, human intelligence, it is not actual human intelligence. It is machine capacity and optimization, hence the preferable term: Human-Level Machine Intelligence (HLMI). Machine learning is explained in more detail, below.

Specialists describe the AI of today as “narrow,” generally good at addressing discrete tasks or “application areas[,] such as playing strategic games, language translation, self-driving vehicles, and image recognition.”²⁵ Narrow AI capabilities exploded in the early 2010s with a machine learning technique called “deep learning,”²⁶ described in greater depth below.

Beyond narrow AI, computer engineers contemplate the emergence of Artificial General Intelligence, or AGI. Artificial General Intelligence is an AI multitasking capacity that can serve multiple purposes. Much like a human, AGI would be able to understand and perform multiple tasks and shift from task to task as needed. Most analysts foresee AGI arriving, if it arrives at all, as a stage in development, like the advent of flight—not necessarily a moment in time, like the Soviet launch of the Sputnik satellite in 1957. AGI will present more complex legal questions than narrow AI. A system that can write and rewrite its own code as well as shift from task to task will be harder to regulate, requiring courts and legislators to wrestle with questions of accountability and responsibility for actions the AI takes or information it provides.

Indications of a potential third wave of AI machine learning were being discussed in 2016, the year of AlphaGo. As the *National Artificial Intelligence Research and Development Strategic Plan* reported in October of that year,

[t]he AI field is now in the beginning stages of a possible third wave, which focuses on explanatory and general AI technologies. . . . If successful, engineers could create systems that construct explanatory models for classes of real world phenomena, engage in natural communication with people, learn and reason as they encounter new tasks and situations, and solve novel problems by generalizing from past experience.²⁷

Today, we may well be on the rising swell of a third wave, and somewhere between narrow AI and AGI. In late 2022, OpenAI released ChatGPT, which stunned users with its ability to respond conversationally to prompts and to generate relatively sophisticated text and research products across subject matter, though not without error. ChatGPT is a large language processing model (LLM), a type of “generative AI.” Generative AI models use machine learning to generate or create new images, text, voices, videos, computer code, or other content; some are even being developed to discover new molecules.²⁸ Yet, as might be expected from models trained on text and images from the internet, ChatGPT and other generative AI models have been shown to create false narratives and reports, to embed racism, nationalism, and other biases, and even to generate fake legal cases. Even when trained on factually accurate data, generative AI models such as ChatGPT have produced false or counterfactual outputs, often referred to as “hallucinations.”

Big tech companies are working on AI products similar to ChatGPT,²⁹ with an emphasis on “big”: Thus far, the success of LLM models like ChatGPT has been contingent on vast amounts of training data (estimated at 45 terabytes for ChatGPT³⁰) as well as huge compute capacity and gigawatt-hours of electricity required to train and test the models on that data.³¹ All of these factors come at significant monetary expense as well. AI researchers are developing methods to reduce the size of generative models, for example by decreasing the number of mathematical connections between artificial neurons.³² Generative AI has been improving “at a dizzying pace, with new models, architectures, and innovations appearing almost daily.”³³

No matter how sophisticated and impressive, ChatGPT and other LLMs, with their errors and limitations, are not yet Artificial General Intelligence, or human level intelligence, though they approach it.³⁴ AGI contemplates that a computer linked to the internet, the Cloud, and the Internet of Things (IoT) might perform multiple tasks, solve problems, or answer questions generally, moving fluidly from one function to the next. Commentators ask three

34. The OpenAI website acknowledges this, stating “We believe our research will eventually lead to artificial general intelligence, a system that can solve human-level problems. Building safe and beneficial AGI is our mission.” <https://openai.com/research/overview> (last accessed Oct. 18, 2024).

threshold questions when it comes to general AI: Will it happen? When will it happen? And will it be a good or bad thing when it does?

From 2015 to 2016, a group of scholars associated with the Oxford Future of Humanity Institute, AI Impacts, and Yale University surveyed “all researchers who published at the 2015 NIPS and ICML [Workshop on Neural Information Processing Systems and International Conference on Machine Learning] conferences (two of the premier venues for peer-reviewed research in machine learning).”³⁵ The survey asked respondents to estimate when human-level machine intelligence (HLMI) would arrive. The study did not define AGI but stipulated that “Human-Level Machine Learning is achieved when unaided machines can accomplish every task better and more cheaply than human workers.” Three-hundred and fifty-two researchers responded, a return rate of 21%. The results ranged across the board: from fairly soon to never to beyond 100 years. What is noteworthy is that the “aggregate forecast gave a 50% chance of HLMI occurring within 45 years and a 10% chance of it occurring within 9 years.” The two countries with the most survey respondents were China and the United States. The median response for the Americans was seventy-six years, for the Chinese, twenty-eight.³⁶ As the survey indicates, experts do not agree on whether or when we will get to AGI.

Some experts believe that the powers and potential of AI are exaggerated. The authors of this reference guide do not share that view. Neither do the governments and companies dedicating billions of dollars to the development of AI. AI tools and methods will continue to change rapidly. The same factors that led to current AI, including data, computational capacity, and innovative modeling, will generate the next waves of AI, and those factors will only grow. The courts, like other elements of society, must adjust to AI, just as they previously adjusted to computers and electronic filing. Preparation starts with an understanding of what AI is, and is not, and the confidence that, explained in plain language, AI, its strengths, and its weaknesses, can be understood by judges, litigants, and jurors.

A Survey of AI Applications “Today”

Contemporary “narrow AI” can be defined as the “ability of computational machines to perform singular tasks at optimal levels, or near optimal levels, and

35. Katja Grace et al., Viewpoint: *When Will AI Exceed Human Performance? Evidence from AI Experts*, 62 J. of Artificial Intelligence Res. 729–54 (July 31, 2018), <https://doi.org/10.1613/jair.1.11222>.

36. *Id.*

usually better than, although sometimes just in different ways [than], humans.”³⁷ Under this umbrella come many single-purpose technologies, e.g., the AI that enables facial recognition and driverless vehicles. These technologies are “intelligent” in only one domain, limiting their ability to be used for multiple purposes or deal with certain complex situations.

Applications of machine learning today fall under three broad categories:

(1) cyber-physical systems, (2) decision sciences, and (3) data products. Cyber-physical systems are engineered systems that integrate computational algorithms and physical components, e.g. surgical robots, self-driving cars, and the smart grid. Decision sciences applications use machine learning to aid people in making important decisions and informing strategy, e.g. pretrial detention, medical treatment, and loan approval. Data products applications are the use of machine learning to automate informational products, e.g. web advertising placement and media recommendation.³⁸

Current AI is particularly good at correlating, connecting, and classifying data; recognizing patterns; and weighting probabilities—which is why it is good, and getting better, at tasks like facial recognition, image compression and identification, and voice recognition. But the field of AI is not static, it is moving at a seemingly exponential pace. That is why it is more important for judges to ask the right questions than to “master” a single iteration of AI or AI application. Binding and precedential case law will prove elusive.

At present, narrow AI can be “brittle,” by which engineers mean incapable of adapting to new circumstances on its own and lacking in situational awareness. To illustrate the point, AI philosophers like to point to the thought experiment known as the Trolley Problem, now more commonly conveyed as a crosswalk problem. In the problem, a driverless car loses its brakes at just the moment it is coming up to a crosswalk at speed. There are various pedestrians in the crosswalk of different ages and of different perceived virtues—for example, a pregnant woman and an armed robber carrying a bag of stolen money. The car’s computer must make a choice: swerve left, swerve right, brake, or drive ahead. An alert human driver, after first trying to brake, would in theory make a values-based, ethical choice about where to aim the car, likely at the presumed bank robber. The AI-driven car, on the other hand, unless it has been specifically trained to identify an “armed bank robber” or a “pregnant woman” and to adjust its decisional weights to favor one over the other in a choice scenario, will likely perceive the persons in the crosswalk as “persons in the crosswalk,” no more. Chances are the software code will select the path of least numerical damage. This weakness in current AI is especially important where an AI application is likely to

37. James E. Baker, *The Centaur’s Dilemma: National Security Law for the Coming AI Revolution* 34 (2020).

38. Varshney, *supra* note 24, at 2.

encounter changing or novel circumstances, like driving, or where there is an incentive for external actors to spoof or fool the AI application, as might be the case with military, intelligence, and law enforcement surveillance tools.

Many narrow AI applications are known to consumers who rely on them daily. If you shop on Amazon, you are using AI algorithms. Amazon back-propagates training data from purchases made on Amazon as well as data from individual consumers. Algorithms then identify patterns in the data and weight those patterns, allowing the algorithm to suggest (predict) additional purchases to the shopper. The algorithm adjusts as it goes based on the responses (or lack of responses) from recipients. This is an example of predictive big-data analytics. It is also an example of a push, predictive, or recommendation algorithm.

Why do companies use AI? Former Secretary of the Navy Richard J. Danzig explains:

... machines can record, analyze and accordingly anticipate our preferences, evaluate our opportunities, perform our work, etc. better than we do. With ten Facebook “likes” as inputs, an algorithm predicts a subject’s other preferences better than the average work colleague, with 70 likes better than a friend, with 150 likes better than a family member and with 300 likes better than a spouse.³⁹

Narrow AI is also embedded in mapping applications, which sort through route alternatives with constant, near-instantaneous calculations factoring speed, distance, and traffic to determine the optimum route from A to B. Then the application uses AI to convert numbered code into natural language telling the driver to turn left or right.

AI is also used to spot minute changes in stock pricing and to generate automatic sales and purchases of stock, as well as to spot anomalies that generate automatic sales and purchases. All of this is based on algorithms created and initiated by humans but programmed to act autonomously and automatically because the calculations are too large, the margins too small, and the speed too fast for humans to keep pace and make decisions in real time. Of course, as one trader’s algorithm gets faster, the next trader must either change their algorithm’s design, speed, or both to achieve an advantage, reducing the window of opportunity for real-time human control even further. AI machine learning and pattern recognition are also used for translation, logistics planning, and spam detection, among many, many more commercial applications. In 2017, Andrew Ng, the former chief scientist for Baidu, declared AI “the new electricity.”⁴⁰

39. See Richard Danzig, *An Irresistible Force Meets a Moveable Object: The Technology Tsunami and the Liberal World Order*, in *The World Turned Upside Down: Maintaining American Leadership in a Dangerous Age* (Nicholas Burns, Leah Bitounis, & Jonathon Price eds., 2017).

40. *Why AI Is the “New Electricity,”* Knowledge @ Wharton Staff (Nov. 7, 2017), <https://perma.cc/HD93-E9WH>.

A prominent illustration of emerging next-generation AI is the driverless vehicle, or more precisely, the software processes and hardware that enable driverless vehicles. AI empowers driverless cars by performing myriad data input and output tasks simultaneously, as a driver does, but in a different way. Human drivers rely on intuition, instinct, experience, and rules to drive—seemingly all at once—using the neural networks of the brain. In driverless cars, sensors instantaneously feed computers data based on speed, conditions, and images of the sort ordinarily processed by the driver's eyes and brain. The car's software processes the data to determine the best outcome based on probabilities and based on what it has been programmed to understand and decide. This requires constant algorithmic calculations that a human actor could not make in real time. Luckily, humans do not rely on math to drive cars. They exercise their judgment and intuition, which is why alert drivers generally handle situational change better than AI applications do. On the other hand, AI can possess 360-degree vision and does not fall asleep at the wheel, text while driving, or drive drunk. Driverless cars will and do make different kinds of mistakes than humans—but in theory and presumably in practice, fewer of them.

One of the most successful applications of AI to date is found in the field of medical diagnostics. Here, narrow AI's capacity to detect and match patterns and find anomalies has led to breakthroughs in the detection of tumors as well as the onset of diabetic retinopathy. In places like India, where there is a shortage of ophthalmologists, the use of such screening diagnostics can help prioritize access to doctors and treatment by identifying at-risk patients.⁴¹ Studies indicate that AI can be or may soon be more accurate than humans in detecting certain cancerous tumors or making prognostic findings about their growth and treatment.⁴² However, that is not the same as saying that humans are prepared to rely on AI alone, or wish to receive medical diagnoses from machines rather than doctors.

Law enforcement authorities use AI for predictive policing and surveillance. Some seventy-five countries use AI-powered surveillance, including many liberal democracies.⁴³ According to a 2019 Government Accountability Office report, the FBI has logged hundreds of thousands of searches of its facial recognition system, which has access to 641 million face photos.⁴⁴ The FBI

41. Cade Metz, *India Fights Diabetic Blindness with Help from AI*, N.Y. Times, Mar. 10, 2019, <https://www.nytimes.com/2019/03/10/technology/artificial-intelligence-eye-hospital-india.html>.

reported its system has proven 86% accurate at finding the right person, if a search was able to generate a list of fifty possible matches.⁴⁵

Generative AI differs from traditional predictive models,⁴⁶ such as those used in driverless cars, shopping algorithms, and image recognition. Those predictive models classify data, identify patterns, and use statistics to predict or match other real-world examples with the data provided: For example, facial recognition applications are trained to identify images of humans and predict which images from a data bank might most closely match a real-world photo of a person.⁴⁷

Generative AI, while still using statistics and prediction,⁴⁸ creates new content. Early models developed in the 2010s could generate deepfake videos of political figures and excellent simulations of famous paintings.⁴⁹ ChatGPT has been used to author academic papers, poems, essays, books, and code;⁵⁰ GPT-4, released in March 2023, passed the July 2022 uniform bar exam with a score “approaching the 90th percentile” of human test-takers.⁵¹ ChatGPT and similar large language models (LLMs) use statistics to auto-fill or complete sentences. Today’s generative models train on datasets of sample text, images, or other content. The models “compress a dataset into a dense representation, arranging similar data points closer together in an abstract space.”⁵² For LLMs, the dataset is vast quantities of sample text, where common parts of words are represented in numbers called “embeddings.”⁵³ The LLM can “sample from this space to create something new while preserving the dataset’s most important features.”⁵⁴ An “attention” feature helps the LLM predict which embeddings from the training data will best match and complete a phrase and eventually a sentence.⁵⁵ Modern LLMs can predict the parts of a sentence in parallel or simultaneously.⁵⁶

Reference Guide on Artificial Intelligence

Because they are based on statistical prediction and the content of training datasets, ChatGPT and similar models still make errors. While GPT-4 outperformed most bar takers, it still only answered 75.7% of the multiple-choice questions correctly and received scores around 4.2 out of 6 on the essays.⁵⁷ As noted earlier, ChatGPT has been shown to generate false information and research (sometimes referred to as “hallucinations”⁵⁸), and sometimes quite persuasively. Some federal judges have ordered that litigants disclose whether they have used generative AI in their research and briefing, and if so, affirm that they have verified its accuracy.⁵⁹ At least one state bar has cautioned members that the use of generative AI for legal research, depending on how it is used, may violate client confidentiality were the AI to incorporate the research into its ongoing dataset.⁶⁰ We surmise the advent of disputes over privilege waiver. The use of AI chatbots as legal “receptionists” may result in the creation of an attorney-client relationship, or appearance of one, without the attorney being aware.⁶¹

Generative AI can reproduce racism, nationalism, sexism, and every other bias found on the internet.⁶² The 2016 chatbot Tay, for example, generated and spread hate within hours of its public release, adopting the language and values found on Twitter.⁶³ (Similarly, non-generative social media “recommendation” or “push” algorithms that promote pre-existing content to certain users allegedly have been used to spread and amplify ethnic hatred, such as against the Rohingya in Myanmar;⁶⁴ disinformation, such as reported by Nobel Peace Prize recipient Maria Ressa in the Philippines⁶⁵ and widely observed in U.S. elections; and terrorist content, as the Supreme Court heard in *Gonzalez v. Google* and *Twitter v. Taamneh*.⁶⁶)

The content created by generative AI models can be so realistic as to be misleading, raising significant concerns about models and their products being used wittingly and unwittingly for disinformation and misinformation, potentially polluting the internet at overwhelming levels. There is also significant concern that generative AI will be used to develop harmful and very real products, such as bioagents.⁶⁷

This survey of today's AI suggests that AI will both improve and necessarily be imperfect. For each potential application, humans must decide whether it is wise and fair to use AI in the first instance. Where it is employed, AI will generally be best used to augment rather than supplant human judgment. One issue AI policy makers, designers, and ethicists must resolve in context is how to structure human-machine teaming to allocate responsibility and accountability. Judges in turn will have to determine whether as a matter of law, or a matter of law and fact, the humans made the correct decisions: that is, whether the humans appropriately applied AI to a problem, selected an appropriate algorithm, and interpreted the results correctly. Judges will also have to consider to what extent, if any, they should rely on AI applications to inform their own decisions.

What Is Machine Learning?

Machine learning (ML) is a subfield⁶⁸ of and “one of the most important technical approaches to AI.”⁶⁹ As the name implies, it is a set of methods computers use to “learn,” both to perform tasks and to improve on that performance, by making predictions or classifications based on input data.⁷⁰ Dr. Kush Varshney writes:

The term machine learning was popularized in Arthur Samuel's description of his computer system that could play checkers, not because it was explicitly programmed to do so, but because it learned from the experiences of previous games. In general, machine learning is the study of algorithms that take data and information from observations and interactions as input and generalize from specific inputs to exhibit traits of human thought. Generalization is a

process by which specific examples are abstracted to more encompassing concepts or decision rules.⁷¹

For example, the constellation of technologies that make up AI allow mathematically driven algorithms to perceive, break down, and connect patterns in data or digital sequences in images. Machine learning allows these machines to not only recognize patterns, such as those employed for facial recognition, shopping, and medical diagnosis, but to then on their own classify, or generalize, by associating certain patterns with desired outputs, e.g., potential matches in a facial recognition database.

How Machines Are Trained to Learn: The Machine Learning Life Cycle

Varshney outlines six stages in the development and life cycle of a machine learning system: (1) problem specification; (2) data understanding; (3) data preparation; (4) modeling; (5) evaluation; and (6) deployment and monitoring.⁷² As we will emphasize, humans are involved at every point along the continuum of that life cycle, infusing their choices into eventual AI outputs.⁷³ Experts also point to the importance of involving all stakeholders—i.e., those individuals or groups who might use or be affected by the AI application, including traditionally marginalized groups—at all stages of the machine learning life cycle.⁷⁴

Varshney, *supra* note 24, at 15, 17 (citing Meg Young, Lassana Magassa, & Batya Friedman, *Toward Inclusive Tech Policy Design: A Method for Underrepresented Voices to Strengthen Tech Policy Documents*, 21 Ethics & Information Tech. 89–103 (June 2019)), <https://doi.org/10.1007/s10676-019-09497-z>; Leslie, *supra* note 73, at 16; *see also* *Artificial Intelligence Ethics Framework for the Intelligence Community*, Version 1.0 (June 2020), <https://perma.cc/T6UT-JJL3> (“Identifying and addressing risk is best achieved by involving appropriate stakeholders. As such, consumers, technologists, developers, mission personnel, risk management professionals, civil liberties and privacy officers, and legal counsel should utilize this framework collaboratively, each leveraging their respective experiences, perspectives, and professional skills.”).

Problem Specification

The machine learning process begins with a question, problem, or task that a machine might address. The goal might be to automate a task or aid and improve upon human decision making,⁷⁵ such as detecting tumors or winnowing job applications. Even in this initial framing, humans are making choices that may reflect their own values and biases. Judges and lawyers will recognize this as analogous to the framing of a legal issue or question, or of a question in a survey or cross-examination. (Indeed, legal minds may find many connections and disjunctions between the rules and decision trees created by AI systems and those established by law.) Within the category of facial recognition algorithms, for example, it is a much different ethical undertaking to code and train a system to track a minority group, such as Uyghurs in China, than it is to develop a system to recognize missing children for Amber Alert purposes. The United States Intelligence Community has adopted an “Artificial Intelligence Ethics Framework” with lists of questions for government actors, including: “What is the goal you are trying to achieve by creating this AI? . . . Is there a need to use AI to achieve this goal? Can you use other non-AI related methods to achieve this goal with lower risk?” as well as “What benefits and risks, including risks to civil liberties and privacy, might exist when this AI is in use? Who will benefit? Who or what will be at risk? What is the scale of each and likelihood of the risks? How can those risks be minimized and the remaining risks adequately mitigated? Do the likely negative impacts outweigh likely positive impacts?”⁷⁶ The European Union has taken the approach of identifying certain AI uses as prohibited, and identifying other AI applications as “high risk,” requiring independent verification and testing.⁷⁷

At this initial stage, the human “problem owners” and AI technologists must also determine the metrics by which they will measure the success of the AI, another value-laden decision point.⁷⁸ For example, if the State Department decided to make foreign aid allocations to nation-states with the help of an algorithm, it might choose to measure success by how much a recipient state’s total GDP rose in future years or, instead, by what percentage of children received secondary-level education and certain vaccines. The two metrics might align, but they might not, or they might align but only to a point. Each metric also reflects different micro- and macro-level values.

Data Understanding

The next step is selecting and collecting the relevant datasets that the machine learning model will use.⁷⁹ The data might be “numbers, photos, or text, like bank transactions, pictures of people or even bakery items, repair records, time series data from sensors, or sales reports.”⁸⁰ Some of the data will be “used as training data, or the information the machine learning model will be trained on.”⁸¹

When designing machine learning algorithms, engineers divide data into three sets: training data, validation data, and testing data.⁸² Training data is intended for the AI, curated and sometimes labeled so that the AI can analyze it, learn from it, and adjust its coding to ultimately form better predictions. Validation data is intended for the developer, who uses this data to stress test the model’s training and decide whether to update its settings and sensitivities. Testing data provides a final round of analysis; this data is used on the trained, tuned model to evaluate the model’s fit to the data and overall accuracy.

The selection of each of these sets of data is critical to the accuracy and fairness of the final product, hence the phrase “garbage in, garbage out.”⁸³ “Algorithmic bias” is discussed at length below, but by way of example here, two common types of bias in machine learning are “temporal bias” and “population bias.” Temporal bias concerns the timing of data collection and how that timing might affect accuracy.⁸⁴ This might occur if a university used an admissions AI algorithm that was trained on admissions data from the 1960s, before many American colleges accepted women. An algorithm so trained might not see fit to admit women (or rather, its outputs would not suggest doing so). Population bias occurs where some inputs are underrepresented and others overrepresented,⁸⁵ illustrated by underperforming facial recognition algorithms. If the training datasets do not contain sufficient numbers of photographs of faces of different skin colors and genders, there will be output disparity across “race” and gender. Social bias in algorithms can also “stem[] from prejudice: labels from historical human decisions contain systemic differences across groups.”⁸⁶ As discussed below, this concern comes up in criticisms of predictive policing algorithms and

criminal-risk assessment tools. Datasets might also include proxies, or pieces of data that might correlate with another type of information, such as a zip code for demographic information or, in some cultures, last names for religion.⁸⁷ Housing and employment data used in criminal-risk assessments have proved to be strong proxies for “race” and class.⁸⁸ An algorithm may not explicitly be programmed to make such a connection but it may nonetheless learn to do so. Proxies can be subtle (and sometimes unexpected by human programmers). For example, an individual’s online presence might serve as a proxy for age: An AI screening tool might distinguish between applicants with social media accounts and those without, or between types of social media accounts, both of which distinctions often reflect a user’s age.

Data Preparation

The data preparation stage of the machine learning life cycle involves multiple steps. Data scientists and data engineers first integrate data from multiple, disparate sets into one set in a single format; they then “clean” it by, among other things, filling in missing information, discarding other information, looking for outliers, and dropping features that might lead to data leakage (where the same data used to train the AI are encountered in actual use, potentially tainting the result by making it “easier” or more likely for the AI to find a match that would ordinarily occur in real-world conditions) or that might be unethical or illegal to consider.⁸⁹ The last step is feature engineering, or “mathematically transforming features to derive new features.”⁹⁰ In short, there is much room for “creativity” and choice⁹¹ at the data preparation phase, so the expertise, care, and worldview of the data scientist and data engineer have real impact.

Modeling—and Types of Models

Once the data are curated and prepped, engineers “choose a machine learning model to use, supply the data, and let the computer model train itself to find patterns or make predictions. Over time the human programmer can also

tweak the model, including changing its parameters, to help push it toward more accurate results.”⁹²

In general, there are, at least currently, three categories of machine learning models: supervised learning, unsupervised learning, and reinforcement learning. Each category is described in Types of Machine Learning Models and Other Terminology, below.

Testing/Evaluation

After a model is made and the machine is trained on training data, it is next “stress-tested”⁹³ with new data. “Some data is held out from the training data to be used as evaluation data, which tests how accurate the machine learning model is when it is shown new data. The result is a model that can be used in the future with different sets of data.”⁹⁴ Experts are quick to point out that “leakage” between the training dataset and the testing dataset will undermine the value of the tests; if the machine is being shown the same data on which it was trained, its performance will seem better than it might be against new data. The remedy is clear: separate and distinct datasets; however, data lineage is not always known, clear, or available in the ways lawyers and judges understand chain of custody.

Deployment and Monitoring

The accuracy or reliability of an AI system can degrade over time if inputs shift away from training data⁹⁵ or immediately if new inputs and training data simply differ. As such, AI systems must be constantly and continuously monitored and tested even after they are deployed in the field.⁹⁶ A system trained to recognize video footage of battlefield tanks at night might, for example, misidentify a dark box that is actually an air-conditioner unit on the side of a building as a tank.⁹⁷ This is an example of brittleness and technical bias.

Precisely because some ML-driven AI continues to learn or degrade as it operates, the relevance and reliability of AI output can be moving targets. It is important to keep in mind that AI models might reinforce inaccurate or biased

97. *Id.*

results as they learn. Opening discovery or testimony to AI/ML potentially opens the door to an array of subordinate questions involving methodologies, data, and testing. Judges may thus have to determine where it is essential for fact finders to understand the underlying methodologies, or just the conclusions or results derived from them.

In sum, not only does the AI field of study continue to evolve, but many individual AI applications also learn and change (for better or worse) over the course of their life cycles. Courts may need to test the reliability and validity of a given individual application both at precise points in its life cycle and against current best practices in the AI field. A court might examine not just how a particular AI application performed during its testing phase, but how it performed later in its life cycle, in the given, factually contested moment. A court might also consider whether a particular AI application meets the current best practices or standards in the AI field, such as those regarding the explainability and transparency of its computations and results. The evolving nature of AI also means that case law precedent may have limited or diminishing value when it comes to certain AI applications. Unlike polymerase chain reaction (PCR) DNA testing, for example, evidence generated by the same AI tool may vary in accuracy and reliability at different times.

Types of Machine Learning Models and Other Terminology

As alluded to above, there are three categories of machine learning models: supervised learning, unsupervised learning, and reinforcement learning. (Those categories, however, “simplify the enormous amount of complexity and variation in these systems.”⁹⁸)

Supervised Learning

“In supervised learning, the input data includes observations and labels; the labels represent some sort of true outcome or common human practice in reacting to the observation.”⁹⁹ For example, a dataset of photographs of lions

98. Ben Buchanan & Taylor Miller, *Machine Learning for Policymakers: What It Is and Why It Matters* 5 (Cyber Security Project, Belfer Center, June 26, 2017), <https://perma.cc/TZ4Q-UAX8>.

and tigers might have photos that humans have labeled lion or tiger.¹⁰⁰ Running through its algorithms, the machine would learn on its own ways to discern whether new photos of big cats were lions or tigers (or perhaps neither). Here, “true outcome” should be read as referring to an objective reality. In this example, the “true outcome” of lion or tiger is straightforward. But one could imagine ways in which the very act of labeling a piece of data might be value-laden—for example, whether a particular applicant was a “strong” or “weak” candidate for a loan. “For the machine learning system to make even better decisions than people, true outcomes rather than decisions should ideally be the labels, e.g. whether an applicant defaulted on their loan in the future rather than the approval decision.”¹⁰¹

Unsupervised Learning

“In unsupervised learning, the input data includes only observations.”¹⁰² Algorithms “analyze and cluster unlabeled datasets” to “discover hidden patterns or data groupings without the need for human intervention.”¹⁰³ Unsupervised learning is a technique for teaching a computer to find links and patterns in large volumes of unlabeled data without a determined outcome in mind. In contrast, supervised learning matches a data point, such as an image, to a known database of labeled data. Unsupervised learning is often used for “exploratory analysis,” with “no simple goal” in mind.¹⁰⁴ It is harder to check or validate because there is no given answer or labeled dataset against which to check the model’s outputs.¹⁰⁵ The government might use an unsupervised learning methodology to search for meaningful patterns and hidden links in phone call records, travel patterns, or trade and commerce records indicating sanctions violations. Here, the algorithm is not searching for a particular number or face but for meaning in otherwise unstructured data. Importantly, it might also find connections without meaning, for example, by “matching” faces in a facial recognition application with similar backdrops or lighting. When this occurs within the program’s internal calculations or neural network as explained below, it may be difficult, or impossible, to discern that the “match” is based on a factor irrelevant to the output objective.

105. *Id.*

Reinforcement Learning

“In reinforcement learning, the inputs are interactions with the real world and rewards accrued through those actions rather than a fixed dataset.”¹⁰⁶ Reinforcement learning introduces a “machine learning agent,” either an incentive or a desired goal, into the algorithmic code that might cause the machine to weight or improve its outcome on its own, as in the case of AlphaGo.¹⁰⁷ A shopping algorithm, for example, might do this by automatically adjusting its code based on whether a recommendation is accepted, rejected, or ignored.

Artificial Neural Networks

One currently popular type of model that crosses all three major categories of machine learning (supervised, unsupervised, and reinforcement) is the artificial neural network. Artificial neural networks (ANN) mimic, or seek to mimic, the brain through a set of algorithms.¹⁰⁸ Metaphorical “neurons” each mark a discrete point in the network where the system interprets a data input and responds to it, based on formulae programmed by humans, or, as the machine learns, by the machine.

Every neural network consists of layers of nodes, or artificial neurons—an input layer, one or more hidden layers, and an output layer. Each node connects to others, and has its own associated weight and threshold. If the output of any individual node is above the specified threshold value, that node is activated, sending data to the next layer of the network. Otherwise, no data is passed along to the next layer of the network. . . . Neural networks rely on training data to learn and improve their accuracy over time.¹⁰⁹

An oversimplified example drawn from IBM’s website¹¹⁰ illustrates the process: Sam wants to go surfing as often as possible but only in good conditions. Sam develops a simple algorithm to help him decide each morning whether it is a good day to go. One input will be the water temperature; one the height of the waves; another the weather conditions; and the last the number of recent shark sightings. Each of these inputs will be assigned a weight, or a multiplier, representative of how much Sam values it. The shark multiplier will be negative. If the sum of the inputs and their multipliers is greater than a predetermined value, that neuron will “fire” or turn “on,” and will send an electronic signal or output

110. See *id.* The website presents a similar example with mathematical formulas.

to the next neuron to start calculating whatever decision it helps the system make (whether Sam should wear a wetsuit, perhaps). If the sum is less than the predetermined value for “getting to surf (yes),” the neuron does not fire, and the output signal never reaches the next neuron.

Deep Learning

Neurons are metaphorically assembled in layers, that is, time-ordered sequences. If, in between the input and output layers, there are three or more (potentially many more) hidden layers, the ANN is called a “deep learning” model.¹¹¹ Deep learning can be used in supervised, unsupervised, or reinforcement learning models.

Neural networks are sometimes referred to as the “black box” of machine learning. Because the machine is learning and adjusting as it goes, engineers may not be able to determine with certainty what the machine is weighing, how, and with how many input and output layers within the internal neural network. This is important where, for example, coding or data bias may impact the quality of the ultimate predictive outcome. A theoretical¹¹² algorithm designed to predict recidivism, for example, might use many different data inputs as well as patterns it derived from the data of the general population in generating a predictive percentage risk that an individual defendant will return to prison. But with deep learning the judge and lawyers might not know what decisional weight, if any, was assigned to “race,” location, past convictions, the letter “S” in a defendant’s name, or population trends inapt to a specific defendant.

Although deep learning and neural networks are the most common AI methods, they are not the only ones. AI is a dynamic field, and new developments could change how algorithms process and ascribe meaning to data.

Importantly, increasingly there are methodologies that engineers can incorporate to make such internal calculations more transparent, or fully transparent, to users. Research is underway in academia and by organizations such as the National Institute of Standards and Technology (NIST) to enable more transparent neural networks that will explain AI outputs on a global or per-decision basis after the fact so that AI users and those who are impacted by AI outputs might more fully understand the parameters and weights that are or were applied within.¹¹³ There are different approaches for doing so. Decision-tree models, for

111. *What Is Artificial Intelligence (AI)?*, IBM, *supra* note 68. See also *What Is Machine Learning (ML)?*, IBM, <https://perma.cc/JSA9-CXM6>.

112. Current recidivism algorithms are often proprietary but may lack sophistication and complexity.

113. *AI Fundamental Research—Explainability*, NIST (June 16, 2022), <https://perma.cc/3YX5-JC8Q>.

example, might run through a series of “if-this, then-that” analyses to essentially map out the input-to-output run of the network.¹¹⁴ Counterfactual algorithms seek to identify factors that were determinative by showing which factors would change the output, e.g., by identifying factors that caused a neural gate to open or close.¹¹⁵ Depending on the algorithm and its use, the factors could be benign, like a color or a shape, or potentially problematic, like “race,” or a proxy for “race.” Generally, the more detailed and layered an algorithm, the more accurate it is likely to be in its outputs (assuming good underlying data and coding methodology), but also the more difficult it will be to explain the output. In addition, not every AI application warrants, or would seem to require as a matter of law, the same measure of explainability. What users and courts require or expect to understand about an AI application that generates a credit score, a thunderstorm warning, or a bail risk decision will likely be different.

Moreover, what is transparent may not be explainable if it comes in the form of mathematical modeling and equations. A 2021 NIST report notes “that the failure to articulate the rationale for an answer can affect the level of trust users will grant that system. Suspicions that the system is biased or unfair can raise concerns about harm to oneself and to society.”¹¹⁶ The report identifies four core principles of “Explainable AI”: (1) “Explanation,” or whether the system provides the evidence that it relied upon for its outputs; (2) “Meaningful,” or whether that evidence or data is understandable to the user or recipient; (3) “Explanation Accuracy,” or whether the explanation actually reflects how the output was generated and the metrics used to make that judgment; and (4) “Knowledge Limits,” or whether the system produces outputs within the parameters of its design and training and whether those outputs reach the intended or appropriate confidence level.¹¹⁷ The study concludes by noting that there are some aspects of decision making and explanation that humans are better at than AI-empowered machines and some that algorithms are better at than humans.¹¹⁸

As with so many aspects of AI, the questions for policy makers and legal decision makers, like judges, are firstly, when to use AI at all for a particular task, and secondly, when using AI, how to structure human-machine collaboration so as to maximize the benefits of AI and minimize and mitigate its risks, including the risks of bias and lack of transparency. We call this latter challenge the Centaur’s Dilemma, after the mythical animal that is half human and

114. P. Jonathon Phillips et al., NISTIR 8312, Four Principles of Explainable Artificial Intelligence 12 (Sept. 2021), <https://doi.org/10.6028/NIST.IR.8312>.

118. *Id.* at 18–21.

half horse as well as the Department of Defense adoption of the “Centaur Model” to describe human-machine teaming. Here the centaur is part machine and part human and the dilemma is to determine how much human choice and control to require and how much autonomous machine choice and control to require (or permit) of each AI application, output, or decision. Three related questions for judges and experts to ask in the context of AI-generated evidence are:

- whether a transparent and explainable methodology was used, and if not, why not;
- whether the methodology used has been demonstrated to be effective in the context for which it is offered; and
- whether the AI-generated evidence is understandable to the factfinder for the purpose for which the AI output is being used or offered.

Judicial Roles and High-Level AI Takeaways for Judges

Judges will play at least five roles related to AI in the courtroom. First, judges will oversee the process of discovery in civil and criminal cases: where AI outputs are at issue or may be offered as evidence, judges will need to determine how much discovery to permit into the AI’s design, background data, and accuracy. Second, they will serve as evidentiary gatekeepers, applying the Federal Rules of Evidence (or state equivalents) to proffers of testimonial and documentary evidence, including and perhaps especially Rules 401, 402, and 403. Third, judges will serve as guardians of the law (some may prefer the phrase “interpreters of the law”), protecting and preserving the rights and values embedded in the Constitution as well as statutes and rules of procedure and evidence. Fourth, judges may serve as potential AI consumers who need to decide whether to receive, review, or rely on AI-generated outputs to inform bail, probation, or sentencing decisions. Some risk-assessment tools rely on predictive algorithms, raising legal concerns about due process, equal protection, and confrontation, triggered in part by technical concerns about accuracy and bias. Fifth, judges will serve as communicators, translating the sometimes complex inputs behind AI into plain-language instructions for jurors and case law precedent for lawyers.

The previous sections introduced the technology behind AI. This section highlights nine technical aspects about AI of which judges should be aware in their roles as referees, gatekeepers, guardians, potential consumers, and communicators. The following sections address bias, predictive algorithms, algorithms used by lawyers, discovery, and AI as evidence.

There Are Many Different Methodologies and Designs

Because there are different AI methodologies, each application should require authentication and validation, not just in concept but as applied in each context and potentially moment in time. As described above, within the category of machine learning, there are multiple ways to teach a machine to learn using data,¹¹⁹ the most common being supervised learning, unsupervised learning, and reinforcement learning. Any of those might make use of artificial neural networks employing deep learning with several or many hidden layers.

Yet there are still other theories and methods for teaching computing machines to learn, each built into the operative algorithm. These alternatives include evolutionary or genetic algorithms, inductive reasoning, computational game theory, Bayesian statistics, fuzzy logic, hand-coded expert knowledge, and analogical reasoning.¹²⁰

In addition to deciding on the learning methodology, computer engineers must also decide how much depth and breadth to apply to any deep learning neural network—in other words, how widely the algorithm will search (breadth, also referred to as width) and how many layers of internal inputs and outputs it will employ before providing an output (depth). With facial recognition, for example, breadth might represent the number of datasets an algorithm searches. Depth might be illustrated by the number of points on a human face the algorithm is programmed to analyze before providing an output. Increases in network size tend to be required to capture the complexity of modern AI algorithms. Such increases create a challenge, however: the greater the depth—the number of layers in the neural network—the harder it will likely become to determine which factors were determinative in the output prediction. This could become important to the extent there is risk or concern that bias or some other factor might undermine outcome accuracy.

Some algorithms are designed to provide outputs, plural—for example, a range of match faces with a facial recognition algorithm, or a range of products with a shopping recommendation algorithm. As mentioned above, given the black box problem of deep learning, there are additional methodologies engineers can incorporate or substitute to make an algorithm's internal calculations more transparent, or fully transparent, to users.

A court will need to satisfy itself that the specific AI application (as opposed to AI generally), its design, and its specific use meet the foundational requirements for the purpose for which it is being offered into evidence or used by a court. Verification will entail considering the theory and methods behind the AI,

119. *Id.* at 3.

120. See The Weaponization of Increasingly Autonomous Technologies: Artificial Intelligence 5, United Nations Institute for Disarmament Research (UNIDIR) No. 8 (2018), <https://perma.cc/HQM5-BHWQ>.

including the nature of the datasets used to train, test, and validate the AI, as well as, in the case of deep machine learning, inquiring into the design of the neural network.

Most AI Is Iterative and Should Be Tested and Validated Continuously

Many AI/ML models learn, for better or worse, as they proceed.¹²¹ That means AI systems need to be tested and validated on an ongoing basis. In other words, if a machine is learning, its variance rates and accuracy should change as well—in theory, in the direction of greater accuracy and lower variance, but, as described above, the machine’s accuracy and reliability may degrade.

If the underlying data are biased or poorly selected in that they do not match real-world conditions, that may undermine the accuracy of the AI or embed bias in the AI’s application. Results from the testing phase may not match actual outputs in the field. In context, judges, experts, and litigators will have ample reasons to test the reliability of any AI evidence offered in court, and judges will need to determine in context just how wide to open the door to expert testimony and discovery about matters like datasets, algorithmic design, search parameters, bias, and neural network architecture.

Humans Are Always Involved

Machines do what they are programmed to do, not because they choose to do so, but because they are programmed to do so—including learning on their own. Software drives machines. And humans, in the first instance, write software and design programs. Behind each AI application there are human choices, human values, and human bias that may impact the operation of the algorithm and the accuracy of its results. Humans select not only the data but also the metrics the algorithm uses to frame and analyze that data.¹²²

In the operation of AI, humans are also involved. Under current vernacular in the AI field, humans are said to be “in-the-loop,” “on-the-loop,” or “out-of-the-loop.” As implied, in-the-loop describes humans in functional control of an application, deciding when and how it is used. On-the-loop describes humans observing AI but not controlling it, but with the option to do so. Out-of-the-loop describes an autonomous or semiautonomous system operating

121. Other models might learn during training but are not capable of further learning on their own during deployment. Still others might be trained and later adjusted or retrained only with human help or supervision.

122. Remarks of Nisheeth Vishnoi, *supra* note 22.

automatically. These terms are imprecise in at least two regards. First, they describe a wide variance of conduct within each category and thus may convey a sense of control and oversight that is, in operation, absent. More to the point, they are insufficiently descriptive to apportion accountability and responsibility for the purpose of legal judgments. Take the example of a “driverless car.” Some driverless cars are configured to employ a safety driver as an observer or, in the case of a semi-driverless car, a driver with shared responsibility for the operation of the vehicle. Other driverless cars, without a human in the car, may operate under remote human control. In each of these three scenarios, at any moment in time the vehicle may be driving autonomously without human control, it may be following the explicit direction of the remote or present driver, or the human driver may be keenly observing the operation of the vehicle without overriding the car’s computers. In each case, humans were out of, in, and on the loop.

However described, a human is always involved with an AI application. For courts, the factual questions will be: Who designed the seed algorithm? Using what metrics or weights? Who trained the algorithm? Using what data? Who collected the data? Who validated the data? Who used the algorithm or monitored its use? These factual questions will lead to legal questions. For example, where *Crawford*¹²³ applies, multiple persons might be called as witnesses regarding the design and operation of an AI algorithm. Because humans are always involved with AI, there will be persons who can, if relevant and material, provide answers to the sorts of questions essential to authenticating and validating the use of AI:

- What is the AI trained to identify, how has it been weighted, and how is it currently weighted?
- Does the system have a method to transparently identify these answers? If not, why not?
- Are the false positive and false negative rates known, if applicable, or hallucination rates? If so, how do these rates relate to the case at hand?
- How has AI accuracy been validated, and is the accuracy of the AI updated on a constant basis?
- What are the AI’s biases? (See “Probing for Bias” questions below.)
- Is authenticity an issue?
- How do each of these questions and answers align with how the AI application is being used by the court or proffered as evidence?

Judges might also consider that a qualified AI expert or witness ought to be able to credibly answer these questions, or perhaps the expert or witness may not be qualified to address the application at issue.

123. *Crawford v. Washington*, 541 U.S. 36 (2004).

AI Predicts, It Does Not Conclude

AI is generally a predictive tool based on statistics. Through weighted calculation an algorithm predicts an outcome. A facial recognition algorithm, for example, might predict the likelihood that one photograph in a set of fifty returned by the machine as potential matches is indeed the correct match. What the algorithm does not do is confirm that an image presented is in fact a match in the same way that a chemical test confirms the presence of a compound. This is one reason why engineers use the term “confidence threshold” in describing the accuracy of an application. The FBI facial recognition algorithm, for example, is designed not to conclusively find a match but to find pictures that might match. As the 2019 GAO report on the subject stated, the algorithm is most accurate when offering a range of potential matches.¹²⁴

In the case of a Google search algorithm, for example, the algorithm is predicting that one of the provided links will respond to the query. This is self-evident if one asks a question like, “Who was George Washington?” The algorithm is likely to provide a Wikipedia link to a webpage about the first U.S. president. It is also likely that many readers will conclude that the algorithm has *answered* the question: “George Washington was the first president of the United States.” It has not. The algorithm has predicted that one or more of the links provided will answer the question, and likely in descending order of probability as the links are listed. Modify the question a bit, and the predictive aspect becomes more evident. If you ask, “Who is my friend George Washington?”—a quite different person than the first president—Google responds with sites listing the first president’s friends. That is the algorithm’s best prediction as to which links will answer the question based on code matching, likely use of the word “friend,” and the way prior readers have responded to similar word searches. In other words, like a shopping algorithm, the search algorithm is tracking whether the searcher “bought” the response by clicking on it and measuring how long the searcher stayed. Of course, it has not answered the question at all and is nowhere near to providing a link that will answer the question about the user’s friend George Washington—not without more details that can help shape the predictive outcome.

In a medical context (perhaps coming before a court in a malpractice case) an input might query, “Is this a picture of a benign or malignant tumor?” To respond to that question, an algorithm trained on prior pictures of tumors might break the picture into quadrants and subcomponents, as a facial algorithm might do, and then compare the picture submitted to database images of tumors. Based on all accessed images of benign and malignant tumors, the algorithm will predict whether the picture is a better match for one or the other. What the algorithm offers that a human does not is the capacity to search multiple databases rapidly for comparative patterns, as well as the ability to break the image into

124. See Harwell, *supra* note 44.

subordinate components in a way humans cannot, and thus to see connections and patterns the human eye cannot. Moreover, the algorithm is neither affected by fatigue nor subject to ordinary human distractions, pressures, and emotions. If the algorithm has not been trained properly, or trained to identify new patterns, it is less likely than a human to identify a rare disease or new manifestation of an existing disease, raising the prospect of a false negative. One can imagine in a malpractice case how the parties might litigate the manner in which any human-machine teaming occurred. Where a tumor was not diagnosed, a plaintiff might argue that doctors placed unreasonable reliance on a “negative” AI output. Alternatively, a plaintiff might argue an unreasonable lack of reliance if a broader use of AI databases was not employed.

For sure, algorithms are used to “make decisions” as well as to predict outcomes. Algorithm-generated credit scores, for example, are used to determine eligibility for loans and credit cards. The algorithm produces the score, but it is humans who decide what parameters should inform that score and it is humans who decide what score should be used as a threshold cutoff for loan eligibility or rates. The algorithm in essence is making a numeric prediction about the reliability of the loan; the human is making a decision to rely on the prediction and at what confidence level to do so. Likewise, driverless cars make “decisions” all the time. However, they do so based on human programming and values embedded in that programming, a centaur model of decision, even in a fully autonomous vehicle.

Currently, Accuracy Often Depends on the Volume and Quality of Data

If an algorithm has only been trained on one picture of a cancerous tumor or has never seen a cancerous tumor, then it will be less likely to correctly identify a tumor in response to a query. This is an important limitation on the capacity and accuracy of current AI. Moreover, volume here is not measured in hundreds, but in hundreds of thousands of pictures. A human performing the same task with only one picture will more likely identify a tumor using intuition, judgment, and experience, as well as external factors the algorithm cannot assess, like the patient’s unique pain threshold or situational responses to touch and feel. As discussed above, today’s large language models (LLMs) train on vast datasets, though researchers are developing other types of modeling less dependent on large datasets, such as information lattice models.

The quality of data is also important and will likely remain so. Data can be flawed in a variety of ways. Dated data, known as stale data, are more likely to generate inaccurate results (“temporal bias”), as are incomplete or underrepresentative data (“population bias”). A facial recognition algorithm trained on driver’s license pictures or parole pictures is more likely to identify pictures reflecting the demographics represented in the databases. This has the potential

to increase the false negative rate for underrepresented groups and to increase the false positive rate for overrepresented groups.

Likewise, data may possess flaws that impact algorithms but not humans. Algorithms may discern links in data or perceive patterns in data creating matches, based on elements or numeric formulas that are unintended or that humans would not discern. In our bank robber scenario, the algorithm may match digital sequences found in the image based on irrelevant factors, such as a common backdrop in a photo or pattern on the robber's face mask. In either instance, there may be a match but not a meaningful match. If this occurs within the neural network, it may skew a result in a manner unseen and unknown to the user. The output is a face, but the user may not know this face has been passed through to the output stage because of similarities in the picture backdrops, not the face itself, because AI systems often are unable to explain their results.

Some AI Is Not Explainable but More Transparent Methodologies Are Being Developed

The black box of neural networks renders many AI outputs unexplainable. However, the field of explainable AI is expanding as is the development of tools allowing reconstruction of the reasoning behind AI outputs. This capacity has many legal implications, such as the ability to reconstruct or explain AI results that are biased, incorrect, or result in accidents (driverless cars) or mistakes (medical diagnoses). Therefore, users of AI, including proponents of its admission into evidence, should articulate what is explainable and not explainable and why, based on the tools available to do so at the time of use or at evidentiary proffer.

As will be seen below, this limitation makes certain predictive algorithms particularly susceptible to error. It is essential that judges and factfinders understand the ways data and design can embed witting and unwitting bias, as discussed in the section below titled "AI Is Biased," impacting the predictive accuracy of AI.

The Heart of AI Is the Algorithm

If the accuracy of an AI application often depends on the amount of data on which it is trained, it depends even more on the algorithm applied to that data. As noted previously, an algorithm is a process that guides the software determining which data are selected and how they are weighted. The *choice* of algorithm is a choice of decisional metrics or framework—an analytical lens or value-laden perspective.

Using the analogy of an algorithm as the recipe a chef uses: the chef chooses not only the end-dish but also dietary restrictions (vegetarian, low sodium),

flavor profile (sweet, acidic, spicy), cultural heritage, ingredient measurement system (metric, English), etc. As this is AI, not a simple algorithm, the chef supplements her recipe every time she cooks in a way that only she knows. What is more, the sous chefs supplement the recipe when no one is looking. Thus, in some cases no one can be quite sure what gives the recipe its distinctive taste; and, if the chef knew, she would not tell because she wants customers to continue to come to her restaurant. Restated, if one knew the Google search algorithm, every search platform could, in theory, be as good, provided of course, that the algorithm could access and apply the same level of data (Google's data) with which to train, test, validate, and apply the algorithm.

Thus, the heart of many disputes about the use of AI-generated evidence in court or the use of AI tools to inform judicial decision making will revolve around access to and disputes over the accuracy and quality of algorithms. This may be the proprietary secret AI companies want most to protect, because it is the recipe to their market success and because too much inquiry may undermine confidence in the AI's capacity.

Here are several questions judges should contemplate before using an AI application or admitting one into evidence:

- To what extent will the court allow parties to discover the content of an algorithm? Will discovery include the data on which the algorithm was trained, tested, and validated?
- In the context presented, do due process, equal protection, or the right to confrontation require access to an underlying algorithm or its supporting training, validation, and use data, or to the human designers, programmers, and users?
- If discovery is permitted, what safeguards, if any, will the court use to protect the proprietary value of the discovered information? In the context of criminal risk assessments, do rights to due process, equal protection, or confrontation require the algorithm and underlying data to be made public?
- To what extent is discovery necessary to apply *Daubert*? (See below.)
- In the context presented, can ex parte and in camera judicial review adequately and legally substitute for public adjudication? Or should the parties or the public have access to the algorithms and data?

These questions might lead to further questions:

- Will the court or a jury be able to understand the underlying technology, and is such understanding necessary for a fair adjudication of the facts?
- If so, what is the appropriate mechanism to provide that understanding?

Narrow AI Is Brittle

As noted earlier, narrow AI is not particularly good yet at situational awareness. The driverless car may not timely identify novel objects on the road. Judges will therefore have to consider whether the scenario or fact for which an AI application is offered presents questions involving situational awareness. If so, they should then ask in what manner the algorithm, the data, and the training are keyed for such circumstances and whether the accuracy rate varies in such contexts. They might ask:

- Is the AI in question brittle?
- What is the error rate, i.e., the rate at which the AI reaches the wrong (false positive or false negative) result?
- Does the AI perform in the same manner and with the same accuracy in “real-world” operation as it does (or did) in lab conditions and testing?

AI Is Also Nimble

Proponents of AI tend to emphasize its strengths, opponents its weaknesses. Of course, the strengths and weaknesses of any AI application must be assessed on a case- and application-specific basis. One strength of AI, however, is its general capacity to identify, aggregate, and derive meaning from data in ways that humans cannot. With driverless vehicles, for example, this capacity is simply illustrated by the fact that, with the right sensors, driverless vehicles can “see” in all directions at once and calculate, with mathematical precision at speed, the distance needed to brake. AI can also identify patterns, anomalies, and links in data that humans cannot. In many cases, AI is better than humans at tasks like comparing pictures of tumors to database images of benign and malignant tumors. And AI can do all this instantaneously and, in many cases, more consistently than humans, a point illustrated with reference to comparisons between humans reviewing documents for security classification or discovery purposes and algorithms doing so. Different humans often reach different conclusions. A good AI will be more consistent, albeit it might be more consistently correct or incorrect in its result. Of course, depending on the context, humans will need to determine whether the patterns and links that are made are relevant and reliable for the purpose presented.

Generative AI Can Hallucinate

AI can create false content, as described above.

AI Is Biased

AI, like humans, has biases. It is also an area of AI that will attract adjudication, as the next section will suggest.

Bias

Bias is often associated with the human application of stereotypes or prejudices to an ethnic, gender, racial, or other identity group. In U.S. law, such categories are generally recognized as “suspect classes” in equal protection law under the Fifth and Fourteenth Amendments.

As judges know, any application of law that treats classes of persons differently from the populace as a whole, if challenged in court, must pass either a strict scrutiny test, intermediate test, or rational basis test, depending on the suspect class. An application of law that is facially neutral but adversely affects one protected group more than another might also be subject to a disparate impact claim. For example, a hiring algorithm that disproportionately favored one group over another might be subject to a disparate impact lawsuit.

However, when technologists consider bias, they are often referring to the variance between what an AI is intended to predict or perform and the accuracy with which the algorithm predicts or performs that function. This “algorithmic bias” might include social biases incorporated into the AI’s design and implementation—but with AI, bias is usually defined more broadly as a witting or unwitting (conscious or unconscious) predisposition that can undermine the accuracy of an AI application or output. Bias thus addresses a range of cognitive tendencies that can adversely affect objective analysis and technical accuracy. Significantly, AI bias also incorporates and describes unintentional design and data flaws that can impair the accuracy of AI outputs. Because humans design AI algorithms and choose the data that trains the software, developers’ choices can incorporate varying types and degrees of bias into the algorithm’s design. Unintentional bias is often difficult to discern because it is embedded in the design of an AI system or in the data used to train an algorithm. Decision makers may subsequently place undue reliance on AI outputs because they do not know to what extent, if any, the outputs are predicated on biased input, e.g., a facial recognition algorithm or a predictive algorithm trained on limited or poor-quality data.

When it comes to algorithmic bias, there are four immediate takeaways for judges:

1. Judges (and the law) use the term *bias* in a different and more specific way than computer engineers. For AI specialists, algorithmic bias refers broadly to the difference between an algorithm’s output and the desired outcome, not necessarily to bias of the sort addressed by the equal

protection clause. Algorithmic bias can be caused by human prejudice of the sort courts typically address, cognitive bias of the sort behavioral scientists typically address, design and data flaws of the sort computer engineers address, or all of these (admittedly overlapping) categories.

2. *There is no such thing as a bias-free algorithm.* There is a tendency to believe that “numbers are neutral” and present objective truths, but numbers may produce erroneous or inaccurate results.¹²⁵
3. Through careful engineering, thoughtful use of data, and adjusted algorithmic weights, it is possible to create AI systems with lower margins of error.¹²⁶ It is also possible that reducing one form of bias by adjusting, for example, the underlying analytical framework or datasets can allow other forms of bias to creep in.
4. Judges, as evidentiary gatekeepers, can mitigate or block the use of weak or biased AI by asking the right foundational questions. Knowing what to ask starts with an understanding of the forms that algorithmic bias might take.

Forms of Algorithmic Bias

The United Nations Institute for Disarmament Research suggests several categories and sources of algorithmic bias.¹²⁷ Starting with the Institute’s findings, we highlight eight forms of potential AI bias: statistical bias, moral bias, training data bias, inappropriate focus, inappropriate deployment, interpretation bias, unwitting human bias, and intentional bias.¹²⁸ We also discuss the issues of overfitting and outliers as potential sources of bias.

Statistical bias

Statistical bias might occur when an algorithm’s predicted outcomes deviate from a statistical standard, such as the actual frequency of real-world outcomes.¹²⁹ This deviation can be caused by bad statistical modeling or incorrect or

129. *Id.* at 2.

insufficient data. The difficulty of calculating the infection or mortality rate of a disease such as Covid-19 illustrates the problems that can result. At the outset of the pandemic, AI-driven modeling of infection rates differed widely, in part because the models could not account for those who had the disease but did not show symptoms. Thus, it was only within closed data samples, such as the passengers aboard a cruise ship, that the models could account for an asymptomatic pool (because all the passengers were tested before they were allowed to leave the vessels). The risk with cruise ship findings was having too small a sample pool, and one not necessarily random or representative of a cross-section of the population in more typical, land-based living conditions.

Moral bias

Moral bias occurs when an algorithm's output differs from accepted norms (regulatory, legal, ethical, social, etc.).¹³⁰ For example, an algorithm may weigh factors that the law or society deem inappropriate or do so with a weight that is inappropriate in the context presented. A hypothetical predictive crime algorithm might use data derived from the current prison population to “predict” rates of recidivism. Given the disproportionate number of people of color imprisoned, the algorithm might produce biased results by explicitly or incidentally weighing “race” and ethnicity or their proxies, and perhaps do so within the black box of a neural network. AI neither thinks nor understands the world like humans, and unless instructed otherwise, its results can reflect an ignorance of norms found in the equal protection and due process clauses.

Training Data Bias

Like humans, AI learns from experience; however, AI experience is based exclusively on data, often hand-selected by a human developer. Inaccuracies or misrepresentations in this data can perpetuate biases by embedding them in algorithmic code or weights.¹³¹ In other words, the results are skewed; the algorithm produces wrong answers. As presented in the discussion of the machine learning life cycle, above, biased data might be outdated (“temporal bias”), under- or over-representative of certain groups (“population bias”), or simply reflective of individual or systemic social prejudices. For example, an algorithm intended to identify potentially successful job applicants might rely on past successful job performance as an indicator of future successful job performance and derive from that data certain preferred hiring characteristics like age, school, and experience.

130. *Id.*

131. *Id.* at 2–3.

But if the data are from a period when women or other marginalized groups were not numerically well represented in the relevant employment market or educational pool, at least 50% of the potential workforce might be excluded from results. Such data might likewise incorporate human bias in the form of a past company policy to only hire persons from certain schools. The criterion might have seemed objective when the company adopted the policy, but it necessarily incorporates the socio-economic and other biases of the college admissions processes of the time. Thus, the algorithm might exclude candidates as good or better than those from whom the dated dataset was sourced.

Similar concerns have been raised about algorithms designed to inform parole decisions by predicting recidivism risk. These algorithms, critics argue, appear¹³² to rely on socioeconomic status, neighborhood location, and past crime statistics as predictive criteria of future criminal conduct, potentially resulting in a self-fulfilling prediction with disparate racial and socio-economic effect. Criminal risk assessments used in bail and sometimes sentencing meet with analogous criticisms, discussed below under Algorithms That Predict Human Behavior. Proxies for suspect categories, such as zip codes or last names, might also introduce bias into data, as discussed above under How Machines Are Trained to Learn: The Machine Learning Life Cycle. Proxies may be hard to detect. Additionally, data used to test or validate algorithms might also infuse bias.

Inappropriate Focus

This occurs when an algorithm's training data are ill-suited to the algorithm's task.¹³³ This might lead the algorithm to identify factors within a neural network that, though objectively reasonable, are logically irrelevant to the desired outcome. An algorithm that matches faces based on colors, backdrops, or lighting demonstrates inappropriate focus bias.

One can readily imagine how similar bias might migrate into datasets designed to train machine-learning AI to predict terrorism recruitment or threats. To begin with, the data may rely too heavily on international versus domestic actors owing to the designer's perceptions or the selection of training data. And because the amount of data may be limited (in contrast to, say, an Amazon or YouTube algorithm), human actors may put too much credence in the reliability of the predictive output. In general, the more data used to train a predictive algorithm, the more accurate the result. An algorithm trained to predict terrorism risk based on a stereotyped "terrorist profile" will, unsurprisingly, be best at locating persons who meet that profile. More persons with the profile

132. They are often proprietary, as was the case for the risk assessment tool at issue in *Loomis v. Wisconsin*, 881 N.W.2d 749, 759 (Wis. 2016), *cert. denied*, 137 S. Ct. 2290 (2017).

133. Baker, Hobart, & Mittelsteadt, *supra* note 8, at 4.

will be identified as potential terrorists, and more may be found to be engaged in suspicious activities because of increased scrutiny, thus appearing to validate the algorithm and the choice of criteria. Potential terrorists who don't fit the profile may be erroneously omitted.

As the example demonstrates, the risk is not just in false positives, which is the focus of much bias analysis to date, but in the potential failure to identify credible risks: false negatives. Disparities in facial recognition data between males and females or people of different ethnicities could lead to greater inaccuracies in identifying female subjects or people of color, increasing the number of false positives—for example, the number of innocent people selected for extra screening or questioning at airports. In contrast, an inability to identify known subjects or threats—for example, a missing or wanted person or Amber Alert kidnap victim on CTV camera feeds—has security implications.

Inappropriate Deployment

This happens when a system is used in a context for which it was not designed, tested, and validated.¹³⁴ For instance, a driverless car trained for driving in the United States might not be able to handle left-hand driving in the United Kingdom. A human (we hope) would adapt to such a change; a driverless car algorithm would need more training.

Interpretation Bias

This occurs where an algorithm's output is confusing or subject to incorrect interpretation by those working with the technology.¹³⁵ Users of facial recognition technology might expect singular, or perfect, matches, in contrast to what most facial recognition algorithms—including the FBI's—actually produce, which is an array of potential matches, none of which might represent the individual sought, leaving the interpretation and conclusions to human users.

Interpretation bias can also occur because of ambiguity embedded in the algorithmic design—for instance by software designers who, unaware of cultural or linguistic cues, overlook or misuse phrases and concepts, skewing results. Sometimes the reasoning behind a match is necessary to understand its value or import. Engineers might design algorithms to search for particular words or phrases, with the goal, for example, of identifying persons engaged in radicalizing internet users. Insufficient knowledge of culture and language, however, could have unintended consequences. Phrases like “the bomb,” “knock 'em

134. *Id.*

135. UNIDIR Resources No. 9, *supra* note 127, at 5.

dead,” and “kill it,” all can mean something in American vernacular quite different from what might be intended in a terrorist cell. By the same token, an algorithm designed by an engineer who, for example, does not know the import of “the fourteen words” (which form two slogans of white supremacists) may inadvertently enable a potential data threat stream to escape detection.

Unwitting Human Bias

This refers to the unintentional infusion into an application of human preferences, stereotypes, values, fears, or knowledge. Consider an algorithm intended to predict risk. An engineer might apply engineering principles to a risk equation. But what is risk? An algorithm will almost certainly incorporate the particular fears, risk tolerances, and perceptions of its designers. (The problem may be compounded when the algorithm is both human and machine generated—a “centaur”—clouding where and how bias might have entered the system.) But the algorithmic equation does not account for human behavior, which is informed not only by the calculation of objective zero-sum costs but also by the emotional impact of fear.

Use of racial, gender, and other social descriptors in algorithms is inherently risky and potentially fraught with ethical and legal issues. One can imagine how both intentional and unintentional human bias might enter the equation as a computer scientist embeds what he or she believes are parameters associated with a “race” or ethnicity into facial recognition software. Racial and ethnic categories are inherently ambiguous social constructions covering wide continuums of individuals. Similarly, one can see how nuance might “fool” an algorithm intended to identify age based on the subtle distinctions of faces alone without allowing for the possibility of make-up or efforts at disguise. Bias may also occur unwittingly in machine-learning applications that may not be designed to depend on social identity descriptors but nonetheless rely on such characteristics within the neural network black box. Bias can lead to both the under- and over-inclusion of the targeted group, as “race,” ethnicity, gender and other social categories are malleable concepts. Scholars like Charles Szymański of the University of Białystok note the risk of unintended age bias, as occurred with the use of an employment screening algorithm that sorted candidates based on whether the candidate submitting an application utilized the default browser or had downloaded a substitute browser. The tool, which was intended to identify technology-savvy applicants, had the unintended effect of excluding candidates based on age.¹³⁶ In effect, the choice of browser served as a proxy for age.

136. Charles F. Szymański, *The Future of Labor Law*, Presentation at Trnava University, Slovakia (Oct. 5, 2022).

Intentional Bias

Scientists, operators, and decision makers may use AI facial recognition tools or predictive algorithms to target disfavored or vulnerable groups. Algorithms can be designed to identify and select certain real and perceived social descriptors associated with “race,” gender, sexuality, national origin, religion, disability, and more. Facial recognition technology can identify and track certain ethnic groups as is the case in China with “Uyghur characteristics.” Clearly pernicious in the profiling of Uyghurs (or more accurately, a band of physical characteristics Chinese state security services associate with Uyghurs), such technology presents one legal question that may arise for judges: Whether, when, and under what controls is the purposeful use of social identity descriptors ever an appropriate search parameter?

On the one hand, there are qualitative differences between the reactive versus predictive uses of social identity descriptors. For example, using an individual suspect or victim description, including descriptors like “race,” gender, and age, in response to a credible, individualized predicate, in context, might make sense. Of course, one needs to consider that the initial social indicator that might trigger the use of an AI application may itself be affected by cognitive, societal, or the personal bias of witnesses. In the context of using facial recognition to search for a known suspect or a person identified in an Amber Alert, one would not necessarily expect law enforcement to employ “race”-, gender-, or age-neutral input or an algorithm incapable of searching for the specific or reported characteristics of the suspect or victim. Using individualized, known suspect descriptions as an “identifying factor” is “perhaps the least controversial use of race in the context of the Fourth Amendment” under federal case law.¹³⁷ However, as already noted, one potential challenge to individually based suspect descriptions is that to the extent social identities are fluid rather than fixed, they may be difficult to code, and they may be difficult for officials to implement fairly and accurately in AI and in general contexts.

On the other hand, using a suspect category and accompanying social identifiers to identify and predict persons who might engage or have engaged in an unlawful act—rather than relying on individualized, behaviorally based reasonable suspicion or probable cause—is an exercise in bias. Courts that have not “sidestepped” the issue have generally rejected explicit racial profiling based on “incongruity” arguments (that a particular person is “out of place” in a particular location or neighborhood).¹³⁸ Likewise, with exceptions in the immigration and border contexts, courts have rejected “propensity” arguments (that membership in a particular social group suggests a “propensity” for an individual to commit or have committed a crime).¹³⁹

138. *Id.* at 462–63.

139. *Id.* at 463–64.

Courts may need to consider whether an AI application might blur the lines between individual suspect identification and group profiling. An AI application—for example a facial recognition database—might cast a wider net than a traditional human law enforcement investigation, to the point where what started as an individual suspect identification begins to look more like group profiling, opening more people (all of whom or all but one of whom might be innocent) to suspicion and investigation.

Overfitting And Outliers

As Matt Mittelsteadt has identified,¹⁴⁰ two significant risks posed by the use of machine learning in criminal risk assessments and other legal contexts are “overfitting” and “outliers.” Overfitting occurs when the ML model is too tailored to the data it has been trained on and does not account for ambiguities or variations.¹⁴¹ Generally in machine learning development, this problem is addressed by ensuring that the data the ML algorithm is trained on are separate from the data it will encounter in use (provided that the training data is still representative of the data that will be encountered in use). A model thus “generalized” should be flexible enough to correctly interpret data it has not encountered.¹⁴² If this data separation is not made, biased results may occur.

As discussed below, some courts have already used algorithms in sentencing. Overfitting, like other biases and weaknesses of AI, presents particular risk in sentencing and other applications where liberty interests are at stake. If a hypothetical ML sentencing algorithm is built on a training set of past offenders, the AI could design its neural network with results custom fit for those specific offenders. If a person reoffends, perhaps with a lesser crime, and his data are used to train the algorithm, there is risk that in calculating a sentence the algorithm might find and match his prior personal data and reproduce the prior sentence; statistically, the sentence will be the best match for his case. In essence, the algorithm might conclude, within its black box, “For someone with this background, we give a sentence of X.” In effect, the sentencing algorithm has shown a focused bias targeting a specific person (or even a person with similar personal data unrelated to any offense; this overlaps with population bias). (Note this is only a hypothetical model: we do not know of any risk assessments currently in use that are designed to correlate sentences with crimes for which an individual has already been convicted, as suggested in the hypothetical above. Rather, in actuality, courts appear to be using risk assessments designed to predict *future* crimes or dangerousness (recidivism), designed for bail or post-sentencing purposes, and importing those

142. *See id.*

risk assessments into the sentencing context, raising constitutional questions about a defendant's right to individualized and accurate sentencing.¹⁴³⁾

Risk in the other direction might produce an “outlier,” which occurs when the input is sufficiently distinct from the scenarios built into training sets to confuse the algorithm. The situation is analogous to sentencing for a crime that is not included in the Sentencing Guidelines and is not readily analogous to an existing offense. Outlier inputs could lead to unpredictable, potentially biased, and incorrect results. New crimes that do not fit the algorithmic model for assessing bail or recidivism risk, or for which there is an exceedingly small dataset, could produce a similar result.

For sentencing, the threshold for not using ML or throwing out algorithmic results could reasonably be low, as the alternative—human decision making—is already the standard. In any event, it would seem incumbent on the proponents of using such an algorithm to demonstrate its validity and explain its functioning, just as a judge should (and in some jurisdictions is required to) put reasoning for a sentence on the record, allowing appellate courts and the parties to understand what occurred and why.

Probing for Bias

With AI as with people, some bias is always present. But steps can and should be taken to minimize bias and mitigate its influence. Mitigating bias starts with the design of an AI system and the nature and quality of the algorithm and the data on which the algorithm is trained, tested, and validated. An additional mitigator is sound process—timely, contextual, and meaningful. For policy makers and engineers, “timely” means at each point where input can directly influence outcomes, i.e., at the conception, design, testing, deployment, and maintenance phases of AI development and use. Sound process includes asking whether AI should be used for a particular purpose in the first instance—that is, whether an AI tool should be developed or employed for a particular use. “Contextual” means specific to the tool and use in question and with actual knowledge of its purposes, capabilities, and weaknesses. “Meaningful” means independent, impartial, and accountable. Specifically, the person using or designing an application should validate its ethical design and use. If a particular community or group of people is likely to be affected by the use of the tool, designers and policy makers should consult with that community or group in deciding whether and how to develop, design, or use that tool.¹⁴⁴ In addition, to the extent feasible,

143. See *State v. Loomis: Wisconsin Supreme Court Requires Warning Before Use of Algorithmic Risk Assessments in Sentencing, Recent Case*, 130 Harv. L. Rev. 1530, 1532–33 (Mar. 2017).

144. Baker et al., *supra* note 96.

the system's parameters should be known or retrievable. The system should be subject to a process of ongoing review and adjustment. The rules regarding the permissible use, if any, of social identifying descriptors or proxies should also be enunciated, clear, and transparent, and they should be subject to constitutional and ethical review.

Asking the right questions is crucial, not just for legal reasons but because the questions invariably underpin judgments about the reliability of the AI at issue. With the caveat that humans may not be able to understand or predict the behaviors of some AI systems with certainty or even reliably (which might counsel against using them at all or in particular contexts), here are some questions to ask to probe for bias:

- Who designed the algorithm at issue?
- What process of review was the algorithm subjected to?
- Were stakeholders—groups likely to be affected by the AI application—consulted in its conception, design, development, operation, and maintenance?
- What is in the underlying training, validation, and testing data? How has the chosen data been cleaned, altered, or assessed for bias? How have the data points been evaluated for relevancy to the task at hand? Is the data temporally relevant or stale? Are certain groups improperly over- or under-represented? How might definitions of the data points used impact the algorithm analysis?
- Do the data or weighted factors include real or perceived racial, ethnic, gender, or other sensitive categories of social identity descriptors, or any *proxies* for those categories? If so, why, and do they pass ethical and constitutional review? Have engineers and lawyers reviewed the way these criteria are weighted in and by the algorithm as part of the design and on an ongoing basis? In accord with what process of validation and review? (If these questions are too difficult for proponents of the AI to answer, is using the AI in a particular context too risky for constitutional rights, human safety, or other important interests?)
- Is there a disparate or adverse impact on the confidence threshold or is it otherwise based on racial classifications, ethnicity, gender, sexuality, ability/disability, nationality, and so on? If so, are there reasons for such disparity that survive constitutional and ethical review?
- Did the developer and user of the AI perform and retain disparate impact assessments before using the AI, or in monitoring the AI post-deployment?
- Is the model the state of the art? How does it compare against any industry standard evaluation metrics or application-specific benchmarks?
- How might the terms or phrasings in the user-generated prompts bias the systems' outputs? Can these prompts be phrased in a more neutral way? Do any of the terms used have alternative meanings?

- Are the algorithm's selection criteria known? Iterative? Retrievable in a transparent form? If not, why not?
- Does the application rely on a neural network? If so, are the parameters and weights utilized within the neural network known or retrievable? Does the design allow for emerging methodologies that provide for such transparency? If a transparent methodology is possible, has it been used? (If not, why not?) If transparency is not possible with state of the art technology, and a less transparent methodology is employed, what is the risk that the system will rely on parameters that are unintended or unknown to the designers or operators? How high is the risk? Is the risk demonstrated? How is the risk mitigated?
- Is the input query or prompt asking for a judgment, a fact, or a prediction? Is the judgment, fact, or prediction subject to ambiguity in response?
- Are there situational factors or facts in play that could, or should, alter the algorithm's predictive accuracy?
- Is the application one in which nuance and cultural knowledge are essential to determine its accuracy or to properly query it?
- Are the search terms and equations objective or ambiguous? Can they be more precise and more objective? If not, why?
- What is the application's false positive rate? What is the false negative rate?¹⁴⁵
- What information corroborates or disputes the determination reached by the AI application? Is the application designed to allow for real-time assessment? If not, is operational necessity the reason, or is it simply a matter of design? Is there a process for such assessment that occurs after the fact?
- Is the AI being used for the purpose for which it was designed and trained?
- Is the AI being used to inform or corroborate a human decision? Are humans relying on the AI to decide or to inform and augment human decisions?

Algorithms That Predict Human Behavior

Most algorithms are based on statistical prediction. In this sense, all algorithms are predictive. There exists a class of algorithms, however, that also seek to make predictions about future behavior based on past data. This happens all the time. Shopping algorithms seek to predict through data about prior purchases (past behavior) the predisposition of individuals to make additional purchases (future

145. Some AI models will not produce false positives or false negatives, e.g., a generative AI model that creates fictional or new artistic content.

behavior). YouTube uses algorithms that seek to predict additional videos a viewer might watch to generate additional views. They are called “recommendation algorithms,” but what they do is push products to viewers using predictions about their future viewing behavior based on past viewing behavior.

Judges may be called upon to determine whether particular algorithms that predict behavior, such as those in the criminal justice system, are constitutional or unconstitutional. As part of that determination, judges may need to examine whether the algorithm is accurate, and by what measure, and whether a particular application presents legal issues, as when, for example, a predictive algorithm embeds certain types of bias. Likewise, issues might occur because litigants are unwilling or unable to determine the parameters or datasets that informed an algorithm’s prediction and thus cannot reliably evaluate its accuracy as applied to the circumstances at hand.

Predictive algorithms are used, or might be used, in a variety of judicial and collateral settings. Some of the most frequently cited applications are in the criminal justice system. Many police departments and courts across the country use algorithmic risk assessments.¹⁴⁶ Police use such tools to predict where crime might occur and by whom.¹⁴⁷ Policing algorithms are not intended to predict individual conduct, though they might include the characteristics of individual actors in an area, like registered sex offenders. Proponents of such algorithms argue that algorithmic tools better focus finite police resources on areas where crime is most likely to occur, based on “neutral” data rather than the hunches, perceptions, or potential biases of police officers. The argument against them is at least twofold. First, such algorithms can generate their own reinforcing and circular logic. The algorithm predicts criminal conduct, police patrols are increased, and additional arrests occur, validating the accuracy of the algorithm. Second, the underlying data are not, in fact, neutral. Such algorithms may have a disproportionate racial and socioeconomic impact where they generate increased patrols in poorer neighborhoods with historically higher recorded crime rates and larger concentrations of people of color. In this way, they may also reflect past police practices and prosecutorial decisions focusing on communities and people of color. They may also have intentional racial impact to the extent they use “race” or socioeconomic status as predictive factors.

Some courts already use actuarial and/or algorithmic risk assessments in pretrial release, probation, and sentencing decisions; parole boards also make use of them.¹⁴⁸ Some of these algorithmic risk assessments are capable of machine

learning,¹⁴⁹ a capacity that will increase with time. Private companies may develop the risk assessment algorithms; Northpointe developed the COMPAS system used by several states.¹⁵⁰ These companies may not release the underlying code for the algorithms (or training, testing, and validation data) for defendants to test and challenge.¹⁵¹

Using risk assessment algorithms to make or inform liberty decisions creates potential Fifth and Fourteenth Amendment due process and equal protection issues. It may also create Sixth Amendment Confrontation Clause questions. To identify a few due process issues:

- How may defendants meaningfully challenge the logic of an algorithm if the source code is kept from them? Is it enough for them to have access only to the inputs and outputs the algorithm processes and generates but not the decisional framework or processes it uses?
- How can a defendant meaningfully challenge an algorithmic risk assessment without access to its training, testing, and real-world-use data?
- If the algorithm uses machine learning, and no one, not even the developer, understands its “analysis,” how can courts ensure due process of law?
- How and should courts test algorithms for accuracy, especially when they predict future (i.e., unrealized) human behavior?
- If a particular risk assessment tool designed for one purpose, such as to predict future behavior (e.g., flight risk or recidivism), is applying that algorithm (along with the data it was trained on and the inputs its considers) for other purposes, such as sentencing for past behavior, is that consistent with due process?
- Should algorithms that depend on group data to predict future behavior be applied against individuals?

As with policing algorithms, any racial and other biases contained in or produced by risk assessments present equal protection issues. The adoption of risk assessment tools has caused controversy in this context,¹⁵² and there is a rich

152. For example, a 2016 ProPublica study determined that COMPAS was almost twice as likely to falsely identify a black person as a repeat violent offender as it was to falsely identify a white person as a repeat offender. The company contested this finding. Julia Angwin et al., *Machine Bias*:

academic literature debating (generally challenging) the efficacy and fairness of these tools.¹⁵³ However, there is yet little case law. Lawmakers or police departments using these tools might seek to replace, improve, or inform judicial decisions with “evidence-based”¹⁵⁴ algorithmic recommendations, or to decrease the incarceration rate by releasing more people before trial and during probation.¹⁵⁵ Critics argue that risk assessment tools not only have racially biased results but, through the ML process, may exacerbate racial inequalities in the criminal justice system. One significant concern is that using historical data to train risk assessment tools may only replicate and repeat at scale “the mistakes of the past.”¹⁵⁶ Over one hundred civil rights groups issued a joint statement detailing their concerns with pretrial risk assessments.¹⁵⁷ While the ideal of “evidence-based” practice may be appealing, the risk that an assessment tool may cause disparate treatment under a mantle of “data-driven” legitimacy warrants careful consideration. Whether any type of unbiased machine neutrality or fairness to all is possible is a matter of debate.¹⁵⁸ Some scholars have concluded that technical flaws in criminal risk assessments, in particular, pose grave concerns and cannot be fixed.¹⁵⁹

Academic commentary highlights several other risks of risk assessments: (1) that the existence of AI risk assessment tools will place pressure on courts to use the tools, whether they are accurate or not; (2) the psychological bias toward relying on empirical evidence more heavily than nonempirical evidence (“anchoring

bias”); and (3) that “most judges are unlikely to understand algorithmic risk assessments,” and therefore may misuse them or give them inappropriate weight.¹⁶⁰

Several generalized arguments for and against the use of predictive algorithms for human behavior emerge. Proponents might argue that predictive algorithms can identify patterns and trends humans cannot see and can do so rapidly, if not instantaneously, thus curtailing additional risk or harm. They might argue that predictive AI rests on the premise, and some would say reality, that neither judges nor law enforcement personnel can reasonably predict conduct based on judgment and intuition alone. AI simply has more data and excels at statistics. In the courtroom, predictive AI could add data to judgments about risk assessment, informing decisions on bail, parole, and sentencing. Moreover, because AI is data driven, some argue that a well-designed algorithm could in theory be more neutral or objective than a human. While AI invariably contains bias, a particular application might, in theory, be less biased than a human subject to implicit or explicit bias. All of these assumptions can be contested, in the abstract as well as with reference to specific AI applications.

Opponents of predictive algorithms make the following arguments.

Western law and criminal procedure are premised on individualized suspicion. This means an individual should be investigated or prosecuted based on articulable facts about them, not patterns found in data about the past conduct of other persons who may simply share one or more social descriptors, or data about past police practices and prosecutorial decisions. This argument is also especially applicable in the sentencing context.

All algorithms are biased in some way by the choices their human designers make: what metrics are used to evaluate data to make predictions, what data the algorithm is trained on, and what data the algorithm is tested on. Further, algorithms reflect human bias and can multiply and magnify bias by repeating it at scale. One of the most common criticisms of criminal risk assessment tools, for example, is that they rely on historical records of arrests, charges, convictions, and sentences, though “[d]ecades of research have shown that, for the same conduct, African-American and Latinx people are more likely to be arrested, prosecuted, convicted, and sentenced to harsher punishments than their white counterparts.”¹⁶¹

Predictive algorithms focus on characteristics that are, at least purportedly, readily discerned and susceptible to data adaptation and recording. Classifications such as “race,” gender, marital status, family status, address, and education likely play a disproportionate role in algorithm design and operation. Conversely, in

160. *State v. Loomis: Wisconsin Supreme Court Requires Warning Before Use of Algorithmic Risk Assessments in Sentencing, Recent Case*, *supra* note 143, at 1535; Ellora Israni, *Algorithmic Due Process: Mistaken Accountability and Attribution in State v. Loomis*, JOLT Digest (Aug. 31, 2017), <https://perma.cc/9NDU-NHXX>.

161. Minow et al., *supra* note 159, at 1.

operation or design, algorithms are less likely to include subjective weights, like role models and community connections and participation, that might also predict behavior and perhaps do so more accurately.

Classifications used as factors in algorithmic predictions are subject to all the risk of bias, intended and unintended. Even when unintentional, this bias may infiltrate an application through training data, how computer engineers assign weights to factors, or the “learning” the AI does on the job.

Some factors do not account for variation or nuance. Factors that appear to be subject to yes/no answers, and thus data scoring, may in reality be more complex and fall along a continuum. “Race” and ethnicity are good examples, even if not used intentionally in predictive tools (one would hope), other than to counter historical or algorithmic bias. Even marital status, a seemingly objective data point, may fall on a contextual continuum ranging from stable to unstable, happy to unhappy. Depending on what an algorithm is intended to predict, nuance can make all the difference in outcomes.

All of these factors are compounded where there is an inability to understand or challenge the underlying algorithm. Judges, of course, will have to determine when algorithm transparency is required as a matter of law, including due process. Lack of transparency undermines the ability of judges and litigators to assess the accuracy and meaning of an algorithmic output by asking questions like:

- What factors, including those that might serve as proxies for suspect categories, did the algorithm rely on?
- How were the factors weighted?
- Do those factors in fact reflect the case and parties in question?

We would encourage courts to look under the hood. Accurately understanding AI outputs often requires knowing not only the AI inputs but also the following: the weights that were attached and allocated to each input; the data the algorithm was trained, tested, and validated on; and an explanation of the methodologies used for prediction. Courts should ask:

- For what purpose was the AI designed, trained, tested, and validated? Is that the purpose for which the court is considering its use? If not, why is the court admitting or using the AI for an alternative purpose? (If, for example, a risk assessment was built to predict flight risk or future behavior, why is it being used at sentencing?) What safeguards is the court using or imposing to ensure appropriate use in context, and will the safeguards suffice?
- On what data was the AI trained, tested, and validated, and were those datasets biased? (See the “Probing for Bias” questions above.)
- What parameters did the algorithm search or use and what weight was given to those parameters in the AI output? Are such parameters and weights discoverable? Do those parameters include “race,” gender, other suspect

categories, or their proxies, such as housing and employment status,¹⁶² as factors? If so, why, and do they pass ethical and constitutional review?

- Does the AI have equal or disparate error rates or impacts across different racial, gender, or other suspect categories? (See the “Probing for Bias” questions above.) Did the developer and user of the AI perform and retain risk assessments and disparate impact assessments before using the AI, or in monitoring the AI post-deployment?
- Does the AI have a mechanism to evaluate its accuracy on an ongoing basis, specifically one to identify false positive and false negative rates, along with the trends associated with each?
- Was the defendant’s data included in the training data for the algorithm in question? If so, is it possible to expunge that data?
- Is the AI transparent in its function, its underlying data and factors, and its methodology of weighting? If not, is a more transparent methodology available?
- Does the application rely on a neural network? If so, what is the risk that the system will rely on parameters that are unintended or unknown to the designers or operators? Is it possible to identify those potential parameters?
- If the answers to these questions implicate proprietary information, what would prevent the court from hearing answers to the questions in camera, with appropriate protective orders and the power of contempt to enforce the court’s orders? Do the rights to due process, equal protection, and confrontation of witnesses require that the defendant or the public have access to all of the information at issue?

If the moving party cannot answer these questions to the satisfaction of the court, or is not prepared to answer these questions, judges might well be skeptical about the reliability of the evidence proffered or the use of a judicial tool.

Algorithms for Lawyers and Non-Lawyers: Technology-Assisted Review and . . . Legal Practice?

A variety of technologies offer litigation, drafting, and other tools for lawyers and non-lawyers. These technologies include: online legal advice tools; e-discovery tools; legal research; document management and creation; document- and case-level analytics; case outcome prediction (for forum and judge shopping); and

162. See Barabas et al., *supra* note 88, at 3.

lawyer-client matching.¹⁶³ We anticipate others. As with behavioral risk assessments, not all are AI-based, but an increasing number rely and will rely on machine learning and other AI methodologies.¹⁶⁴

Technology-assisted review (TAR), sometimes referred to as computer-assisted review (CAR) or “predictive coding,” is used for document review and production.¹⁶⁵ (TAR is not a brand name but rather a collective acronym for this type of software.) With the first generation of TAR (referred to as TAR 1.0), a lawyer first reviews and labels a set of “seed” documents for issues such as privilege, relevancy, and responsiveness, and then the algorithm learns to do the same based on the human-inputted labels.¹⁶⁶ The second generation (TAR 2.0) uses a similar model but with continuous active learning by the machine.¹⁶⁷ “Lawyers can also use TAR to structure the case, identify parties to depose, develop strategic defenses, and [complete] other tasks related to the case.”¹⁶⁸

Other examples of legal tools include those that provide automated legal advice, assist unrepresented litigants with legal proceedings, or draft documents, such as answers, discovery requests, motions, and simple briefs.¹⁶⁹

The quality of any such tools will depend significantly on the datasets available for training them; where data is not publicly available, large law firms and other businesses may have better access to confidential data (with permission from clients), and therefore better tools at their disposal.¹⁷⁰ This type of technology, however, does allow for the possibility of increasing access to justice for those who cannot afford traditional representation.¹⁷¹ It may also raise ethical issues about confidentiality, representation, competence, and diligence, as discussed earlier.¹⁷²

Legal research tools also use machine learning, for example to do natural language searches instead of Boolean searches,¹⁷³ or “analyze a draft argument to

173. Boolean searches use words such as “and,” “or,” and “not,” and punctuation such as quotation marks to expand, limit, and qualify searches. Shauntee Burns, *What is Boolean Search?*, New York Public Library (Feb. 2011), <https://perma.cc/CL8E-4WP3>. The 19th century mathematician, George Boole, like many AI designers today, was seeking to use mathematical principles and logic

gain further insights or identify relevant authority that may have been missed.”¹⁷⁴ Many of these tools use natural language processing (NLP):

At a high level of abstraction, NLP aims to identify patterns in human language in ways that facilitate problem-solving. . . .

. . . The current research frontier, and a rapidly advancing one, is a mix of linguistics and “deep learning” (i.e., neural network) techniques. In a nutshell, deep-learning NLP machines make language computationally tractable by converting words, sentences, documents, or, in the legal context, entire cases into unique vectors, called “embeddings.” Each vector can be envisioned as an arrow from the origin to a point that represents the item of interest in a large, n-dimensional space, its magnitude a function of the presence of words, case citations, indexing concepts, or other features. Once this vast vector space has been constructed and human-annotated labels affixed to training materials (again, words, sentences, documents, cases), a sophisticated machine learning model can manipulate the vectors mathematically using large numbers (on the order of billions) of calculations to model relationships between them. With sufficient data and computing power, the system’s outputs enable a range of legal tasks, such as identifying relevant or privilege documents, past legal decisions that may be controlling, or, though . . . it is far trickier, the winning argument in a case.¹⁷⁵

A more complex and forward-leaning NLP application is Open AI’s ChatGPT 3 research app, publicly released in late 2022, and as of 2024, in a fourth public and for fee iteration (ChatGPT 4 and ChatGPT 4-Plus). Chat GPT 5 was released in summer 2025, showing the rapidity with which generative AI is developing. ChatGPT and other products use large language models (LLMs) to generate language or text, “writing” sentences that are often difficult to distinguish from a human’s. Open AI, a nonprofit funded by Microsoft, opened up ChatGPT to the public for use, in the process raising questions about work product and academic integrity across disciplines.¹⁷⁶ As described above, ChatGPT can incorporate research into its products as well, but that research may not always be reliable. The further development of this type of AI (large language models) presents fundamental questions for the legal profession—about the thoroughness and transparency of research and work product, about the very writing of law—that go well beyond the scope of this reference guide.¹⁷⁷ That said, many

to derive greater meaning from data and do so more rapidly than with existing 19th century constructs.

177. Engstrom and Gelbach’s article, *supra* note 163, takes on many of these and other issues.

of the issues raised here, such as bias of all types and explainability and transparency, will shape future discussion.

AI and Discovery

If not in the form of an AI-generated brief (or hopefully and better, a human-generated brief aided perhaps by AI tools), a judge's consideration of AI at trial may start with discovery. Pretrial discovery is governed by the Constitution, case law, Federal Rule of Civil Procedure 26 (among other civil rules), and Federal Rule of Criminal Procedure 16. Rule 26 mandates parties make certain initial disclosures, "without awaiting a discovery request," including "a copy—or a description by category and location—of all documents, electronically stored information, and tangible things that the disclosing party has in its possession, custody, or control and may use to support its claims or defenses; unless the use would be solely for impeachment."¹⁷⁸ Additionally, with respect to expert testimony, "a party must disclose to the other parties the identity of any witness it may use at trial to present evidence under Federal Rule of Evidence 702, 703, or 705."¹⁷⁹ Unless otherwise stipulated or ordered by the court, the disclosure must be accompanied by a written report providing "a complete statement of all opinions the witness will express" and "the facts or data considered by the witness in forming them." Rule 16 of the Federal Rules of Criminal Procedure states, *inter alia*, that upon request "the government must permit the defendant to inspect and to copy or photograph. . . documents [and] data. . . within the government's possession, custody, or control [if] (i) the item is material to preparing the defense; (ii) the government intends to use the item in its case-in-chief at trial; or (iii) the item was obtained from or belongs to the defendant."¹⁸⁰ Documents and data might be argued to include documentation of algorithms and design and the data used to train, test, and validate AI models.

We forecast that as part of the discovery process at least four issues relating to AI will arise, and arise with frequency:

Timing, timeliness, and timelines: As noted above, Rule 26 provides for certain initial disclosures regarding documents and potential expert witness testimony, "without awaiting a discovery request." "A party must make the initial disclosures at or within 14 days after the parties' Rule 26(f) conference unless a different time is set by stipulation or court order." We surmise that, in some contexts, 14 days may be an unrealistic period of time for a party to determine which data and how much to turn over where the party intends to rely on AI-generated outputs as

178. Fed. R. Civ. P. 26.

179. Fed. R. Civ. P. 26(a)(2). Federal Rules of Evidence 702, 703, and 705 address "testimony by expert," "bases of an expert," and "disclosing the facts or data underlying an expert," respectively.

180. Fed. R. Crim. P. 16(a)(1)(E).

evidence. Consider a medical malpractice suit placing at issue a doctor's use of AI imagery as a diagnostic tool. Litigators are not likely to voluntarily turn over data without first being ordered to do so following a discovery conference.

Interpretation and Scope of Data Discovery: The timeline will also be impacted by the uncertain scope of Rule 26 when it comes to how much of the underlying data is required to be disclosed where an expert witness relies on an AI output “or electronically stored data that may be used to support its claims of defenses.” Judges, for example, will surely need to resolve on a case-by-case basis the parameters of “data considered by the witness in forming” an opinion when that opinion derives from the use of AI or AI outputs. Referring to our medical malpractice suit, for example, the parties are likely to dispute whether “data considered in forming an opinion” should include the data, or a characterization of the data, used to train, test, and validate an AI screening algorithm. An AI specialist could well argue that such data is necessary to determine whether the algorithm was trained to detect the disease in question, or to detect the disease in question with a comparative population and demographic base.

Similar interpretive issues are likely to arise in a criminal discovery context where, for example, the government intends to introduce AI outputs, such as a potential facial or voice recognition match placing a defendant at the scene of a crime. The challenge for courts and for discovery is that most facial or voice recognition tools are predictive rather than determinative in nature, and most are more accurate when more potential matches are identified (assuming that a true match is in the database). Restated, there are few Jason Bourne moments where the target is conclusively identified. The question for criminal discovery is just how much discovery a court should allow into the underlying AI tools based on the argument that any information—the algorithmic math, the training data, testing data, and validating process, for example—might undercut the predictive accuracy of the recognition tool in the case at hand and thus serve as potentially exculpatory evidence.

Supplementing Disclosures and Responses: Federal Rule of Civil Procedure 26 states that parties must supplement or correct their disclosure or response “in a timely manner if the party learns that in some material respect the disclosure or response is incomplete or incorrect.” AI tools are often iterative and changing, like a generative AI that is absorbing and incorporating new data into its outputs. That may present two challenges, one on either side of the same coin. First, in what manner to delimit the duty to supplement where the ongoing use of an AI tool may reveal earlier strengths and weaknesses at the time the output evidence was generated. Here the qualifier “material” will carry considerable weight and likely draw judges into disputes over whether iterative AI changes are material to understanding AI outputs offered into evidence. Second, the iterative nature of AI may make it difficult to fix and assess the quality and accuracy of AI outputs in a moment in time, such as the time and date an AI tool was used to assess a medical condition or may have impacted the performance of an AI-empowered vehicle.

The duty of continuing disclosure in Federal Rule of Criminal Procedure 16 is drafted differently than Rule 26. Rule 16(1)(c) states that: “A party who discovers additional evidence or material before or during trial must promptly disclose its existence to the other party or the court if: (1) the evidence or material is subject to discovery or inspection under this rule; and (2) the other party previously requested, or the court ordered, its production.” Where the government relies on an AI-generated output as evidence, updated information associated with that AI might be “additional new evidence or material.” Where new information about an AI output in a criminal context might be viewed as exculpatory under *Brady*,¹⁸¹ it might be constitutionally required as well, as in the case of new information decreasing the probability that an AI facial recognition algorithm correctly identified the defendant as a suspect. Similarly, if an AI model itself were to be considered a government witness, disclosures of material evidence that might impeach its veracity or accuracy might be required under *Giglio*.¹⁸²

Protective Orders, and Proprietary and Trade Secrets: One issue we forecast that will be argued in court, but for which courts are already well empowered and equipped, is the protection of trade secrets embedded in AI in the form of algorithms, data, parameters, and weights. Some litigants using AI in court, such as the government in the case of *Loomis*,¹⁸³ have argued that they cannot disclose the underlying algorithms, parameters, and weights, even to the court, because the underlying information is proprietary. We are skeptical of such assertions, which may arise in a variety of civil and criminal contexts. Civil Rule 26 provides clear and broad authority for courts in civil litigation to issue protective orders “requiring that a trade secret or other confidential research, development, or commercial information not be revealed or revealed only in a specified way.” Likewise, Criminal Rule 16 provides courts authority to issue protective and modifying orders “at any time the court may, for good cause, deny, restrict, or defer discovery or inspection, or grant other appropriate relief,” and do so *ex parte*. As discussed above, in the specific context of courts themselves using predictive algorithms for bail, probation, sentencing, or similar purposes, there are weighty due process, equal protection, and Confrontation Clause issues that might require *public* disclosure of algorithms and data, and indeed suggest any use of such tools is unconstitutional. In other contexts, it would seem the moving party should either be prepared to disclose material information about the AI outputs they intend to use at trial (potentially subject to appropriate protective orders) or the court should decline to admit such outputs into evidence. Where there is room for reasonable

181. *Brady v. Maryland*, 373 U.S. 83, 87 (1963); *Giglio v. United States*, 405 U.S. 150, 154 (1972).

182. See *Giglio*, *supra* note 181, at 154.

debate, and judicial discretion and ruling, is on whether a particular parameter, dataset, or algorithm, for example, warrants protection or is in the public domain.

Judges as AI Gatekeepers

As evidentiary gatekeepers, judges will need to determine whether and when AI evidence will assist the factfinder and is admissible in court. The Federal Rules of Evidence and their state equivalents will help guide this determination. The Supreme Court’s *Daubert*,¹⁸⁴ *Crawford*,¹⁸⁵ and *Carpenter*¹⁸⁶ cases may also inform the evidentiary questions presented by AI. Neither these cases nor the Rules, however, were written with AI in mind. And currently few federal or state cases or jury instructions address AI. Judges will, of course, interpret and apply these cases and rules to AI in the specific contexts presented and do so consistent with the law of the jurisdiction in which they preside.

We briefly discuss here how the Federal Rules of Evidence and the *Daubert* factors might apply to AI-generated evidence not as a legal primer for an audience that needs no such explanation, but to highlight the complexity of applying the rules of evidence and case law to AI. We identify four threshold considerations when considering AI evidence given its technological characteristics and iterative nature. Courts, in time, will use their knowledge of the law to address myriad constitutional and evidentiary questions AI may raise.

Federal Rules of Evidence 401–403, 702, 901–902

As judges know, under Federal Rule of Evidence 401, evidence is relevant if “(a) it has any tendency to make a fact more or less probable than it would be without the evidence; and (b) the fact is of consequence in determining the action.”¹⁸⁷ Rule 402 states that relevant evidence is admissible unless the Constitution, a federal statute, the other Federal Rules of Evidence, or other rules prescribed by the Supreme Court apply and would exclude the evidence.¹⁸⁸ Due process or Confrontation Clause concerns, for example, might bar or limit certain AI evidence from admission. Statutes addressing data privacy and use may do so as well. Rule 403 allows a court to exclude relevant evidence if its probative value is substantially outweighed by a danger of: creating unfair prejudice; confusing

184. *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993).

185. *Crawford v. Washington*, 541 U.S. 36 (2004).

186. *Carpenter v. United States*, 138 S. Ct. 2206 (2018).

188. Fed. R. Evid. 402.

the issues; misleading the jury; causing undue delay; wasting time; or needlessly presenting cumulative evidence.¹⁸⁹

Many of the threshold evidentiary issues associated with AI will be litigated under Rules 402 and 403 or their state equivalents. Relevancy in most or all jurisdictions is broadly defined, and most AI applications are essentially tools for assessing probability, in theory, making them inherently relevant in assessing, under Rule 401, whether something is “more or less probable.” (Litigants might still argue that certain AI outputs are too inaccurate or biased to be relevant or that they are inapt for the purpose offered.) The primary issues, then, are (1) the reliability of AI generally and (2) the appropriateness of use in the context presented. Rules 402 and 403 are pertinent because the evidentiary use of AI will invariably present questions about discovery and due process, such as whether there is a right to access an underlying algorithm or data used to generate evidence or inform judicial decisions. Another issue is the risk that litigation over AI will present the figurative “trial within a trial” and potentially confuse the jury under Rule 403. Also, courts might apply Rule 403 to exclude AI evidence that is biased or otherwise unreliable. Inquiry is prudent; otherwise, juries may assume AI evidence has the imprimatur of “science” or “technology” in the context presented, potentially lending it false authority or undue weight, or permitting its use in a manner for which it was not intended.¹⁹⁰

Judges will need to decide in what manner and to what extent to require authentication of the AI evidence offered and how, if at all, to validate its reliability. These criteria will likely bring Federal Rules of Evidence 702 and 902 into play, as well as *Daubert* and *Crawford*.

AI and the interpretation of AI outputs are complex. Courts will have to determine the appropriate means to verify AI outputs. This might involve expert testimony, or it might be done through technical means, such as cryptographic hashes embedded in an image at the time it is created. Courts will need to determine who is qualified to testify about the accuracy and fairness of an AI application. Of course, steady, purposeful, and consistent application of the Federal Rules of Evidence or their state equivalents on the record is a good place to start.

It is intuitive, but worth remembering that proponents of AI-generated evidence will seek to simplify its admission by limiting or eliminating as many threshold foundational requirements as possible. Opponents of admission will seek to undermine its relevance and reliability in general or for the purpose for

189. Fed. R. Evid. 403.

190. Andrea Roth, *Machine Testimony*, 126 Yale L. J. 1972 (2017) (“Moreover, just as the Framers were concerned that factfinders would be unduly impressed by affidavits’ trappings of formality, ‘computer[s] can package data in a very enticing manner.’ The socially constructed authority of instruments, bordering on fetishism at various points in history, should raise the same concerns raised about affidavits.”) (internal citations omitted).

which it is offered. To challenge relevance and accuracy, opponents will seek access to the underlying algorithm, the data on which it was trained, tested, and validated, as well as knowledge of what occurs and what is weighted inside any machine-learning black box. Thus, courts will face a layered adjudicative challenge each time AI-generated evidence is offered.

Where AI outputs are admitted, opponents may seek to cross-examine the software engineers responsible for its design. Each AI application is different. It will have a different purpose, rely on a different algorithm, use a different machine learning methodology or methodologies, and will train, test, and validate using different data. Consequently, AI issues are generally not subject to resolution through the application of case-law precedent in the same way that, for example, DNA analysis is now widely accepted in court. A single or lead case will not likely resolve when to admit AI-generated evidence. Adjudication is to be expected for each application and in each context for which the application is offered as evidence. Further, because AI is a constellation of technologies and applications, it is not a single process or technology that can be validated once and generally adopted. In each instance where AI evidence is offered, there may be a legitimate need to explore the underlying technology and different components of that technology for use in that instance or for the proffered purpose. Courts should also consider the following analytical factors.

Context

Courts should pay attention to whether a particular AI application is a good “fit”¹⁹¹ for the purpose for which it is proffered. Some criminal risk assessment algorithms, for example, are designed for the purpose of determining which individuals might benefit from alternatives to incarceration, such as parole or counseling. These algorithms might have less relevance and reliability if used to determine sentencing.¹⁹² That will depend on all the factors noted above, including the input factors, the weight assigned to those factors, the data on which the algorithm was trained, tested, and validated, and the nature of the confidence thresholds applied to the output. Courts should pause and ask not only whether the AI at issue is relevant and material to the matter before the court but for what purpose the AI was specifically designed and whether the outputs will materially and fairly inform the fact finder. Courts should inquire about the contents of the datasets on which the algorithm was trained, tested, and validated.

191. See *Daubert*, 509 U.S. at 591–92.

192. See Christopher Bavitz et al., *supra* note 158, at 6–7 (discussing the Wisconsin Supreme Court’s warning in *State v. Loomis*, 881 N.W.2d 729 (Wis. 2016) that the risk assessment tool COMPAS was not developed for use at sentencing).

Case-Specific Reliability

Even when an algorithm is being used for the purpose for which it was designed, there may be data or design reasons why output reliability will decrease in a specific context. An AI algorithm may have been designed for and tested on a population substantially different from the population for which the output is offered, with less accurate results than the lab-tested confidence threshold¹⁹³ (“inappropriate deployment” as discussed above in the section titled “AI Is Biased”). As previously noted, according to the FBI, the Bureau’s facial recognition application has an 86% percent match rate (confidence threshold) when an input image is compared to at least fifty potential output matches drawn from state license databases. However, the same algorithm would not have the same match accuracy if run against a different input demographic, say, the population of another country—not because the algorithm is necessarily intentionally biased but because it has not been trained against a comparative population pool. (In fact, output disparity across gender and ethnicity has been an issue with some facial recognition algorithms.¹⁹⁴ As a result, facial recognition accuracy has been a focal point of AI design initiatives, and therefore we anticipate future American facial recognition applications will help mitigate this issue.)

Inapt Factors

There is a risk with ML that a neural network will rely on inapt factors in making its output predictions. Judges will want to know whether this is possible and, if so, regarding which factors, before allowing a jury to assess the weight of AI evidence or before judges use an algorithm themselves to assess bail or recidivism risk. For example, a judge would want to determine, consistent with case law and the Constitution, which factors were included and weighted within any AI-driven bail, parole, confinement, or sentencing tool, to ensure that inappropriate, inapt, or unconstitutional factors were not included and that any factors, even if appropriate, were not given undue weight by the neural network. A judge would also want to know if any factors might be working as proxies¹⁹⁵ for suspect categories.

195. See Barabas et al., *supra* note 88.

Underlying Bias

Courts will also want to investigate the ways in which a given AI application is biased, or may be biased, before admitting its outputs into evidence or relying on it to inform a judicial decision, as discussed earlier.

Daubert

One way to conceptualize AI and appreciate its evidentiary complexity in relation to other technology is to apply the (non-exhaustive) list of factors the Supreme Court developed in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*¹⁹⁶ to determine whether expert testimony based on a specific, scientific methodology should be admitted.¹⁹⁷ *Daubert* and, in certain states, its predecessor, *Frye v. United States*,¹⁹⁸ govern the admission of expert testimony based on scientific methodology. *Daubert* uses a “factors” approach, while *Frye* uses a “general acceptance” standard. Each of the *Daubert* factors opens wide the door to debate over many AI attributes. Analysis under *Frye*, too, is likely to be complicated, requiring judges to determine when a scientific method is “sufficiently established to have gained general acceptance in the particular field to which it belongs.”¹⁹⁹ In theory, making such a determination will entail examining not only the specific algorithm and use in question but also identifying the relevant field of acceptance and what acceptance means for something like facial recognition or behavior prediction—all in a context where algorithms may be iterative and/or the data they are trained on are iterative and changing.

The *Daubert* factors include:²⁰⁰

- whether the theory or technique in question can be and has been tested,
- whether it has been subjected to peer review and publication,
- its known or potential error rate,
- the existence and maintenance of standards controlling its operation, and
- whether it has attracted widespread acceptance within a relevant scientific community.

With AI, these factors would need to be applied to individual algorithms and applications rather than “AI” generally, which, as stated above, generically

196. *Daubert*, 509 U.S. at 579.

197. We are not aware of a court having done so at the time this reference guide was drafted.

198. *Frye v. United States*, 293 F. 1013 (D.C. Cir. 1923).

199. *Id.* at 1014.

200. *Daubert*, 509 U.S. at 593–95.

describes a constellation of technologies and methodologies. We address each factor in turn.

Testing

The first step suggested by *Daubert* is to identify the theory, technique, or component that is subject to evaluation. There are many options with AI. Is it: The sensor(s) that fed data to the AI system? The algorithm? The math behind the algorithm? The dataset used to train the algorithm? The training methodology? Or is it the system as an integrated whole that is subject to review?

The second step is to decide what test is appropriate and what baseline to use to establish accuracy. Medical diagnostic AI, for example, might be compared to physician-diagnosed outcomes. It is true that medical diagnostics are subject to social influence and human and machine bias. But in medicine there is often a fixed data point, an established fact or yes/no answer to whether a disease or tumor is present, against which testers can measure the algorithm's accuracy.

In contrast, an algorithm intended to predict future behavior, such as a criminal assessment tool, cannot be tested with the same degree of scientific or evidence-based meaning, given the weight placed on social factors. Recidivism algorithms, for example, attempt to predict future human behavior, using circumstantial factors drawn from a base population. In such contexts, there is no certain result and no control group, and confirming predictions is difficult. Human circumstances are endlessly complex, creating multiple influences on behavior—without necessarily *determining* behavior. Nor is there a way to verify, after an individual has been jailed or sentenced, how an individual's future behavior is affected by imprisonment. The experience of imprisonment itself might turn a person toward or away from future crime, making it difficult or impossible to verify the machine's prediction. In short, predictive algorithms in the criminal context are especially difficult to test, to peer review, and to assess for accuracy and error rates.

Peer Review

An example innovation in AI-enabled medicine highlights the question of machine reliability and illustrates the importance of peer review. In April 2019, NPR reported that Stanford computer scientists had created an algorithm for reading chest X-rays to diagnose tuberculosis.²⁰¹ They hoped to use it to diagnose the disease in HIV patients in South Africa, and the machine's results were

201. Richard Harris, *How Can Doctors Be Sure A Self-Taught Computer Is Making The Right Diagnosis?*, NPR (Apr. 1, 2019), <https://perma.cc/Y2WM-FF4N>.

already better than doctors’.²⁰² To corroborate their success, the Stanford scientists submitted their results to other scientists for review.²⁰³ One noticed a peculiarity in the AI’s decision making.

[The peer reviewers] Zech and his medical school colleagues discovered that the Stanford algorithm to diagnose disease from X-rays sometimes “cheated.” Instead of just scoring the image for medically important details, it considered other elements of the scan, including information from around the edge of the image that showed the type of machine that took the X-ray. When the algorithm noticed that a portable X-ray machine had been used, it boosted its score toward a finding of TB.

Zech realized that portable X-ray machines used in hospital rooms were much more likely to find pneumonia compared with those used in doctors’ offices. That’s hardly surprising, considering that pneumonia is more common among hospitalized people than among people who are able to visit their doctor’s office.

“It was being a good machine-learning model and it was aggressively using all available information baked into the image to make its recommendations,” Zech says. But that shortcut wasn’t actually identifying signs of lung disease, as its inventors intended.²⁰⁴

The machine was making a correlational, rather than causal, connection between the use of a portable machine and TB. Without informal peer review, humans might not have discovered that aspect of how the AI algorithm was making decisions, a clear example of both how AI adapts and often does so in the black box. The TB-scan example also demonstrates the disruptive role of unknowns, here an unwitting, algorithmic bias (“inappropriate focus”). The original programmers evidently did not anticipate that the machine would teach itself to evaluate information beyond the scan itself. It is impossible for a programmer to anticipate every real-world factor a machine will encounter and attempt to interpret.

Peer review may be particularly challenging with AI. For example, it is hard to imagine a credible peer review that does not include access to the underlying algorithm, parameter weights, and the data on which an algorithm was trained, tested, and validated. How else could a peer validate the accuracy and use of an application? Moreover, peer review should be case or use specific. An AI that is good at predicting the need for substance abuse counseling may not be suited for predicting other types of risk or need. The usefulness of any peer review will also vary in accordance with the talent and capability of the individuals or entities conducting the peer review.

202. *Id.*

203. *Id.*

204. *Id.*

Error Rates

Judges will also need to ask the right questions to determine whether error rates are accurate and meaningful. For example, will or might error rates vary depending on whether the AI application is tested and reviewed using the relevant local population (database) to which it will be applied, as opposed to a national population, or perhaps a more idealized lab database?²⁰⁵ What types of bias might be affecting the accuracy of any reported error rates? (See suggested questions under “Probing for Bias,” above)

Standards Controlling an AI Application’s Operation and Maintenance

AI imposes operational and maintenance obligations. At this point in time, however, operational standards, if any, are set voluntarily. The Intelligence Community and the Department of Defense have each published principles for the ethical use of AI, while many companies have their own internal standards. In the absence of uniform statutory standards, courts might begin by asking: What dataset is used? Is that dataset updated appropriately? Is the machine learning monitored by continued testing against known results to ensure the machine is not learning bad habits? Courts might also ask all the questions about bias suggested in “Probing for Bias,” above.

Acceptance

Courts will also need to determine what widespread acceptance within the relevant scientific community means in the context of AI. There is a big difference between general acceptance of the field and acceptance of a specific application. Many computer engineers and government actors accept the premise and use of facial recognition, but privacy advocates do not. Skepticism will remain with any specific application. The point is also illustrated by driverless cars. General acceptance of the concept has not at present translated to acceptance of a model of fully autonomous driverless car that is ready for commercial sale and public use. What then would constitute appropriate general acceptance?

Proprietary Algorithms

How does one test the accuracy or conduct a peer review of a proprietary algorithm or an iterative or evolving ML algorithm? Google is not likely to disclose

205. See Barabas et al., *supra* note 88, at 3, and Bavitz et al., *supra* note 158, at 7.

its search algorithm for public or peer inspection and risk its market position in the search engine arena. Unless courts can demonstrably protect such trade secrets while also testing their validity, applying the *Daubert* factors to many or most AI applications in open court may be difficult. (Jurists or lawmakers²⁰⁶ may determine defendants or the public should have access to certain underlying algorithms and data, such as in instances where liberty interests are at stake. Courts will need to determine whether the Fifth, Sixth, and Fourteenth Amendments require it.)

In other contexts, where courts seek to allow litigants to test the validity of AI applications while still protecting proprietary information, they might exercise their general power to oversee how evidence is entered, to enforce rulings, and to seal records. A parallel can be found in the way classified information is protected while still allowing certain litigation to proceed, with records reviewed by judges and sometimes by cleared counsel. Also relevant is the 1996 Defend Trade Secrets Act (18 U.S.C. § 1835), which specifically directs federal courts to protect trade secrets in proceedings arising under Title 18 of the U.S. Code. Section 1835(a) states,

In any prosecution or other proceeding under this chapter, the court shall enter such orders and take such other action as may be necessary and appropriate to preserve the confidentiality of trade secrets, consistent with the requirements of the Federal Rules of Criminal and Civil Procedure, the Federal Rules of Evidence, and all other applicable laws.

In context, specific statutes also provide intellectual property protections for AI, such as those protections found in § 705 of the Defense Production Act (DPA), which allow the president in the first instance and courts in the second instance, through the power of contempt and jurisdiction found in § 706, to protect intellectual property relevant to DPA enforcement or defend against DPA actions.

Deepfakes and Evidence

AI's capacity to convert symbolic language (coded numbers) into natural language and to discern, recognize, and formulate patterns at the pixel level makes it a tool of choice not only for identifying voices and pictures but also for mimicking voices and altering images. Moreover, AI can do so with real-life

206. For example, an Idaho law, Section 19–1910 of the Idaho Code, states, “All pretrial risk assessment algorithms shall be transparent, and all documents, records, and information used to build or validate the risk assessment shall be open to public inspection, auditing, and test. No builder or user of a pretrial risk assessment algorithm may assert trade secret or other protections in order to quash discovery in a criminal matter by a party to a criminal case.” <https://perma.cc/J3QQ-GTZ4>.

precision, creating images or recordings known as “deepfakes.” Hollywood has, of course, known about deepfakes for years, though in movies they’re called “special effects,” as in *Star Wars* or *Forrest Gump*. What makes deepfakes noteworthy for courts is not only the lifelike quality attainable but the accessibility of this capability to the general population. Tools now readily available on the internet allow non-specialists to alter photographs and mimic speech with startling realism, capable of fooling practically everyone—including triers of fact.

Deepfakes today are often created with “generative adversarial networks,” or GANs. GANs “are two-part AI models consisting of a generator that creates samples [e.g., of images, film, or audio] and a discriminator that attempts to differentiate between the generated sample and real-world samples.”²⁰⁷ The discriminator (or sometimes multiple discriminators) provides feedback to the generator that helps it improve its realism.²⁰⁸

Deepfakes can have artistic and educational value, such as in bringing historical figures back to life in film, but also nefarious purposes, such as the creation of non-consensual pornography and national security threats.²⁰⁹ Deepfake technology, its “accessibility [by the public], usability, and the verisimilitude of its outputs,” will only improve over time; meanwhile, the U.S. government, academia, nonprofits, and industry all have sought to improve technology for detecting deepfakes,²¹⁰ creating a bit of an arms race.

In addition to improving deepfake detection, technologists have also sought to improve methods for authenticating genuine records.²¹¹ There are tools and methods to authenticate images, such as using a cryptographic hash, a numerical value based on the zeros and ones in the digital sequence of an image.²¹² For example, *The Economist* reports of an app, eyeWitness to Atrocities, developed by a London charity, that:

When a photo or video is taken by a phone fitted with that app, it records the time and location of the event, as reported by hard-to-deny electronic

207. Kyle Wiggers, *Generative Adversarial Networks: What GANs Are and How They’ve Evolved*, VENTUREBEAT (Dec. 26, 2019), <https://perma.cc/LLR4-G5LP>; see also Riana Pfefferkorn, “Deepfakes” in the Courtroom, 29 B.U. Pub. Int. L.J. 245, 249 (2020), <https://perma.cc/9T7R-3GAU>.

Delfino, *Pornographic Deepfakes: The Case for Federal Criminalization of Revenge Porn’s Next Tragic Act*, 88 Fordham L. Rev. 887 (2019).

210. Pfefferkorn, *supra* note 207, at 250.

211. *Id.* at 251

212. See NIST Special Publication 800-152, *A Profile for U.S. Federal Cryptographic Key Management Systems* (Oct. 2015), <https://perma.cc/45Q6-K3ZQ>. This defines “hash function” as “[a]n algorithm that computes a numerical value (called the hash value) on a data file or electronic message that is used to represent that file or message, and depends on the entire contents of the file or message. A hash function can be considered to be a fingerprint of the file or message.”

witnesses such as GPS satellites and nearby mobile-phone towers and Wi-Fi networks. This is known as the controlled capture of metadata, and is more secure than collecting such metadata from the phone itself, because a phone's time and location settings can be changed. Second, the app reads the image's entire digital sequence (the zeros and ones which represent it) and uses a standard mathematical formula to calculate an alphanumeric value, known as a hash, unique to that picture.²¹³

The metadata is sent to a secure server, separate from where the image is stored. Later, the image can be examined, and any difference from the recorded hash value would indicate an alteration in the image.²¹⁴ Such a process depends on calculating and recording the numeric value at the time of origin in a chain of custody manner. In short, there are different and developing mechanisms to tag social media posts, pictures, and other data. As discussed below, one question is when courts should require factual as well as legal authentication before admitting images, videos, or voice recordings into evidence.²¹⁵

For all these reasons, deepfakes may present evidentiary challenges to civil and criminal justice systems—for example, if the video or audio recording is a deepfake used to show guilt or innocence, or liability or lack thereof. A litigant might also proffer a deepfake as evidence without realizing it is a deepfake.²¹⁶ Scholars have also expressed concerns that a jury's general awareness of deepfakes, or a litigant's false defense that something is a deepfake, may also cause a jury to discount a genuine recording and generally undermine faith in the justice system.²¹⁷

Under Federal Rule of Evidence 901, “To satisfy the requirement of authenticating or identifying an item of evidence, the proponent must produce evidence sufficient to support a finding that the item is what the proponent claims it is,” with the jury or trier-of-fact ultimately determining the weight of the evidence.²¹⁸ Scholars identify some risks, including:

213. See *Proving a Photo Is Fake Is One Thing. Proving It Isn't Is Another*, *The Economist* (Jan. 9, 2023), <https://perma.cc/2F8T-JMER>.

214. *Id.*

215. Media outlets and NGOs like Bellingcat have developed the use of AI applications that can help identify the location of a photo or video as well as the date and time it was taken. There are also AI apps that reverse search photos to match those photos with historical or social media photos to verify locations and personal identities. There are AI apps as well that can colorize black and white photos to help match them against colored photos. Such tools have proven useful in documenting and validating the documentation of war crimes committed by Russian soldiers and units in Ukraine. See Foeke Postma, *Using New Tech to Investigate Old Photographs*, Bellingcat (Aug. 9, 2022), <https://perma.cc/T7E5-G89N>.

218. John P. LaMonaga, *A Break From Reality: Modernizing Authentication Standards for Digital Video Evidence in the Era of Deepfakes*, 69 *Am. U. L.R.* 1945, 1963 (citing *United States v. Branch*,

Reference Guide on Artificial Intelligence

- as deepfake technology becomes better and more accessible, an authenticating witness may not be able to tell whether an item proffered as evidence is genuine or fake; nor would jurors be able to do so later, when weighing the evidence;
- a witness might allow a deepfake to inform and shade imperfect human memory; and
- where authentication is based on the fact that an item comes from an archive or system of records (for example, police body cam video archives), possible manipulation via cyber-hacking or otherwise might not be evident.²¹⁹

Courts and legislatures might examine whether existing rules of evidence for authentication and expert witness testimony are sufficient to address the issue of deepfakes. Scholars diverge on this point.²²⁰ Scholars and practitioners tend to agree, however, that trials will require expert testimony by digital forensic specialists as well as increased litigation over the authenticity and veracity of photographic, video, and audio evidence.²²¹

Federal Rule of Evidence 902(13) and (14), adopted in 2017, set forth “certified records generated by an electronic process or system” and “certified data copied from an electronic device, storage medium, or file,” respectively, as “items of evidence that are self-authenticating.” Items with cryptographic hashes, discussed above, might be authenticated under these rules. The committee notes on the 2017 amendments suggest that 902(13) and (14) were adopted to avoid “the expense and inconvenience of producing a witness to authenticate an item of electronic evidence” only to have the other party stipulate to authenticity or fail to challenge the authentication testimony. The amendments do, however, provide for a party to challenge self-authentication: “the proponent must give an adverse party reasonable written notice of intent to offer the record—and must make the record and certification available for inspection.”²²² A party suspicious of a deepfake would have “fair opportunity to challenge” the record and certification.²²³ Again, digital forensic experts would be in demand.

Conclusion

The multidisciplinary AI field presents a myriad of complex evidentiary challenges. The law rarely, if ever, keeps pace with technology. The legislative and appellate processes simply do not move at the same pace as technological change and could not if they tried. Moore's Law is faster than case law. Likewise, scholars and commentators are currently better at asking questions than they are at answering them. Artificial Intelligence itself is a fast-moving field encompassing a constellation of technologies.

Judges and lawyers do not need to be mathematicians or coders to understand AI and to wisely adjudicate the use of AI in courts or by courts. Judges need to define and understand their roles as overseers of discovery, evidentiary gatekeepers, constitutional guardians, translators, and in some cases, potential AI consumers. Perhaps the most important thing courts can do is ask careful and informed questions. Judges should also put their analysis and application of the answers on record as to whether, why, how, and subject to what evidentiary standards and determinations AI has been admitted into evidence or used by courts. This will allow full and informed appellate review. We hope this reference guide provides a foundation judges can use for understanding AI and building a common law of AI.

Glossary of Terms

This glossary is borrowed from our publication *An Introduction to Artificial Intelligence for Federal Judges*,²²⁴ co-authored by Matthew Mittelsteadt.

algorithm. “[A] step-by-step procedure for solving a problem or accomplishing some end.”²²⁵ A familiar example is a recipe, which details the steps needed to prepare a dish. In a computer, an algorithm is implemented in computer code and details the discrete steps and calculations a computer needs to implement to complete a task. An algorithm is the “engine” an AI uses to “think” and make predictions. In the field of AI, the term “algorithm” is often used synonymously with “computer program.” A program, however, is a more specific term, referring to an algorithm written in computer code and packaged for execution.

algorithmic bias. According to McKinsey, “[w]hile ‘bias’ can refer to any form of preference, fair or unfair,” undesirable AI bias is bias that leads to “discrimination against certain individuals or groups of individuals based on the inappropriate use of certain traits or characteristics.”²²⁶ As AI is designed by humans, AI will always be biased and will assume the biases of its engineers, potentially leading to poor or discriminatory results. As noted throughout this guide, causes of bias can stem from the statistical, such as errors in model design, to the social, to the use of inapt data to the context presented. Bias can also be caused by incomplete datasets. For instance, a facial recognition AI trained only on male faces may perform poorly when analyzing female faces.

artificial general intelligence (AGI). In the future it is possible we will move past narrow AI and develop artificial general intelligence that does not have a narrow function and can serve multiple purposes. AGI can be conceived of as an AI system that equates to or surpasses the general-purpose intelligence of the human brain.²²⁷ AGI does not have a precise definition, and the line that divides it from narrow AI is grey. As such, the introduction of AGI will likely be a gradual process, and it is unlikely there will be a precise “Sputnik moment” that introduces the age of AGI.

artificial intelligence (AI). There is no agreed upon or general definition of AI. However, one practical definition is that artificial intelligence is any machine

that can “perform tasks that would otherwise require human intelligence.”²²⁸ The NSCAI expands on this idea, noting “AI is not a single piece of hardware or software, but rather, a constellation of technologies that gives a computer system the ability to solve problems and to perform tasks that would otherwise require human intelligence.”²²⁹ AI is implemented in computers as algorithms based on models such as artificial neural networks (ANN), which are often iteratively designed through methods such as machine learning (ML) or deep learning (DL). One statutory definition of AI is found in the National Defense Authorization Act of 2020, which states:

The term “artificial intelligence” means a machine-based system that can, for a given set of human-defined objectives, make predictions, recommendations or decisions influencing real or virtual environments. Artificial intelligence systems use machine and human-based inputs to—

- (A) perceive real and virtual environments;
- (B) abstract such perceptions into models through analysis in an automated manner; and
- (C) use model inference to formulate options for information or action.

Section 5002(3) of the NAI Act 2020 (Division E of NDAA 2020).

artificial neural network (ANN). The model (or “tool”) used in deep-learning AI best defined as a computer system that works to achieve intelligence through a network structure that works to simulate the human brain.²³⁰ An ANN analyzes data by passing data through multiple layers of artificial neurons that sift through and decipher the data. This layered network structure allows the system to analyze discrete data elements, draw connections between discovered data patterns, and ultimately derive meaning and form predictions. Neural networks can be wide, meaning each layer has large numbers of neurons, or deep, meaning data must pass through many layers of neurons before a final conclusion is drawn. Engineers determine the width and depth of the network based on their interpretation of the tools and structures a specific AI application needs for success.

autonomous systems. AI-controlled machines and vehicles such as driverless cars and aerial drones that can operate and make decisions with little or no human control. Such systems already exist. In most cases, stringent safety demands have forestalled widespread use.

228. Baker, *supra* note 37, at 21.

229. NSCAI, *supra* note 1, at 8.

230. *What Is a Neural Network?*, IBM, *supra* note 110.

black box. A term used to describe the often-mysterious nature of AI decision making and the problem of AI explainability.²³¹ Most AI programs write their own algorithms through machine learning, which can result in complex code and decision-making processes indecipherable even to engineers. Such complexity limits human ability to understand how an AI makes decisions, and what factors, including biases, may have influenced those decisions. However, considerable research is underway by organizations such as the National Institute of Standards and Technology (NIST) to enable more transparent neural networks, which may allow judges and lawyers to more fully understand the parameters and weights applied within.²³²

confidence score. Any expression of certainty in the predictive accuracy of an AI or ML application.²³³ AI applications are imperfect and offer approximate results, decisions, or predictions that can be provided with a level of confidence. Few, if any, results an AI produce should be treated as a certainty. For example, the FBI facial identification software mentioned in the introduction to this guide is not designed or intended to match a single identity with a face. Rather it offers the user a range of potential matches based on potential pattern similarities or matches. The algorithm is reported to be accurate 86% of the time when the algorithm output offers the user at least fifty potential match pictures.²³⁴ Put another way, the AI has 86% confidence that the match will be one of the fifty given matches.

deep learning. A machine-learning approach characterized by the use of a multilayered artificial neural network.²³⁵ Deep learning can use but does not necessarily require labeled datasets.²³⁶ This approach has exploded in popularity over the last decade²³⁷ and is the predominant form of machine-learning AI. Common applications use deep learning, including many driverless cars and voice-recognition AI.

facial recognition. A prominent class of AI applications that can detect a face and analyze its features (or “biometrics”) and even predict the identity of that face. These AI applications are notable for their common use in criminal justice and national security as a means of identifying suspects or threats.

Facial recognition algorithms can also be used to surveil more generally. Facial recognition may also be used as a biological “password” to authenticate an individual’s identity (for example, to unlock a smartphone).

human in-the-loop. An autonomous AI system designed to work cooperatively with a human to complete its tasks. Often these AI defer to human judgment when making certain decisions, especially those with significant consequences or moral weight. Human in-the-loop systems generally seek a “best of both worlds” approach that maximizes the benefits of both human and AI decision making.

human on-the-loop. An autonomous AI system designed to work under human oversight, allowing the human to easily intervene if the AI’s decisions are in error, pose significant danger, or are ethically compromising.

human out-of-the-loop. An autonomous AI system designed to operate without human oversight or involvement. Such systems do not facilitate easy human intervention if unethical or dangerous decisions are made.

lethal autonomous weapons systems (LAWS or simply AWS). Autonomous systems that can use deadly force, which have received outsized legal, ethical, and political attention given widespread concerns about giving inhuman systems the power to take a human life.

machine learning (ML). A method of creating AI that relies on data, algorithms, and learned experience to refine algorithms and form intelligence.²³⁸ The premise of machine learning is that “intelligence” is not innate but must be learned through experience. Machine-learning AI algorithms are “trained” by engineers who feed it mass amounts of data that it slowly learns to interpret and understand. In response to the data, the AI gradually tweaks its code to steadily improve its abilities. These tweaks add up over time, helping the AI create stronger predictions. Forms of machine learning include the following:

- **supervised learning** (“learning through instruction”): A form of machine learning where engineers specify a desired outcome and feed the AI algorithm curated and labeled data to guide AI toward that outcome.²³⁹ For example, to teach a facial recognition AI to match names and faces, labeled facial data would be fed to the AI algorithm so it could learn which faces correspond to which names. This method is ideal for tasks with agreed upon “correct” answers or decisions.
- **unsupervised learning** (“self-taught learning”): A form of machine learning where unstructured and uncured data are fed to a machine-learning algorithm that finds trends, patterns, and relationships in that

238. *What Is Machine Learning (ML)?*, IBM, *supra* note 111.

239. *Id.*

data.²⁴⁰ This is useful for finding insights humans may have overlooked or cannot perceive. This method is ideal for applications without a firm answer and for general data analysis.

- **reinforcement learning** (“learning by doing”): A form of machine learning where the algorithm learns through trial and error.²⁴¹ Its learning is often guided by a goal (e.g., winning a game of chess) and adjusts its parameters to better reflect trials that helped it to reach or come close to that goal. This method is useful for discovering optimal solutions in many rule-based systems, including chess, chemistry, physics, and traffic pattern analysis.

narrow AI. “[T]he ability of computational machines to perform singular tasks at optimal levels, or near optimal levels, and usually better than, although sometimes just in different ways, than humans.”²⁴² Under this umbrella falls many single-purpose or limited-purpose AI technologies, such as facial recognition algorithms, driverless cars, and drones. These technologies are intelligent in one or a few domains, limiting their ability to handle complexity or tasks outside of their intended purpose. All AI currently in use falls in this category.

natural language processing (NLP). AI algorithms designed to process, analyze, and recognize written or verbal human speech at human levels.²⁴³ NLP has a wide variety of applications. Familiar applications include virtual assistants such as Amazon’s Alexa or Apple’s Siri. In national security and criminal justice, NLP can be used to analyze and understand language recordings and written information, drawing conclusions, insights, and patterns from that data. This offers a powerful intelligence and investigative tool. It can also be used to match a voice to an identity (much like facial recognition) and for language translation.

superintelligence (SI). AI philosophers also contemplate the emergence of superintelligence, a stage of AI evolution marked as beyond human intelligence.²⁴⁴ SI has sparked widespread concern, and its risks and benefits are unclear. Stephen Hawking highlighted this uncertainty in 2015, exclaiming that “AI may be the best thing to ever happen to humanity or the worst.”²⁴⁵ A malicious SI could cause incalculable harm and a beneficial SI could prove an invaluable tool. It must be noted that many engineers and government officials

Introduction

Climate science examines the structure and dynamics of the Earth's climate system and how that system is influenced by human and natural processes.¹ The climate system consists of five interacting systems: the atmosphere, hydrosphere, cryosphere, lithosphere, and biosphere.² Thus, climate science spans multiple disciplines, including atmospheric science, physical geography, and oceanography. It also encompasses research on the interactions between the global climate system and other natural and human systems, which implicates fields such as biology, economics, and social sciences. Owing to the complexity and pervasiveness of the climate system, it is difficult to establish precise boundaries for this field—but for the purposes of this reference guide, we focus on the physical science aspects of climate science.³

Climate scientists use observational data, physical understanding, statistical analysis, and climate models to understand and characterize the complex interactions among different components of the climate system. One key focus of this research is to understand the mechanisms of observed climate change and to characterize how humans are affecting the global climate system through greenhouse gas (GHG) emissions and other climate forcing factors.⁴ The Intergovernmental Panel on Climate Change (IPCC), an intergovernmental organization tasked with assessing scientific knowledge about climate change, is generally viewed as the leading scientific authority in this field.⁵ The IPCC periodically publishes assessment reports synthesizing the latest research on climate change. The IPCC's Sixth Assessment Report (AR6) found that: “[i]t is unequivocal that human influence has warmed the atmosphere, ocean and land,” and this has caused “[w]idespread changes in the atmosphere, ocean, cryosphere, and

1. For a more detailed definition, see *Climate Science*, in Stanford Encyclopedia of Philosophy (May 11, 2018), <https://perma.cc/SCN3-5Y4M>.

2. “Climate” describes weather conditions averaged over a period of time, typically decades or more. The atmosphere is the gaseous envelope surrounding the Earth; the hydrosphere refers to the components of the earth system composed of water; the cryosphere refers to the components of the earth system composed of ice; the lithosphere is the rocky outer portion of the Earth; and the biosphere refers to all life on Earth. Please refer to the glossary for more detailed definitions of these and other technical terms used in this chapter.

3. Although our focus is on physical climate science, it is necessary to discuss the interactions between physical climate science and other fields when discussing certain areas of the science. See, e.g., sections titled “Impact Detection and Attribution” and “Source Attribution” below.

4. A climate forcing factor is any substance, activity, or event that affects the flow of energy coming into or out of the global climate system, thus affecting the amount of heat retained within the system. Anthropogenic climate forcers include GHGs, aerosols, and changes in land use that make land reflect more or less solar energy. There are also natural climate forcers, such as solar radiation and the particulate matter from volcanic eruptions.

5. For more information about the IPCC and its assessment methodology, see section titled “Scientific and Consensus Reports” and Appendix below.

biosphere.”⁶ The global warming attributable to human activities is unprecedented in the last 2,000 years⁷ and “is already affecting every inhabited region across the globe, with human influence contributing to many observed changes in weather and climate extremes.”⁸

The increasing effect of anthropogenic climate change has contributed to growth in climate-change-related litigation in the United States and other jurisdictions. Much of this litigation seeks to establish legal obligations on the part of governments to control GHG emissions, prepare for the effects of climate change, and disclose climate-change-related risks in government documents; some litigation seeks the opposite. There are several ways in which climate science may factor into the resolution of climate-related lawsuits. First, climate science can be used to assess causation—for example, whether and to what extent an actor has caused or contributed to climate-change-related risks or injuries. Second, climate science can be used to assess whether climate-related impacts or risks are foreseeable, which is potentially relevant to determining whether a defendant is required or authorized to take some action in response to climate change. Third, climate science can be used to determine the scope of a defendant’s legal obligations and authorities—for example, whether the defendant has an obligation to reduce GHG emissions or take measures to prepare for the impacts of climate change.

The purpose of this reference guide is to help judges evaluate the admissibility and weight of expert testimony and documentary evidence involving climate science.

The second part of this reference guide, “Foundational Components of Climate Science,” describes the data and methodologies used in climate research, the scientific disciplines that constitute this field, the types of qualifications held by experts in this field, and the primary sources of climate research.

The third part of this reference guide, “Climate Change Detection, Attribution, and Projections,” provides a more in-depth discussion of research on anthropogenic climate change. It describes research methodologies and the status of scientific knowledge across three disciplines: (1) climate change detection and attribution research, which examines whether observed changes in natural and human systems can be attributed to human influence on climate; (2) source attribution research, which examines the relative contributions of different entities to

6. IPCC, *Climate Change 2021: The Physical Science Basis*, Contribution of Working Group I to the Sixth Assessment Report of the IPCC (Valérie Masson-Delmotte et al. eds.) [hereinafter IPCC AR6 WGI], <https://perma.cc/D93G-EPRC>. Other scientific bodies have also found unequivocal evidence of anthropogenic climate change. See National Academy of Sciences, *Climate Change: Evidence and Causes: Update 2020* [hereinafter NAS Update], <https://perma.cc/9XTW-S7DA>; U.S. Global Change Research Program, *Fourth National Climate Assessment*, Vol. 1, *Climate Science Special Report* (Donald J. 8. *Id.* at 10.

anthropogenic climate change; and (3) predictive research, which provides insights on future climate change and its impacts under different emissions trajectories and warming scenarios.

The last part of this reference guide, “How Climate Science Factors into Litigation,” discusses the role of climate science in litigation. It provides a brief overview of the types of legal claims that implicate climate science, focusing on federal claims, and describes how different areas of climate research may factor into judicial assessments of causation, foreseeability, and legal obligations and authorities. There are various contexts where judges may confront genuine scientific questions and areas of uncertainty in this field—for example, when tasked with determining whether a specific plaintiff’s injuries were caused by climate change, and whether and to what extent a defendant contributed to those injuries. This reference guide seeks to provide the scientific context necessary for answering such questions, while also recognizing the normative and legal considerations that will factor into this type of analysis.

Foundational Components of Climate Science

Scope of Research

The Earth’s climate system is enormous and complex, consisting of many nested and interlinked subsystems, including the atmosphere, hydrosphere, cryosphere, lithosphere, and biosphere. The interactions between these components produce the conditions known as “climate”—i.e., weather conditions averaged over a period of time, typically decades or longer. Although the climate system is global, climate is typically characterized in reference to a particular region or locale as a result of spatial variations in climatological conditions.

Climate science is the field of study aimed at characterizing the climate system and understanding the physical processes and parameters that ultimately determine climate conditions. Owing to the breadth and complexity of the climate system, climate research spans many different scientific disciplines. For example, research on the physical science of climate and climate change (i.e., understanding of the physical properties of the climate system and how it is changing) encompasses: (1) mathematics and statistics; (2) basic sciences, e.g., physics and chemistry; (3) earth sciences, e.g., atmospheric sciences, climatology, physical geography, oceanography, meteorology, hydrology, biogeochemistry, and cryospheric sciences; and (4) computer sciences and data analysis. Most climate research involves collaboration across these different fields.

Climate science also encompasses research on the interactions between the climate and other natural and human systems, with a significant body of work

aimed at characterizing the effects of climate change on people, infrastructure, and ecosystems. Research on climate change impacts implicates both physical climate science (including the subfields noted above) and other disciplines, such as (1) biological and ecological sciences; (2) social sciences and economics; (3) epidemiology, population health, and health impact research; (4) fire dynamics; and (5) engineering and other fields relevant to assessing impacts to transportation, energy, and other infrastructure systems. Although studies on climate impacts vary considerably in terms of their focus (i.e., the impact(s) being studied), these studies typically utilize common methodologies, datasets, and models, as discussed below.

Core Concepts and Methods

The foundational components of climate science are:

- **Physical understanding of the climate system**, i.e., understanding of the physical properties of the climate, including the different component systems and interactions between those systems, as well as the effect of exogenous variables on the system.
- **Climate datasets**, which include direct observations of climate variables, paleoclimate reconstructions, and reanalysis datasets.
- **Statistical techniques** and **climate models**, which are used to evaluate patterns, trends, causal relationships, variability, and uncertainty within the climate system, and to develop projections of future climate change.

These components are interconnected and mutually reinforcing—for example, physical understanding of the climate system is based on observations and statistical analysis, and climate models incorporate a combination of physical understanding, observational evidence, and statistical techniques in order to derive insights on how changes in a particular input to the climate system can affect other variables within the system. The sections below provide more detailed explanations of each component and its role in climate research.

Physical Understanding

In the early 1800s, physicists and other scientists began conducting experiments and developing theories to explain the physical mechanisms behind global and regional climate conditions. It was hypothesized that the Earth had undergone significant climate changes in the past based on observations of the natural

world, but the mechanism behind these changes had yet to be discovered.⁹ In the 1820s, the physicist Joseph Fourier developed an early theory of what would eventually be recognized as the “greenhouse effect.” Fourier had calculated that an object that is the same size as the Earth and same distance from the sun would be considerably colder than the Earth if it were heated by incoming solar radiation alone. Fourier hypothesized that the Earth’s atmosphere trapped incoming solar radiation in the form of heat, thus causing the planet to be warmer than would otherwise be the case.¹⁰ Several decades later, scientists such as Eunice Foote and John Tyndall recognized that atmospheric gases, particularly carbon dioxide (CO₂) and water vapor, may be responsible for this warming effect. They correctly hypothesized that these gases absorbed incoming solar radiation—preventing it from being re-emitted to space—thus increasing the energy and heat content of the Earth’s atmosphere. These scientists were also able to demonstrate and measure the greenhouse effect of CO₂ through lab experiments in the 1850s and 1860s.¹¹ Subsequently, in the late nineteenth century, the Swedish chemist Svante Arrhenius hypothesized that human-caused GHG emissions from fossil fuel use and other combustion sources were large enough to cause global warming.¹²

Since those early experiments, scientific knowledge of the climate has advanced significantly. IPCC AR6 found that physical understanding of the fundamental features of the climate system is “robust and well established,”¹³ and scientists can explain many of the core processes that determine climate conditions. Some areas of physical understanding that are integral to climate research include: (1) the greenhouse effect and radiative forcing; (2) the carbon cycle and other biogeochemical cycles that govern the movement of chemical elements among different parts of the climate system and connected systems; (3) the mechanisms of atmospheric and ocean circulation and their relationship to the hydrological cycle; (4) the role of feedback loops, tipping points, and cascading impacts in the climate system; and (5) natural variability in the system.

9. For example, in the early 1800s, Jean-Pierre Perraudin hypothesized that glaciers might be responsible for giant boulders seen in alpine valleys, and Luis Agassiz subsequently hypothesized that glaciers had covered much of Europe and North America during what he referred to as an “Ice Age.” See E. P. Evans, *The Authorship of the Glacial Theory*, 145 N. Am. Rev. 94 (1887), <https://perma.cc/Y9AG-4P9P>.

The greenhouse effect and radiative forcing

The greenhouse effect plays a fundamental role in shaping climate conditions, as it ultimately determines the amount of incoming solar energy that is retained within the system. The heat-trapping properties of GHGs are now well understood and can be quantified over different time horizons. Water vapor is the most abundant naturally occurring GHG in the atmosphere and is responsible for approximately half of the Earth's natural greenhouse effect. Other common GHGs in the atmosphere include CO₂, methane (CH₄), nitrous oxide (N₂O), fluorinated gases, chlorofluorocarbons (CFCs), and hydrochlorofluorocarbons (HCFCs). As discussed in the second part of this reference guide, "Climate Change Detection, Attribution, and Projections," large increases in GHG concentrations due to fossil fuel emissions and other human activities are the dominant cause of observed global warming and climate change.¹⁴

The effects of anthropogenic GHG emissions on the atmosphere are an example of radiative forcing—a change in the energy flux within the Earth's atmosphere. Positive radiative forcing occurs when the Earth receives more incoming energy from sunlight than it radiates into space, and this net gain of energy causes warming. There are a number of natural processes that can affect net radiative forcing—these include changes in the percentage of incoming solar radiation absorbed by the Earth, volcanic activity, orbital cycles, and changes in global biogeochemical cycles (discussed below). There are also other human drivers that can affect atmospheric energy flux—for example, land use changes can have positive or negative effects on radiative forcing, and aerosol emissions have negative radiative forcing and thus contribute to cooling of the climate system.

Scientists have been systematically studying the interactions between both human and natural forcing since the early 20th century.¹⁵ Although the heat-trapping properties of specific substances are fairly well understood, there is still some uncertainty about the effect of certain processes (e.g., land use changes) on climate forcing, as well as the relative contributions of different forcing agents to observed climate changes, especially at regional scales. Nonetheless, physical understanding of radiative forcing associated with GHGs is sufficiently robust to

14. Observations have demonstrated that atmospheric moisture content (water vapor) is increasing along with other GHGs, and this amplifies the greenhouse effect. However, the increase in atmospheric moisture content is directly attributable to human-induced global warming (from GHG emissions). In other words: increased water vapor is a consequence of anthropogenic climate forcing; it is not an indicator of "natural" climate change. Were these other GHG concentrations to somehow drop to pre-industrial levels, water vapor would almost instantaneously return to pre-industrial levels as well. See B.D. Santer et al., *Identification of Human-Induced Changes in Atmospheric Moisture Content*, 104 Proc. Nat'l Acads. Scis. [hereinafter PNAS] 15248 (2007), <https://doi.org/10.1073/pnas.0702872104>.

15. IPCC AR6 WGI, *supra* note 6, at 150.

support assessments and projections of global warming. For example, each additional increment of CO₂ added over the past century and projected to be added for the coming decades is expected to yield a comparable change in direct radiative forcing. Furthermore, past projections of global temperature change in response to radiative forcing have been broadly consistent with subsequent observations.¹⁶

Biogeochemical cycles

Biogeochemical cycles govern the transfer of chemicals among different components of the climate system and other earth systems. Some of the cycles that are integral to the study of climate include the carbon cycle, nitrogen cycle, water cycle, and phosphorus cycle. Here we focus on the carbon cycle owing to the dominant role of CO₂ in global climate change. The water (or hydrological) cycle is also integral to the study of climate, as discussed in various contexts below.

The carbon cycle describes how carbon moves between the atmosphere, hydrosphere, biosphere, cryosphere, and lithosphere.¹⁷ Most of the carbon on the planet is stored in the lithosphere, primarily in sedimentary rock deposits, and a small fraction stored in fossil fuels. Carbon is also stored in the atmosphere (as CO₂),¹⁸ in the oceans (as dissolved atmospheric carbon and in carbonate sediments), and in the biosphere (as organic molecules in organisms and soil). Oceans and terrestrial systems are generally characterized as “sinks” or “reservoirs” of carbon because, at today’s high atmospheric concentrations of CO₂, they typically absorb more carbon than they release into the atmosphere.

The primary pathways through which carbon is released into the atmosphere include human combustion of fossil fuels, industrial processes, wildfires, volcanic eruptions, biological respiration, and decomposition of organic matter. Once CO₂ enters the atmosphere, it can remain there for a very long time—potentially thousands of years or more—but there is significant variation in the atmospheric lifetime of individual CO₂ molecules.¹⁹ A large proportion (20–30%) of the CO₂ that enters the atmosphere is absorbed by the oceans, where it dissolves into seawater and forms carbonic acid (resulting in ocean acidification). The initial process of ocean absorption can occur within a relatively short time frame (e.g., within five years), but much of that carbon is circulated back into the

16. *Id.* at 150.

17. For a more detailed overview of the carbon cycle and how it is influenced by human activities, see U.S. Global Change Research Program, *Second State of the Carbon Cycle Report*, (N. Cavallaro et al. eds., 2018), <https://perma.cc/KT2H-GTUK>.

18. Atmospheric carbon also comes from methane (CH₄), which is converted into CO₂ as it combines with oxygen.

19. Because of variation, the IPCC does not recognize a specific lifetime for CO₂ molecules. See IPCC AR6 WGI, *supra* note 6, at 302.

atmosphere on a short time frame as well (e.g., within ten years or less).²⁰ Thus, carbon is constantly cycling between the oceans and atmosphere.

Carbon is also constantly cycling between the atmosphere and biological systems on land (i.e., forests, grasslands, and other ecosystems). The amount of carbon stored in the terrestrial sinks is largely based on the carbon uptake of vegetation through photosynthesis, with large interannual variability due to natural changes in vegetation as well as human land uses. There are some instances in which terrestrial sinks may become carbon sources—specifically, when the amount of carbon that is released is greater than the amount of carbon that is absorbed. This may occur, for example, as a consequence of wildfires or ecosystem degradation.²¹

Human activities, including land use changes and the burning of fossil fuels, have disturbed the natural carbon cycle, releasing more than two trillion metric tons of CO₂ and methane (CH₄) into the atmosphere since the onset of the industrial revolution. A portion of those emissions remains in the atmosphere; the remainder is absorbed by ocean and terrestrial sinks. The “airborne” fraction of anthropogenic carbon emissions has remained constant at approximately 44% over the past six decades,²² but the capacity of ocean and terrestrial sinks to absorb carbon is expected to decline as the CO₂ concentrations increase.²³

Atmospheric and ocean circulation and the hydrological cycle

The movement of air, water, and heat in the climate system plays an integral role in shaping regional climate conditions, including regional temperature, precipitation, humidity, and aridity, as well as extreme weather events. In particular, regional climate is influenced by atmospheric circulation (the large-scale movement of air and heat in the atmosphere), ocean circulation (the large-scale movement of water in oceans), and the hydrological cycle (the circulation of water between different earth systems), in addition to other factors.²⁴ Understanding

22. IPCC AR6 WG1, *supra* note 6, at 676.

23. *Id.* at 677.

24. Some of the other factors that shape regional climate include the amount of sunlight the area receives (which depends, in large part, on latitude); altitude, topographical features, and the shape of the land (i.e., “relief”); and proximity to oceans and large water bodies.

the mechanisms and relationships between these large-scale processes is key to understanding the climate system and climate change.²⁵

These circulatory processes are governed by thermodynamics as well as other physical processes (e.g., gravity, surface friction, planetary rotation).²⁶ Thermodynamic processes are those that involve the exchange of heat, work, temperature, and energy. There is strong theoretical understanding of how thermodynamics influence certain aspects of the climate system, which contributes to high confidence findings for certain trends and impacts, particularly those that are directly attributable to temperature changes.²⁷ Radiative forcing is an example of a thermodynamic process that is well understood. Dynamic processes are those that deal with the movement of bodies in response to physical forces (e.g., the physical transport of air masses of a given temperature and moisture content).²⁸ As noted by Screen et al. (2018), the dynamic manifestations of climate change are not as well understood as thermodynamic aspects, but they are strongly constrained by well-understood principles, especially the conservation of energy and mass, and the knowledge gap is narrowing as a result of recent research unpacking the causal mechanisms behind observed changes in circulation patterns.²⁹ More limited understanding of dynamic processes contributes to uncertainty about certain aspects of climate and climate change, including uncertainties about the relationships between increasing GHG concentrations, changes in hydrological and cryospheric processes, and changes in clouds.³⁰

Feedback loops, tipping points, and cascading impacts in the climate system

Understanding the climate system and anthropogenic influence on that system requires understanding of feedback loops, cascading impacts, and tipping points. Feedback loops are causal processes that occur when outputs of a system are routed back as inputs, resulting in acceleration of a process or change (positive

25. Coupled models have been developed to simulate the interactions between atmospheric and ocean circulation and other components of the climate system. See section titled “Statistical Techniques and Climate Models” below.

26. The hydrological cycle is also influenced by chemical and biological interactions, which is why it is characterized as a biogeochemical process.

27. IPCC AR6 WGI, *supra* note 6, at 430.

28. The term “dynamic” is also used in climate science to describe systems that are characterized by change and complexity. Here, we specifically refer to dynamics as a subdivision of physical mechanics.

29. J.A. Screen et al., *Polar Climate Change as Manifest in Atmospheric Circulation*, 4 Current Climate Change Reps. 383 (2018), <https://doi.org/10.1007/s40641-018-0111-4>.

30. See, e.g., Eilat Elbaum et al., *Uncertainty in Projected Changes in Precipitation Minus Evaporation: Dominant Role of Dynamic Circulation Changes and Weak Role for Thermodynamic Changes*, 49 Geophysical Resch. Letters e2022GL097725 (2022), <https://doi.org/10.1029/2022GL097725>.

feedback) or deceleration (negative feedback).³¹ One key example of a feedback loop in the climate system is water-vapor feedback: warmer temperatures increase water vapor in the atmosphere, and the water vapor, which is a GHG, traps additional heat. Researchers believe that this may play an important role in current and future warming trends.³² Another important feedback loop is the ice-albedo feedback loop, whereby warmer temperatures result in the melting of ice caps, glaciers, and sea ice (all of which have high albedo, i.e., they reflect more sunlight back to space), thus decreasing the albedo of land and ocean surfaces, and accelerating the warming process.

The term “tipping point” describes a threshold that, when surpassed, will result in large and typically irreversible changes.³³ Tipping points are common throughout the climate system as well as other systems that are affected by climate change. Key examples of important tipping points within the climate system are the temperature at which the melting of the Greenland ice sheet becomes irreversible (a process that would ultimately trigger meters of sea-level rise as well as changes in atmospheric and ocean dynamics), the collapse of Arctic winter sea ice, the dieback of the Amazon rainforest, the irreversible loss of mountain glaciers, and the collapse of boreal permafrost. Generally speaking, the existence of tipping points is known with much higher confidence than the temperature thresholds at which they will occur. Some critical tipping point thresholds may have already been surpassed, although the full effects have not yet manifested because of time lags and/or incomplete understanding.³⁴ This highlights an important aspect of tipping points: critical thresholds can be “locked in” before the actual event occurs (e.g., the near complete melting of the Greenland ice sheet may already be inevitable because of existing warming).³⁵ Although much is unknown about the timing and potential consequences of climate tipping points, there are significant risks associated with surpassing these thresholds, since consequences can be so large.³⁶

Cascading impacts are a related concept. These can be conceptualized as a series of impacts that occur together due to interdependencies within a

36. Timothy M. Lenton et al., *Climate Tipping Points—Too Risky to Bet Against*, 575 Nature 592 (2019), <https://doi.org/10.1038/d41586-019-03595-0>.

system, flowing out to other domains, and potentially amplifying risks and hazards.³⁷ Cascading impacts can occur as a result of feedback loops and surpassing tipping points. Cascading impacts are a particular concern when evaluating the effects of climate change on human and natural systems. For example, changes in bioclimatic conditions caused by global warming can result in a cascade of ecosystem alterations (e.g., extinctions leading to alterations in food webs that have cascading effects on other species, potentially even triggering further extinctions).

Natural variability

Natural variability in the climate system refers to those variations in climate that are caused by events and processes of nonhuman origin, in conjunction with the chaotic nature of the system. It includes variability that is internally generated within the system, like the El Niño Southern Oscillation (ENSO),³⁸ as well as variability driven by natural external factors, such as variations in solar activity and volcanic eruptions. Natural variability can play a prominent role in explaining variations in global climate over certain time spans (years, months, days). Put another way, the chaotic nature of the climate system—whereby small differences in initial conditions can ultimately “excite” different patterns of internal variability at different points in time leading to large differences in climate states—means that even in the presence of anthropogenic forcing, a broad range of temperature trends ranging from positive to negative can be experienced in models—and presumably observations as well if we had more than one sample to draw from—on a timescale of years at the global scale, and decades at the regional scale. However, the influence of natural variability tends to be small when evaluating recent large-scale trends over periods of multiple decades or longer.³⁹ Understanding natural variability is important for climate change attribution and projections, insofar as it is necessary to ascertain whether an observed trend, impact, or event is a consequence of anthropogenic forcing rather than natural variability within the system. Some patterns of natural variability, like ENSO, may themselves be impacted by anthropogenic warming in ways that are not yet completely understood.

Although there is still some uncertainty about the physical drivers of natural climate variability, researchers have developed techniques for reproducing many aspects of variability in climate models based on increasing physical

37. See Judy Lawrence et al., *Cascading Climate Change Impacts and Implications*, 29 *Climate Risk Mgmt.* 1000234 (2020), <https://doi.org/10.1016/j.crm.2020.100234>.

38. ENSO is an interaction between the tropical Pacific atmosphere and ocean that produces roughly year-long global impacts approximately every five to seven years.

39. See IPCC AR6 WGI, *supra* note 6, at ch. 3.

understanding of the climate system.⁴⁰ The effects of natural variability are sometimes quantified using a signal-to-noise ratio, which compares the strength of an anthropogenic climate change signal against natural variability noise. The challenge of distinguishing the anthropogenic signal is more pronounced in regional climate assessments because natural variability plays a larger role in shaping regional (in contrast to global) climates (i.e., there is a larger signal-to-noise ratio at global scales, where some variability tends to cancel out). There can also be additional sources of internal variability at even finer scales, such as variations in ocean current location that can impact weather and climate at the scale of a nearby coastal city, for example. The accuracy with which scientists can distinguish anthropogenic signals from natural variability noise also depends on the type of impact being studied, and the temporal boundaries of the study.

Climate Datasets

In order to study climate and climate change, scientists need to be able to characterize past and present climate conditions across different geographic and temporal scales. They rely on climate datasets that provide quantitative information for various climate variables (e.g., sea surface temperature) over a given period. These datasets serve multiple purposes: they are used to develop and assess physical understanding of the climate system, to establish a baseline for evaluating changes in the climate system, and to develop, refine, and calibrate climate models.

Observational data are data that can be observed and measured. Much of the observational data used in climate research comes from instrumental records of climate variables. Examples include ground measurements of CO₂ concentrations, surface temperatures, and sea levels; satellite measurements of sea surface temperature, water vapor, precipitation, and sea ice; and aircraft measurements of cyclone wind speed.⁴¹ The first quasi-global instrumental datasets for land and sea surface temperature can be traced back to the mid-1800s (when national

40. See, e.g., Feng Zhu et al., *Climate Models Can Correctly Simulate the Continuum of Global-Average Temperature Variability*, 116 PNAS 8728 (2019), <https://doi.org/10.1073/pnas.180995911>.

41. Instrumental records are sometimes described as “direct” measurements of climate variables, but the directness of the measurement depends on the instrument being used. For example, surface thermometers provide relatively direct measurements of temperatures, whereas satellite microwave sensors record microwave emissions from which scientists can derive measurements of climate variables such as temperature and columnar water vapor. It is also important to keep in mind that instrumental records are not perfect—they may be subject to errors (e.g., calibration errors, sources of systematic error in the instrument, or interpretation techniques). However, scientists use calibration, validation, and verification techniques, often involving cross-comparison between different datasets, to ensure the accuracy of instrumental records.

and colonial weather services built networks of surface stations and began maintaining standardized weather logs).⁴² Since then, the instrumental record has grown significantly as a result of the expansion of ground measurement stations, as well as the advent of satellite remote sensing of climate variables in the 1980s. The instrumental record of current climate variables is now fairly comprehensive, but there are still spatial and temporal gaps in the instrumental record, particularly with regard to historical climate conditions and sea-level rise.

Paleoclimate reconstructions are used to evaluate climate conditions in periods prior to instrumental records. Paleoclimate research uses geological and biological evidence to reconstruct historical climate conditions for which direct measurements are not available. Paleoclimate researchers can obtain data on past climate conditions (e.g., precipitation and temperature) from sediments, rocks, tree rings, corals, ice sheets, and other physical formations. Paleoclimate reconstructions provide insights on baseline climate conditions and natural variability in those conditions before humans began influencing the atmosphere or using instruments to measure different climate variables.

Statistical Techniques and Climate Models

Statistical analysis refers to the mathematical formulas and techniques that are used in empirical analysis of data. Scientists use statistical techniques to fill gaps in observational datasets. Reanalysis datasets are generated by combining available observations with statistical analyses and climate models to infer climate conditions where direct observational data are not available. For example, interpolation can be used to fill in gaps in space and time for a climate variable based on the locations and times for the data that are available for the given variable, and thus plays a key role in data reanalysis.⁴³ Reanalysis datasets can be used to create “a coherent, long-term record of past weather by compensating for the inherent limitations of the different instruments used to take measurements at different points in the history of weather observation.”⁴⁴

Statistical analysis is also used in conjunction with observational data and climate models to detect changes in the climate system and other interconnected systems, is used to determine whether these changes are attributable to human influence (“detection and attribution” research),⁴⁵ and is used to predict

42. IPCC AR6 WG1, *supra* note 6, at 175.

43. Statistical interpolation involves estimating an unknown value based on related known values. There are many interpolation techniques, but the simplest example is linear interpolation—i.e., if observations show a linear increase in a variable over time, scientists can infer the value of that variable at a specific point in time even without a direct measurement.

44. National Oceanic and Atmospheric Administration National Centers for Environmental Information, *Reanalysis*, <https://www.ncei.noaa.gov/products/weather-climate-models/reanalysis>.

45. See section titled “Detection and Attribution” below.

future changes based on different warming trajectories.⁴⁶ For example, scientists will use statistical trend detection to determine whether there have been statistically significant changes in climate variables (e.g., precipitation) and related variables (e.g., crop yield).⁴⁷

Climate models use quantitative methods, including predictive equations and statistical techniques, to simulate interactions within the climate system. Scientists can set up different model experiments to evaluate the effect of one or more climate drivers (e.g., GHGs, aerosols, and solar flux) on one or more variables. As with statistical analysis, climate models can be used for the purposes of climate change detection and attribution as well as the projections of future climate change. Generally speaking, climate models are based on “well-established physical principles and have been demonstrated to reproduce observed features of recent climate . . . and past climate changes.”⁴⁸ Well-understood physical laws that are solved mathematically through space and time in climate models include the conservation of mass and energy. Indeed, many aspects of climate change can be modeled with a fair degree of accuracy, particularly at continental and global scales.⁴⁹ Climate models reproduce key planetary features like jet streams and ocean currents, as well as the relatively rapid warming of the northern hemisphere high latitudes in recent decades. Furthermore, a recent study found that past climate models had accurately predicted subsequent increases in global mean surface temperature (GMST), particularly when accounting for differences in projected and actual future forcings.⁵⁰ However, because of the complexity of the climate system with its nonlinear interactions and hyperlocal nature of important physical processes (e.g., thunderstorms, or shear stress at the edge of an ice sheet), there are limitations in the ability of models to accurately and precisely simulate causal relationships and processes, particularly when predicting effects of climate change at smaller spatial and/or temporal scales. Many of these complexities are partially addressed using parameterizations, which are simplified statistical estimates of complex phenomena.

There are several types of climate models with different applications, including the following: global circulation models (GCMs), which simulate general circulation of the Earth’s atmosphere and oceans; energy balance models (EBMs), which simulate changes in temperature based on the balance between incoming

and outgoing solar radiation; earth system models (ESMs), which simulate the interactions of the atmosphere, hydrosphere, geosphere, biosphere, and cryosphere to assess how changes in climate (e.g., warmer temperatures) affect and are affected by other interconnected systems such as changes in vegetation; and regional climate models (RCMs), which simulate the interactions between the climate and other earth systems at a finer resolution than ESMs. Coupled GCM and ESM models use understanding of thermodynamics, fluid motion, and other physical processes to simulate interactions between multiple components of the climate system, including atmospheric and ocean circulation. The Coupled Model Intercomparison Project (CMIP) of the World Climate Research Programme is an international initiative that combines, synthesizes, and compares different climate models in order to develop more accurate climate simulations. The CMIP model ensembles are updated periodically—the latest IPCC assessment uses results from CMIP Phase 6 (CMIP6) models, which “include new and better representations of physical, chemical, and biological processes, as well as higher resolution” compared to past climate models.⁵¹

Generally speaking, model-based approaches can support more robust findings than the use of observational data and statistical analysis alone. However, models have limitations that should be kept in mind when evaluating their results. The usefulness and accuracy of a model depends on how well the model can reproduce patterns associated with each climate forcing, and there are uncertainties in our knowledge about how individual climate forcings affect different aspects of the climate system. Comparing model results to observations can help assess the accuracy of the model, but observations cannot tell us all we need to know for several reasons. First, there is uncertainty in observational measurements for reasons discussed above. Second, internal climate variability, unrelated to climate forcing, is difficult to disentangle from climate forcing. Third, because multiple anthropogenic and natural forcings have occurred simultaneously in the past, unpacking the relative contribution of each forcing is a major challenge.

The above challenges exist to a certain degree even for variables like global average temperature where the relationship between rising GHG concentrations and average temperatures is fairly direct. Inevitably, there will be some degree of uncertainty and room for error in model results due to the complexity of the physical systems being modeled, so scientists have tools for managing and communicating uncertainty and error rates.⁵² Scientists are also constantly refining the techniques used to reduce uncertainty in their analyses, such as

51. According to the IPCC, the use of CMIP6 “has improved the simulation of the recent mean state of most large-scale indicators of climate change and many other aspects across the climate system.” However, there are still some differences between CMIP6 model results and observations, particularly with regard to regional precipitation. IPCC AR6 WGI, *supra* note 6, at 12.

52. See section titled “Managing and Communicating Uncertainty” below.

through additional and lengthened observational datasets, improvements to models, new analytical methods, and expert judgment. For example, new statistical approaches are being used to better account for internal climate variability and uncertainties in models and observations.⁵³

Another limitation to GCMs and other large-scale models is that they produce results at large spatial scales and thus cannot simulate local climate features and their impacts with precision. To address this issue, researchers are developing dynamical and statistical downscaling techniques that can be used to transform climate model outputs into more localized data products for regional or local climate impact assessments, although these approaches can run up against inherent uncertainties at fine spatial scales.⁵⁴

Managing and Communicating Uncertainty

Owing to the complexity of the climate system, researchers inevitably confront uncertainty when evaluating causal relationships and processes within the system. This is not unique to the field of climate science: uncertainty exists across all scientific disciplines, and understanding sources of uncertainty is part of the scientific process. Climate scientists use standard techniques and practices for managing and communicating uncertainty and ensuring the validity of research findings. These include statistical- and model-based approaches that actually reduce uncertainty in research findings,⁵⁵ as well as methods of framing and communicating uncertainty along with findings.

The IPCC, for example, uses probabilistic language to describe the assessed likelihood of an outcome or result and uses other language to communicate confidence and level of agreement in findings. Specifically, the IPCC describes (1) the assessed likelihood of an outcome or result (very likely, likely, etc.); (2) the availability of evidence to support particular findings (limited, medium, robust); (3) the level of agreement about findings (low, medium, high); and (4) scientific confidence in the findings (very low, low, medium, high, very high), which is based on both the level of agreement and availability of evidence for the

53. IPCC AR6 WGI, *supra* note 6, at 205. See also *id.* § 3.2.

54. “Dynamical downscaling refers to the use of high-resolution regional simulations to dynamically extrapolate the effects of large-scale climate processes to regional or local scales of interest. Statistical downscaling encompasses the use of various statistics-based techniques to determine relationships between large-scale climate patterns resolved by global climate models and observed local climate responses.” NOAA Geophysical Fluid Dynamics Lab’y, Climate Model Downscaling, <https://perma.cc/7ZBZ-NQ9D>.

55. See, e.g., Flavio Lehner et al., *The Potential to Reduce Uncertainty in Regional Runoff Projections from Climate Models*, 9 Nature Climate Change 926 (2019), <https://doi.org/10.1038/s41558-019-0639-x>.

finding.⁵⁶ The full list of terms used to communicate likelihood in the most recent IPCC report is as follows: virtually certain, 99–100% probability; very likely, 90–100%; likely, 66–100%; about as likely as not, 33–66%; unlikely, 0–33%; very unlikely, 0–10%; and exceptionally unlikely, 0–1%. Additional terms (extremely likely, 95–100%; more likely than not, >50–100%; and extremely unlikely, 0–5%) are also used when appropriate.⁵⁷ The use of such calibrated uncertainty language can make scientific findings more accessible to scientists and nonscientists alike.

Importantly, a finding of “low evidence” or “low confidence” does not equate to a finding that a particular proposition is not true or valid—it simply means that there is not enough evidence for IPCC scientists to reach agreement on the proposition. As new scientific data become available for subsequent assessments, the IPCC often revises these statements to reflect greater levels of confidence (e.g., the IPCC expressed greater confidence in the attribution of extreme events to climate change in AR6 than it had in past assessments).⁵⁸

In individual studies, uncertainty is typically managed using similar statements about probabilities as well as confidence levels and intervals. A confidence interval reflects a range of possible true values for the parameter being studied. Confidence intervals are typically expressed as the mean estimate of the parameter $\pm$ variation in the estimate at a designated confidence level (typically 95%, although 90% and 99% are also used). The confidence level reflects the likelihood that the parameter will fall within the upper and lower bounds of the confidence interval. For example, a study may conclude with 95% confidence that anthropogenic climate forcing increased the likelihood of a specific extreme event by a factor of 4 ± 1 (with $4x$ being the mean estimate, and $3\text{--}5x$ being the confidence interval). Some studies will present findings at lower confidence bounds to provide additional insights on likely or probable findings (e.g., a 66% confidence level, corresponding with a “likely” finding).⁵⁹

Scientific studies also typically include information about Type I (false positive) and Type II (false negative) errors. If Type I errors are high, then the study may have produced a spurious association between anthropogenic forcing and an observed trend. Conversely, if Type II errors are high, then the study may be underestimating or wholly missing the effects of anthropogenic forcing on an observed trend. Climate researchers, and academic researchers more generally, tend to be more concerned with avoiding Type I errors to ensure that they do

57. IPCC AR6 WG1, *supra* note 6, at 4.

58. See section titled “Extreme Event Detection and Attribution” below.

59. See, e.g., Mark D. Risser & Michael F. Wehner, *Attributable Human-Induced Changes in the Likelihood and Magnitude of the Observed Extreme Precipitation During Hurricane Harvey*, 44 *Geophysical Resch. Letters* 12,457 (2017), <https://doi.org/10.1002/2017GL075888>.

not overstate the magnitude of anthropogenic climate change. Indeed, the high burden of proof assumed in standard statistical tests leads to researchers being very conservative in their estimates of climate change and its effects.⁶⁰

A metric known as the p -value provides further insights on the validity of climate studies. The p -value is the quantification of the probability of a Type I error, such as the probability that an observed trend such as global surface warming would occur due to chance alone. A p -value of 5% or less is commonly used as a threshold of validity in climate studies and other areas of natural science.⁶¹ The frequent use of such a low p -value thus reflects the aversion of scientists to false positives/Type I errors.

Sources of Climate Research

Because of the breadth and complexity of climate science, scientific organizations like the IPCC play an important role in the synthesis and dissemination of climate research. The U.S. federal government also funds research and publishes reports on climate science, and there are thousands of individual researchers, academic institutions, and NGOs contributing to this field. This section provides context on different sources of climate research and highlights some considerations to help judges assess the credibility, weight, and admissibility of research depending on the source. The Appendix to this reference guide provides additional information about some of the organizations and sources discussed herein.

Scientific and Consensus Reports

There are several major organizations that periodically publish reports on the state of climate science. These include the IPCC, the World Meteorological Organization (WMO), the American Meteorological Society (AMS), the American Geophysical Union (AGU), the National Academies of Sciences, Engineering, and Medicine (National Academies or NASEM), and the U.S. Global Change Research Program (USGCRP). The WMO, for example, is a leading source of climate data products and it publishes an annual *State of the Global Climate Report*

60. William R.L. Anderegg et al., *Awareness of Both Type I and 2 Errors in Climate Science and Assessment*, 95 Bull. Am. Meteorological Soc'y 1445 (2014), <https://doi.org/10.1175/BAMS-D-13-00115.1>.

61. A p -value less than or equal to 5% is often described as the threshold for statistical significance, but this does not relate to the magnitude of impact—rather it is associated with probability. If the p -value is >5%, then there is a reasonable probability that an observed trend (for example) might be due to chance alone.

that summarizes the latest observations and findings for various global climate indicators including GHGs, global temperature, ocean heat content, sea level, marine heat waves, the cryosphere, and precipitation.⁶²

The IPCC is widely considered to be the leading scientific body for the assessment and synthesis of research on climate change. The IPCC does not conduct new research. Rather, it publishes assessment reports based on a synthesis of thousands of published, peer-reviewed studies from scientific journals.⁶³ These assessment reports are prepared with input from thousands of scientists with diverse expertise across the field of climate research.⁶⁴ A key benefit of the IPCC reports is that they identify scientific findings that have multiple lines of evidence, have been replicated, and have stood the test of time. There is a robust process for analyzing existing research and reaching conclusions on the basis of the reviewed science, as detailed in the Appendix to this reference guide. Thus, the IPCC reports and findings contained therein reflect a level of scientific scrutiny and agreement that is unique in this field.

Taking into account the procedures underpinning IPCC reports, the U.S. Supreme Court and federal appellate courts have recognized these reports as an authoritative and credible source of climate science.⁶⁵ However, it is possible that judges may confront disputes regarding the accuracy of IPCC findings, particularly if there is more recent and credible scientific research that calls those findings into question.⁶⁶ Although IPCC reports are typically afforded greater weight in the scientific community than individual studies, the science is constantly evolving, and subsequent research may provide new insights on the nature of climate change and its consequences. This progression toward greater scientific confidence

62. See WMO, State of the Global Climate, <https://perma.cc/B4X9-9SDV>.

63. The reports also draw on so-called “grey literature” (i.e., non-peer-reviewed reports, including technical reports, conference proceedings, statistics, and observational datasets), but there are strict guidelines for its inclusion.

64. The scientists involved in the assessments are selected through a nomination process. Prior to initiating an assessment, the IPCC issues a call to governments and IPCC observer organizations for nominations; the authors are then selected by the Bureau of Scientists on the basis of their expertise. The IPCC seeks to build author teams that reflect a range of scientific, technical, and socioeconomic expertise. See IPCC, Factsheet: How Does the IPCC Select Its Authors? (2021), <https://perma.cc/8MGL-R9LL>.

65. See *Massachusetts v. EPA*, 549 U.S. 497 (2007); *Coal. for Responsible Regul. v. EPA*, 684 F.3d 102 (D.C. Cir. 2012); *Ctr. for Biological Diversity v. Nat’l Highway Traffic Safety Admin.*, 538 F.3d 1172, 1189 (9th Cir. 2008); *Diné Citizens Against Ruining Our Env’t v. Haa-land*, 59 F.4th 1016 (10th Cir. 2023).

66. By “more recent” research, we mean research that was published after information was collected for the latest IPCC assessment (and therefore could not have been incorporated into the assessment).

in both the attribution and prediction of climate change impacts is evident across IPCC assessments.⁶⁷

There are other synthesis reports that serve as important sources of climate data; some of these reports provide more targeted assessments of specific topics and/or geographic regions. For example, the USGCRP periodically publishes *National Climate Assessments* (NCAs) that integrate, evaluate, and interpret scientific findings related to climate change and its effects on the United States, including effects on the natural environment, agriculture, energy production and use, land and water resources, transportation, human health and welfare, human social systems, and biological diversity. The reports also analyze broader trends in global climate change, both human-induced and natural, and projections for the subsequent 25 to 100 years.

Peer-Reviewed Research

The assessments performed by the IPCC and other authoritative science bodies are based primarily on syntheses of peer-reviewed climate research. Litigants may also rely on individual peer-reviewed studies and articles to support scientific claims. The benefit of peer review is that it ensures that research has been examined by one or more scholars with expertise in the subject matter (although it does not generally involve repeating any of the measures or calculations or otherwise reproducing the work). Examples of peer-reviewed research include original research studies (i.e., primary research), review articles, and expert judgment reports.⁶⁸ The most robust climate studies tend to be those that combine good observational data, physical understanding, rigorous statistical analysis, and detailed models to generate findings, along with clear communication and transparency with respect to research parameters, assumptions made, confidence in findings, and potential areas of uncertainty or bias.

Importantly, different publications have different standards for what qualifies as peer review, and there are some journals that purport to publish peer-reviewed research that do not actually have a legitimate peer-review process—these are sometimes referred to as “predatory journals.” In order to distinguish between legitimate and illegitimate publications, judges can refer

67. See, e.g., IPCC AR6 WGI, *supra* note 6, at 52 (“new techniques developed since AR5, including attribution of individual events, have provided greater confidence in attributing changes in climate extremes to climate change”).

68. Here, “expert judgment reports” specifically refers to peer-reviewed articles containing findings based on expert judgment and expert surveys (not to be confused with expert reports submitted as part of litigation). See, e.g., Jonathan L. Bamber et al., *Ice Sheet Contributions to Future Sea-Level Rise from Structured Expert Judgment*, 116 PNAS 11195 (2019), <https://doi.org/10.1073/pnas.1817205116>.

to online lists of such journals;⁶⁹ judges can also examine the credentials of the journal editors, the authors of the particular study at issue in the case, and the authors of other studies published in that same journal.⁷⁰ Another indication of the quality of a journal is whether the publication has been indexed by major journal-indexing groups such as Scopus, Web of Science, PubMed, and Google Scholar.

Individual studies and reports are typically not afforded the same weight within the scientific community as IPCC assessments and other major scientific reports, but they can serve as important supplements to such reports, as they may provide insights on areas of climate science that are not covered elsewhere (e.g., assessments of climate change impacts at a more local or granular scale, or findings based on data that are too recent to have been included in a prior synthesis report).

It is also important to note that the fact that a scientific resource is *not* peer reviewed does not in and of itself mean that the resource is faulty or illegitimate. There are credible scientific data and research products that do not undergo formal peer review—this includes, for example, some of the data and research products published by government agencies. Courts can consider other factors when evaluating the credibility of such resources, including the credentials of the publishing organizations and scientists, whether the findings are consistent with those from expert bodies like the IPCC, and whether the underlying methodologies have been subject to peer review.

Expert Testimony and Reports

Expert witnesses can play an important role in communicating and interpreting scientific evidence in climate litigation. Part of this role may involve simply summarizing findings from the IPCC and other authoritative bodies and explaining the relevance of those findings to a particular case. Expert witnesses may be needed to support or refute factual claims that are beyond the scope of broad-scale climate assessments like IPCC reports—e.g., claims about the effects of climate change on a particular locale or individual. When that is the case, expert witnesses may provide testimony and reports based on individual studies or impact assessments (including government assessments). They can also answer questions to help clarify the methods and findings from specific studies—for example, explaining why a particular time frame or historical baseline was used

69. See, e.g., Beall's List of Potentially Predatory Journals and Publishers, <https://perma.cc/63GD-ZS25>.

70. See section titled “Expert Testimony and Reports” for further insights on engaging with expert witnesses.

in a study, or explaining the level of uncertainty inherent in a particular finding.

There are contexts where expert witnesses may draw inferences about the effects of climate change in the absence of a targeted study on those effects.⁷¹ For example, an expert may infer that climate change has contributed to more severe heat waves in a particular location based on regional analyses of climate impacts and physical understanding of the strong causal relationship between climate change and extreme heat.⁷² The reasonableness of such inferences would depend on factors such as the nature and location of the impact, the strength of the “signal” of anthropogenic climate change relative to natural variability, and the level of spatial or temporal variability in the impact. In particular, when evaluating the potential causal link between climate change and a specific event or impact, a judge could consider whether (1) a widespread pattern in a geographic area has been observed and attributed to climate change, (2) there is not too much spatial or temporal variability in the impact, and (3) the expert is inferring that this pattern applies to a particular locale.

There are some threshold considerations when assessing the admissibility of expert testimony on climate science.⁷³ First, the field of climate science is so broad that it is impossible to articulate general criteria for expert qualifications in this field—whether a witness is qualified to speak will be a case-by-case determination that is entirely dependent on the scope of their testimony. For example, an expert who is testifying on the reliability of global climate models should have expertise on the physical processes that drive global climate change (which could be gleaned through, e.g., research in atmospheric sciences or meteorology) and/or the statistical and mathematical techniques deployed in those climate models; an expert who is testifying on the biological impacts of climate change should have expertise in biological sciences; and so forth.

Second, when evaluating whether the testimony would pass the *Daubert* test (i.e., whether it is based on reliable principles and methods), courts may consider factors such as: (1) whether the testimony is based on principles,

71. See Elisabeth A. Lloyd & Theodore G. Shepherd, *Climate Change Attribution and Legal Contexts: Evidence and the Role of Storylines*, 167 *Climatic Change* 27 (2021), <https://doi.org/10.1007/s10584-021-03177-y>. The authors note that “proceeding from the general to the specific is a process of deduction and is an entirely legitimate form of scientific reasoning” and “well aligned with the concept of legal evidence.” *Id.* (abstract).

72. See section titled “Extreme Event Detection and Attribution” below.

73. As discussed in Liesa L. Richter and Daniel J. Capra, *The Admissibility of Expert Testimony*, in this manual, when such disputes arise, judges must find that the expert witness is qualified to provide testimony on the subject matter, that the witness’s scientific and technical knowledge will help the trier of fact understand the subject matter, that the expert’s opinion is based on sufficient facts or data, that the expert’s opinion is the product of reliable principles and methods, and that the witness has reliably applied those principles and methods to the facts of the case. See also Fed. R. Evid. 702; Fed. R. Evid. 104(a).

methodologies, or findings that have been accepted as credible by the IPCC and other scientific institutions; (2) whether the underlying methods and findings have been subjected to peer-review processes; and (3) whether the research is accompanied by information about confidence levels and error rates.⁷⁴ When confronted with novel research findings or methodologies, judges can consider whether the novel aspects are rooted in existing and accepted scientific techniques to determine whether they represent a significant departure from general practices. In many cases, so-called “novel” techniques used in climate studies are based on minor changes to (or advances in) well-established research methods (and in some cases, they are adapted from other disciplines). For example, extreme-event attribution generally relies on the same climate models used in past studies to attribute changes in average conditions and to predict future changes,⁷⁵ and probabilistic or risk-based extreme-event studies also use concepts and methods developed in epidemiological research.⁷⁶

Climate Change Detection, Attribution, and Projections

Litigants typically use climate science to support or refute claims about the causes and impacts of climate change. For example, a plaintiff may use climate science to demonstrate that the GHG emissions attributable to a defendant’s conduct have caused or contributed to an injury incurred by the plaintiff or society at large. There are several areas of climate research that are particularly relevant to litigation. First, detection and attribution research examines whether and to what extent specific trends, events, and impacts can be attributed to human influence on the climate system. Second, source attribution research evaluates the respective contributions of different actors, activities, sectors, and jurisdictions to anthropogenic climate change and its impacts. Third, projections of future climate change

74. As discussed above, studies often include information about Type I (false positive) and Type II (false negative) errors, as well as the *p*-value (the probability of obtaining results at least as extreme as the observed result, assuming that the null hypothesis is correct). A 5% *p*-value cutoff is commonly used to ensure the validity of results. In addition, climate studies and IPCC reports use confidence levels to communicate the likelihood that a finding is valid, and most individual studies use a high confidence level (e.g., ≥ 90%) corresponding with a low margin of error. These confidence statements may not be directly relevant to the *Daubert* inquiry insofar as they deal with the validity of findings rather than methodologies. However, they are relevant when assessing the credibility and probative value of expert testimony. See *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993) (listing nonexhaustive factors in determining reliability of a scientific expert method).

75. See section titled “Impact Detection and Attribution” below.

76. See Theodore G. Shepherd, *A Common Framework for Approaches to Extreme Event Attribution*, 2 Current Climate Change Reps. 28 (2016), <https://doi.org/10.1007/s40641-016-0033-y>.

provide insights on the scope and magnitude of future climate change under different warming and emissions trajectories. Finally, there is research aimed at estimating remaining carbon budgets that would limit global warming to targets such as 1.5°C, 2.0°C, or “well below” 2.0°C. For each of these research areas, we describe the underpinning methods and parameters, and we summarize key research findings, focusing on findings from the IPCC and other scientific bodies.

As detailed below, there is scientific consensus on the reality of anthropogenic climate change, and scientists can detect, attribute, and predict many of the trends and impacts caused by climate change with a high level of confidence. But some gaps remain in scientific knowledge of the climate system and uncertainty about the effects of climate change, particularly when looking at the regional or local impacts of climate change.

Detection and Attribution

Detection and attribution research examines the causal links between human activities, changes in the climate system, and corresponding impacts on other interconnected systems.⁷⁷ Research in this field has demonstrated that human activities are the dominant cause of observed climate change,⁷⁸ and that human-induced climate change is causing pervasive impacts to human and natural environments around the world.⁷⁹ Some of the observed changes include rising sea levels, ocean warming and acidification, melting sea ice, thawing permafrost, increases in the frequency and severity of many types of extreme events, and corresponding impacts on people, communities, and ecosystems.⁸⁰ These findings are based on multiple lines of evidence, including physical understanding of the climate system and the greenhouse effect, comparisons between observational data and climate models, paleoclimate reconstructions, and “fingerprinting”

77. This discussion of attribution research has been adapted and, in some cases, excerpted from the authors’ prior publication on this topic. See Michael Burger et al., *The Law & Science of Climate Change Attribution*, 5 Colum. J. of Env’t Law 57 (2020), <https://perma.cc/N7A7-4XMP>. The discussion of scientific findings has been updated to reflect new resources, including the latest IPCC assessment (AR6).

78. NAS Update, *supra* note 6, at ch. 2. See also IPCC AR6 WGI, *supra* note 6; NCA4 Vol. I, *supra* note 6.

79. The weight of the scientific evidence demonstrates that anthropogenic climate change “is already affecting every inhabited region across the globe, with human influence contributing to many observed changes in weather and climate extremes.” IPCC AR6 WGI, *supra* note 6, at 10. See also NCA4 Vol. I, *supra* note 6, at 36 (“Evidence for a changing climate abounds, from the top of the atmosphere to the depths of the oceans.”).

80. See sections titled “Source Attribution” and “Projections of Future Climate Change” below.

studies that examine the influence of anthropogenic forcing on specific climatological trends and events.⁸¹

Detection and attribution research can be categorized into different subfields, each of which corresponds with a different link in the causal chain connecting human activities to climate-change-related harms:

- **Detection and attribution of climate change** focuses on the link between anthropogenic climate forcing and corresponding changes in the climate system, including the atmosphere, hydrosphere, cryosphere, land surface, and biosphere.
- **Extreme-event attribution** examines how global climate change has affected the probability, frequency, severity, and other characteristics of extreme events such as heat waves, storms, floods, droughts, and wildfires.⁸²
- **Impact attribution** examines how global climate change is affecting human and natural systems. This research deals with a broad range of physical, social, health, economic, and biological impacts at global, regional, and local scales.⁸³

Below, we provide a general overview of methods and parameters used in attribution research. This is followed by a more targeted discussion of the three subfields identified above (climate change, extreme-event, and impact attribution).

81. IPCC AR6 WGI, *supra* note 6; NAS Update, *supra* note 6, at ch. 2. For additional information on fingerprinting studies, see generally this section and the subsection titled “Attribution to anthropogenic climate change” below.

82. We discuss extreme-event attribution as a separate category of attribution research because extreme events do not fit neatly into the “global climate change” or “impact” attribution categories. Weather is part of the climate system, but extreme events are often discussed as impacts of climate change, and there are unique challenges associated with efforts to ascertain the effect of climate change on a particular extreme event.

83. The distinction between “changes in the global climate system” and “the impacts of climate change” is not always clear because of the broad definition of the global climate system. The IPCC defines *impacts* or *effects* to include physical impacts such as floods, droughts, and local sea-level rise, as well as any other “effects on lives, livelihoods, health and well-being, ecosystems and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure.” IPCC AR6 WGI, *supra* note 6, at 201. In many cases, a change in an essential climate variable (e.g., sea-level rise) could be viewed as a physical impact of climate change. For the purposes of this reference guide, we classify studies on regional changes in essential climate variables as “climate change attribution” where the primary goal of the study is to better understand how humans are affecting the global climate system, and we classify studies on floods, droughts, and local sea-level rise as “impact attribution,” where the primary goal of the study is to better understand how climate change is affecting a particular region or locale.

General Methods and Parameters

Detection of change

Detection and attribution is a two-step process used to identify a causal relationship between one or more drivers and a responding system. The first step—detection of change—involves demonstrating that a particular variable has changed in a statistically significant way without assigning cause.⁸⁴ To accomplish this, scientists will compare historical climate data with contemporary observations to assess the magnitude of change, and they will also evaluate whether the observed change may be due to internal variability or external forcing on the climate system. An identified change is detected in observations if the likelihood that it occurred because of internal variability (i.e., chance) alone is determined to be small, for example, less than 10%.⁸⁵

Scientists typically use instrumental records to identify an event or process that will be the subject of the detection and attribution study. The subject could be a gradual process, such as increases in average sea surface temperature or global mean sea level, or it could be a sudden-onset event, such as a heat wave. Scientists will also use instrumental records in conjunction with other sources of climate data (e.g., reanalysis datasets and paleoclimate reconstructions) to characterize baseline climate conditions and to evaluate how those conditions have changed over time.

Attribution to anthropogenic climate change

The second step—attribution—involves sifting through a range of possible causative factors to determine the role of one or more drivers with respect to the detected change. This is typically accomplished by using physical understanding, as well as climate models and/or statistical analysis, to compare how the variable responds when certain drivers are changed or eliminated entirely. The goal of such studies is to determine whether, how, and to what extent anthropogenic drivers have contributed to the observed change.

Many attribution studies use a probabilistic approach—i.e., researchers will seek to quantify the probability of a particular outcome (e.g., how likely is the occurrence of three inches of rainfall in a day at a given locale) occurring with and without anthropogenic influence on climate. However, researchers can

84. David R. Easterling et al., *Detection and Attribution of Climate Extremes in the Observed Record*, 11 *Weather & Climate Extremes* 17 (2016), <https://doi.org/10.1016/j.wace.2016.01.001>; Gabriele Hegerl, *Towards Detection and Attribution of Impact-Relevant Climate Change: The WG1 Perspective*, in *IPCC Expert Meeting on Detection and Attribution Related to Anthropogenic Climate Change*, Meeting Report 25–27 (Thomas Stocker et al. eds., 2010), <https://perma.cc/X3HY-VR9L>.

85. IPCC AR6 WGI, *supra* note 6, at 196.

also use a mechanistic approach to attribution, whereby they seek to examine how climate change has influenced one or more physical characteristics of an event or process.⁸⁶ Mechanistic studies can provide insights on, for example, the change in magnitude or severity of an extreme event that can be attributed to climate change.⁸⁷ In the rainfall example above, a mechanistic approach might look at the weather system that produced the heavy rain and describe how one part of climate change that we understand well—e.g., the warming of the atmosphere and its resulting increase in the amount of moisture the atmosphere can hold—contributed to the event. Mechanistic and probabilistic analyses can be combined in order to develop a more complete picture of whether and to what extent climate change is influencing various processes and events.⁸⁸

Researchers use both statistical techniques and climate models when detecting and attributing change. As an example of statistical techniques, scientists use linear regression methods⁸⁹ and variants such as “optimal fingerprinting” to determine whether a change in a climate variable is statistically significant or simply part of natural variability.⁹⁰ This analysis is part of the detection of climate change and corresponding impacts, but it can also be used to support attribution statements (e.g., a finding that the spatial pattern of warming in the atmosphere was likely caused by anthropogenic emissions because it is statistically unlikely that the spatial pattern would have occurred in the absence of anthropogenic forcing on the climate). This is sometimes referred to as observation-based attribution.⁹¹

86. See section titled “Projections of Future Climate Change” below for further discussion of the mechanistic approach and its role in extreme-event attribution (also referred to as the “story-line” approach to extreme-event attribution).

87. See, e.g., Michael Wehner & Christopher Samson, *Attributable Human-Induced Changes in the Magnitude of Flooding in the Houston, Texas Region During Hurricane Harvey*, 166 *Climatic Change* 19 (2021), <https://doi.org/10.1007/s10584-021-03114-z>. See also Luke J. Harrington et al., *Integrating Attribution with Adaptation for Unprecedented Future Heatwaves*, 172 *Climatic Change* 1 (2022), <https://doi.org/10.1007/s10584-022-03357-4> (discussing the differences and similarities between probabilistic and mechanistic approaches to extreme-event attribution).

88. For example, findings from both probabilistic and mechanistic studies are synthesized in IPCC assessments and other climate reports.

89. Linear regression is a statistical method used to summarize and study relationships between two continuous (quantitative) variables.

90. Optimal fingerprinting regresses observed climate variables on expected responses to, or signals of, specific forcings to determine whether and to what extent the signals are present in the observation. See Zhuo Wang et al., *Toward Optimal Fingerprinting in Detection and Attribution of Changes in Climate Extremes*, 116 *J. Am. Stat. Ass’n* 1 (2021), <https://doi.org/10.1080/01621459.2020.1730852>; K. Hasselmann, *Optimal Fingerprints for the Detection of Time-Dependent Climate Change*, 6 *J. Climate* 1957 (1993), [https://doi.org/10.1175/1520-0442\(1993\)006<1957:OFFTDO>2.0.CO;2](https://doi.org/10.1175/1520-0442(1993)006<1957:OFFTDO>2.0.CO;2).

91. Nat’l Acad. of Sci., Eng’g, & Med. (NASEM), *Attribution of Extreme Weather Events in the Context of Climate Change* (2016), <https://perma.cc/D56R-G9DJ>.

However, in practice, most studies do not rely exclusively on observation-based statistical analysis for attribution because of short observation records and complex forcing changes over the historical period.⁹² Climate models are typically used for attribution because they allow scientists to separate out the effects of different forcings and processes on the observed variable. That said, observation-based attribution findings can serve as a useful supplement to model-based findings.⁹³

Attribution studies utilizing climate models generally involve at least two sets of simulations: one that reflects the actual world, and another that reflects a counterfactual world without anthropogenic climate change (or without some component of anthropogenic climate change). These model simulations are ideally run at least several times based on differing initial conditions and for long duration, allowing scientists to better differentiate the climate change signal from the noise of natural variability. Observational data and physical understanding provide the basis for calibrating and verifying models.

Several modeling centers have now developed standardized climate simulations designed for detection and attribution specifically, based on different parameters (e.g., researchers can evaluate the probability of an event or impact occurring both with and without certain observed changes in the climate, such as changes in sea surface temperature). Owing to advances in parallel computing and model simplifications, these can be run rapidly and at high spatial resolution, yielding quick results. Indeed, when the above packages are combined with forecasts of variables with high predictability, such as sea surface temperature, projected results can be made available *in advance* of actual events. Furthermore, the tools and outputs, and models themselves, are increasingly being made publicly available. This has furthered the proliferation of attribution research in recent years.

Challenges associated with downscaling and exogenous variables

Attribution becomes increasingly complex and challenging as the focus of research moves away from long-term, broad-scale changes in the climate system and toward more localized, discrete events and impacts. One key challenge is conducting the analysis at the appropriate spatial and temporal scale. Natural variability, unrelated to changes in anthropogenic climate forcing, is larger at fine spatial and temporal scales, making it harder to identify signals associated

92. *Id.*

93. Andrew D. King et al., *Attribution of the Record High Central England Temperature of 2014 to Anthropogenic Influences*, 10 *Env't Rsch. Letters* 1 (2015), <https://doi.org/10.1088/1748-9326/10/5/054002>; Gabriele C. Hegerl, *Use of Models and Observations in Event Attribution*, 10 *Env't Rsch. Letters* 1 (2015), <https://doi.org/10.1088/1748-9326/10/7/071001>.

with anthropogenic or other forcings.⁹⁴ When models are used to assess extreme events or impacts that occur at finer spatial and temporal scales than the models themselves, some type of downscaling or error correction is needed, which can introduce additional uncertainties.⁹⁵

Impact attribution studies must also account for nonclimate or exogenous variables, that is, characteristics of human and natural systems that are not part of the climate system.⁹⁶ Consider a study examining the relationship between climate change, a heat wave, and public health impacts: the study would need to account for both climate variables at a fairly discrete geographic and temporal scale (e.g., temperature and humidity during the event) as well as nonclimate variables (e.g., population risk factors for heat-related morbidity, access to air-conditioned facilities and emergency services) to ascertain the extent to which climate change caused or contributed to observed health outcomes. Confounding variables (e.g., air quality), which influence both dependent and independent variables in a study, are of special concern, as they can lead to spurious associations between a driver and an event or impact.⁹⁷ The number of exogenous and confounding variables increases as attribution research moves toward an analysis of discrete impacts on humans, communities, and ecosystems.

To manage exogenous variables, some studies use a single-step attribution approach, i.e., “a single modelling setup to relate changes in drivers to changes in some aspect of a climate, natural, or human system.”⁹⁸ As an example, single-step attribution has been used to evaluate the relationship between very warm regional temperatures and human influence on the climate.⁹⁹ Other studies use a multistep approach that links separate single-step analyses into an overall attribution assessment. Multistep studies often examine how one or more core climate variables have changed in response to human activities, and then explore

94. See IPCC AR6 WGI, *supra* note 6, at 117 (discussing how internal variability is stronger and uncertainties in observations, models, and external forcings are larger at the regional scale, as compared with the global scale).

95. See, e.g., NOAA Geophysical Fluid Dynamics Lab’y, Climate Model Downscaling, <https://perma.cc/7ZBZ-NQ9D>.

96. This may be somewhat of an oversimplification, as many variables that may appear to be outside of the climate system are still, to some extent, interdependent with that system.

97. In an impact or event attribution study, the dependent variable would be the impact or event under examination (e.g., a heat wave or an uptick in hospitalizations) and the independent variable would be the climate-change-related driver of the impact or event (e.g., increases in GHG concentrations or, in some studies, increases in climate variables such as mean temperature).

98. Dáithí Stone et al., *The Challenge to Detect and Attribute Effects of Climate Change on Human and Natural Systems*, 121 Climatic Change 381, 390–91 (2013), <https://doi.org/10.1007/s10584-013-0873-6>.

99. See Peter A. Stott et al., *Single-Step Attribution of Increasing Frequencies of Very Warm Regional Temperatures to Human Influence*, 12 Atmospheric Sci. Letters 220 (2011), <https://doi.org/10.1002/asl.315>.

the implications of that change with respect to one or more specific impacts.¹⁰⁰ Multistep attribution is useful for examining causal relationships in complex systems, but one potential drawback of this approach is that additional, cascading uncertainty and potential for error is introduced with each new step that is added to the analysis. Attribution researchers can also use an indirect two-step approach by referencing findings from other studies or IPCC reports to establish the first step in their causation analysis (e.g., the link between anthropogenic forcing and warmer average temperatures), and then they can focus on the second step (e.g., the link between warmer average temperatures and heat waves).¹⁰¹

Climate Change Detection and Attribution

Studies in this category examine the effects of anthropogenic climate forcing on specific components of the climate system and metrics such as average temperature and precipitation. This research provides foundational knowledge about global climate change that is subsequently used in extreme-event and impact attribution studies.

Methods and parameters

Scientists detect changes in the climate system through instrumental records, such as the CO₂ readings from the Mauna Loa Observatory in Hawaii, remote sensing from satellites, and other platforms. Some of the key variables being monitored include atmospheric concentrations of GHGs and other radiative forcers, atmospheric and surface temperature, water vapor (humidity), precipitation, sea ice, sea levels, ocean heat content, and ocean acidity. Scientists also use climate reanalysis datasets to fill gaps in instrumental records, as well as paleoclimate reconstructions to provide a perspective on longer-term climate change and variability. Paleoclimate reconstructions provide a means of comparing the current climate with that of past periods in Earth's history. The reconstructions

101. See, e.g., Peter Stott et al., *Future Challenges in Event Attribution Methodologies*, in *Explaining Extreme Events of 2016 from a Climate Perspective*, 99 *Bull. Am. Meteorological Soc'y* S1, S155 (2018), <https://doi.org/10.1175/BAMS-D-17-0118.1> [hereinafter BAMS 2016], referencing Russell E. Brainard et al., *Ecological Impacts of the 2015/16 El Niño in the Central Equatorial Pacific*, in BAMS 2016 at S21, <https://doi.org/10.1175/BAMS-D-17-0128.1>. See also David J. Frame et al., *The Economic Costs of Hurricane Harvey Attributable to Climate Change*, 160 *Climatic Change* 271 (2020), <https://doi.org/10.1007/s10584-020-02692-8>.

offer important insights, including: (1) how sensitive different aspects of the climate system are to different climate forcings at various timescales and (2) more robust estimates of natural variability than can be gleaned from the relatively short observational and instrumental record.

In order to attribute changes in the climate system to human influence, researchers must demonstrate that a detected change is “consistent with the estimated responses to the given combination of anthropogenic and natural forcing” and “not consistent with alternative, physically plausible explanations of recent climate change that exclude important elements of the given combinations of forcings.”¹⁰² The foundation for this analysis is physical understanding of how the climate system reacts to different radiative forcings, such as GHGs, atmospheric aerosols, solar radiation, and reflectivity (albedo), all of which influence the balance of energy in the global climate system. Scientists must also account for the global carbon cycle in order to ascertain how changes in radiative forcings will affect different components of the climate system (e.g., the relative uptake of heat and carbon dioxide by oceans). Finally, scientists must account for natural variability within the climate system in order to ascertain whether an observed change is caused by human forcing or natural variability.

The CMIP model ensembles (discussed in the section titled “Statistical Techniques and Climate Models” above) are commonly used in climate change attribution studies. Owing to ongoing advances in physical understanding, observations, and computational power, climate models now operate at finer and finer spatial scales, include interactions across more and more components of the climate system, and generate thousands of years of model output under different forcings and initial conditions. As models have grown in sophistication and complexity, their utility for climate attribution has grown—in 2014, IPCC AR5 found that models driven by historical greenhouse gas emissions and natural forcings (e.g., volcanoes and solar variability) could already “reproduce observed continental-scale surface temperature patterns and trends over many decades, including the more rapid warming since the mid-20th century and the cooling immediately following large volcanic eruptions.”¹⁰³ Models have continued to improve since then.

IPCC AR6 assessed results from climate models participating in CMIP6 and found that:

102. IPCC, *Climate Change 2001: The Scientific Basis*, Working Group I Contribution to the Third Assessment Report of the IPCC 56 (J.T. Houghton et al. eds.), <https://perma.cc/3GBS-NLYT> [hereinafter IPCC TAR WGI].

103. The IPCC issued this statement with *very high confidence*. IPCC, *Climate Change 2013: The Physical Science Basis*, Working Group I Contribution to the Fifth Assessment Report of the IPCC 15 (Thomas F. Stocker et al. eds., 2013) [hereinafter IPCC AR5 WGI], <https://perma.cc/3LKN-28W5>.

[The CMIP6 models] include new and better representations of physical, chemical and biological processes, as well as higher resolution, compared to climate models considered in previous IPCC assessment reports. This has improved the simulation of the recent mean state of most large-scale indicators of climate change and many other aspects across the climate system. Some differences from observations remain, for example in regional precipitation patterns.¹⁰⁴

However, there are still some significant differences between model results and some observations, particularly with regard to the hydrological cycle and precipitation patterns, and remaining uncertainties in cloud cover and cloud types. Global and even regional models are often too coarse in resolution to accurately and precisely simulate certain aspects of precipitation, particularly heavy precipitation (as there is significant variation in precipitation at relatively small spatial and temporal scales). This is a good example of a “downscaling” challenge in climate science that researchers are actively seeking to address.¹⁰⁵ Such downscaling challenges are most apparent in extreme-event and impact attribution, but they also appear, to a lesser extent, in climate change attribution studies. This is because many of the observed changes in the global climate system vary on a regional basis, the result of factors including differences in forcings and the higher natural variability at finer spatial scales.

Status of research

The existing body of research shows that human activities have unequivocally warmed the climate, and this has caused “[w]idespread changes in the atmosphere, ocean, cryosphere, and biosphere.”¹⁰⁶ Scientists have also made considerable

105. See, e.g., Jie Chen & Xunchang John Zhang, *Challenges and Potential Solutions in Statistical Downscaling of Precipitation*, 165 *Climatic Change* 1 (2021), <https://doi.org/10.1007/s10584-021-03083-3>.

106. IPCC AR6 WGI, *supra* note 6, at 148. See also USGCRP, *Fifth National Climate Assessment*, chs. 2–4 (A.R. Crimmins et al. eds., 2023), <https://doi.org/10.7930/NCA5.2023> [hereinafter NCA5] (“[t]he evidence for warming across multiple aspects of the Earth system is incontrovertible, and the science is unequivocal that increase in atmospheric greenhouse gases are driving many observed trends and changes”). The finding that human activities have “unequivocally” caused climate change is based on the continuing upward trend in GHG emissions and related trends in climate variables such as temperature increases, ice-mass loss, and sea-level rise. Scientific confidence in this finding has increased with each subsequent IPCC assessment. See IPCC AR6 WGI, *supra* note 6, at 182 (“The Second Assessment Report (SAR) stated that ‘the balance of evidence suggests a discernible human influence on global climate.’ Five years later, the Third Assessment Report (TAR) concluded that ‘there is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities.’ The AR4 further strengthened previous statements, concluding that ‘most of the observed increase in global average temperatures

progress toward quantifying the effect of human activities on different components of the climate system, although there is still uncertainty about some precipitation and hydrological changes attributable to climate change. There is also some uncertainty about the respective influence of different climate forcings on observed changes, including the influence of nonhuman forcings, as well as the magnitude of internal variability and its influence on observed changes. The following paragraphs provide an overview of key findings for specific variables and components within the climate system.

Chemical composition of the climate: Since the onset of the Industrial Revolution, human activities have caused significant increases in atmospheric GHG concentrations. Between 1750 and 2019, CO₂ concentrations increased 47% to 410 parts per million (ppm); CH₄ concentrations increased 156% to 1,866 parts per billion (ppb); and N₂O concentrations increased 23% to 332 ppb.¹⁰⁷ The current levels of these GHGs in the atmosphere are unprecedented on timescales spanning from thousands to millions of years.¹⁰⁸ Because of the global carbon cycle, not all GHGs remain in the atmosphere. Approximately 44% of anthropogenic CO₂ emissions have accumulated in the atmosphere, with the remainder absorbed by land and ocean CO₂ sinks.¹⁰⁹ Scientists predict that the fraction of CO₂ absorbed by land and oceans will decrease as cumulative CO₂ emissions increase.¹¹⁰

Atmospheric and surface temperature: IPCC AR6 found “unequivocal” evidence that human influence has warmed the atmosphere, oceans, and land; this warming trend is unprecedented in at least the last 2,000 years and cannot be explained by natural drivers or internal variability.¹¹¹ The USGCRP, National Academies, and other major scientific organizations have reached

since the mid-20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations.’ The AR5 assessed that a human contribution had been detected in: changes in warming of the atmosphere and ocean; changes in the global water cycle; reductions in snow and ice; global mean sea level rise; and changes in some climate extremes. The AR5 concluded that ‘it is extremely likely that human influence has been the dominant cause of the observed warming since the mid-20th century.’”) (citations omitted).

107. IPCC AR6 WGI, *supra* note 6, at 281. This rate of change in CO₂ and CH₄ concentrations is unprecedented in at least the past 800,000 years. *Id.* at 69. GHG concentrations have continued to rise since AR6. In 2022, CO₂ concentrations reached 418 ppm, CH₄ concentrations reached 1,923 ppb, and N₂O concentrations reached 336.16 ppb. NOAA Glob. Monitoring Lab’y, *Carbon Cycle Greenhouse Gases*, <https://perma.cc/U45E-HU3R>.

108. NAS Update, *supra* note 6, at 9. IPCC AR6 found that in 2019, atmospheric CO₂ concentrations were higher than at any time in at least 2 million years (*high confidence*) and atmospheric CH₄ and N₂O concentrations were higher than at any time in at least 800,000 years (*very high confidence*). IPCC AR6 WGI, *supra* note 6, at 8.

109. IPCC AR6 WGI, *supra* note 6, at 690. Specifically, the IPCC estimates that 23% of anthropogenic CO₂ emissions have been taken up by ocean sinks, and 31% have been taken up by terrestrial ecosystems (or “land sinks”). *Id.* at 80.

110. *Id.* at 744.

111. *Id.* at 4, 6.

similar conclusions.¹¹² As of 2019, the decadal average global surface temperature had increased approximately 1.09 [0.95–1.20] °C over preindustrial levels, with larger increases over land (1.59 [1.34–1.83] °C) than the ocean (0.88 [0.68–1.01] °C).¹¹³ The observed warming trend is consistent with physical understanding and model simulations of the climate forcing effects of human drivers (see Figure 1). IPCC AR6 found that it is *likely* that humans are responsible for approximately 1.07 [0.8–1.3] °C of the observed increase in global surface temperature, with well-mixed GHGs contributing to a warming of 1.0–2.0 °C and other human drivers (primarily aerosols) contributing to a cooling of 0.0–0.8 °C.¹¹⁴

Figure 1. Changes in global surface temperature relative to 1850–1900.

Panel (a) shows changes in global surface temperature reconstructed from paleoclimate archives (solid gray line, years 1–2000) and from direct observations (solid black line, 1850–2020), both relative to 1850–1900 and decadal averaged.

Source: Figure SPM.1 in IPCC, *Summary for Policymakers*, in *Climate Change 2021: The Physical Science Basis*, Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change 3–32 (Masson-Delmotte et al. eds.), <http://doi.org/10.1017/9781009157896.001>.

112. See NCA5, *supra* note 106; NAS Update, *supra* note 6.

113. IPCC AR6 WGI, *supra* note 6, at 5. The figures cited here include average estimates as well as ranges (in square brackets). These ranges reflect the 90% confidence interval (meaning that there is an estimated 90% likelihood of the value being within that range). *Id.* at 41. The IPCC AR6 uses the period of 1850–1900 as a proxy for pre-industrial temperature levels (as well as other pre-industrial climate conditions). *Id.* at 163 (see Cross-Chapter Box 11.1).

114. *Id.* at 5. Similarly, NCA4 found that there was “a likely human contribution of 93%–123% of the observed 1951–2010 change” in global temperature. NCA4 Vol. I, *supra* note 6, at 14.

The gray shading with white diagonal lines shows the *very likely* ranges for the temperature reconstructions. Panel (b) shows changes in global surface temperature over the past 170 years (black line) relative to 1850–1900 and annually averaged, compared to CMIP6 climate model simulations of the temperature response to both human and natural drivers (brown) and to only natural drivers (solar and volcanic activity, green). Solid colored lines show the multimodel average, and colored shades show the *very likely* range of simulations.

Ocean warming: As the atmosphere has warmed, so too have the oceans. IPCC AR6 found, with *high confidence*, that approximately 91% of the extra heat added to the climate system had been added to the ocean.¹¹⁵ The total ocean heat content has increased substantially, and ocean surface temperature has increased, on average, by 0.88 [0.68–1.01] °C since preindustrial times. It is extremely likely that human influence is the primary driver of ocean warming.¹¹⁶

Sea-level rise: Global sea levels have risen as a result of the melting of land-based ice and the increase in ocean heat content (since warmer waters occupy more volume from thermal expansion). Global mean sea level increased by 0.20 [0.15–0.25] meters between 1901 and 2018, and the rate of sea-level rise has been accelerating since the 1990s.¹¹⁷ It is *very likely* that human influence was the main driver of these increases, at least since 1971.¹¹⁸

Ocean deoxygenation: Ocean deoxygenation (oxygen decline) is another consequence of ocean warming (the solubility of dissolved oxygen decreases as sea water becomes warmer). There is *high confidence* that oxygen levels have dropped in many upper ocean regions since the mid-20th century, and *medium confidence* that human-induced ocean warming contributed to this drop.¹¹⁹

Ocean acidification: Researchers estimate that the surface ocean has absorbed approximately one quarter of all human CO₂ emissions,¹²⁰ causing the pH of the ocean surface to decrease. Researchers are *virtually certain* that human-caused CO₂ emissions are the main driver of ocean acidification.¹²¹

Cryosphere: There has been a substantial decline in sea ice, terrestrial glaciers, and snowpack in the past century, with considerable geographic variation in the magnitude and rate of decline. For example, IPCC AR6 concluded that (1) there has been a substantial reduction in Arctic sea ice over the period of 1979–2019, and in 2011–2022, average annual Arctic sea ice reached its lowest

115. This is consistent with the IPCC's prior assessment (AR5), in which it found that approximately 90% of the accumulated energy from human-induced climate change was stored within the oceans. See IPCC AR6 WGI, *supra* note 6, at 283 (comparing statements from AR5 and AR6).

121. *Id.* at 5.

level since at least 1850 (*high confidence*); (2) there have also been substantial reductions in ice sheets: between 1992 and 2020, the Greenland ice sheet lost 4,890 [4,180–5,640] billion metric tons of mass, and the Antarctic ice sheet lost 2,670 [1,800–3,540] billion metric tons of mass; (3) glaciers lost 6,200 [4,600–7,800] billion metric tons of mass between 1993 and 2019 (*very high confidence*), and glaciers lost more mass in 2010–2019 than in any other decade since the beginning of the observational record (*very high confidence*); (4) permafrost temperatures have been increasing around the world (*high confidence*) resulting in permafrost thaw in some regions (*medium confidence*); and (5) Northern Hemisphere spring snow cover has decreased since 1978 (*very high confidence*), and Northern Hemisphere spring snow cover has likely decreased since 1950 (*high confidence*).¹²²

Hydrological cycle and precipitation: Ascertaining the effect of anthropogenic forcings on the hydrologic cycle and precipitation is one of the more challenging areas of climate change attribution,¹²³ but there is evidence that the global hydrological cycle is intensifying as a result of anthropogenic climate change. IPCC AR6 expressed *high confidence* that climate change has contributed to an overall increase in atmospheric moisture content (i.e., water vapor) as well as precipitation intensity.¹²⁴ Scientists also expect that global warming will cause an overall increase in global precipitation,¹²⁵ but this “has not yet been detected and attributed to human activities given large observational uncertainties and low signal-to-noise ratio.”¹²⁶ There is evidence that climate change is causing regional increases or decreases in average precipitation, with some areas becoming wetter and others becoming more arid.¹²⁷ Increases in the frequency and intensity of heavy precipitation events have also been attributed to human influence.¹²⁸

122. *Id.* at 1215–16.

123. Part of the challenge is detecting change—spatial gradients of precipitation can be quite large in some regions, and historical rainfall records are incomplete and contain mixed findings about the extent to which precipitation patterns have (or have not) changed since the preindustrial era. It is also difficult to attribute precipitation changes to human influence on climate because precipitation is characterized by large natural variability across a range of timescales, ranging from the intra-annual to the centennial.

124. IPCC AR6 WGI, *supra* note 6, at 1057, 1080–81. It is also *extremely likely* that climate change has driven more evaporation over the oceans, which contributes to increased water vapor as well as heavier precipitation. *Id.* at 1080.

126. *Id.* at 1079.

127. *Id.* at 1057. *See also* WMO (2022), *supra* note 62 (finding that many of the world’s regions experienced above-normal precipitation in 2022, without specifying the extent to which this trend is attributable to anthropogenic climate forcing).

128. IPCC AR6 WGI, *supra* note 6, at 8.

Extreme Event Detection and Attribution

There are multiple pathways through which climate change can influence the intensity, duration, frequency, and other characteristics of extreme events. A warmer climate increases the probability and frequency of very hot days and nights, thus contributing to heat waves. A warmer climate also contributes to increased land evaporation and drier conditions, potentially increasing the severity of droughts and wildfire conditions. The intensification of the global hydrological cycle and increases in atmospheric moisture content contribute to more severe precipitation events. Increases in atmospheric moisture content and heat, coupled with increases in sea-surface and ocean temperature, also contribute to more severe tropical cyclones. All things being equal, more heat in the climate system corresponds with more energy to power storms, since atmospheric heat can be converted into kinetic energy (e.g., in the form of high winds).

Methods and parameters

An “extreme” weather or climate event is defined by the IPCC as “the occurrence of a value of a weather or climate variable above (or below) a threshold value near the upper (or lower) ends (tails) of the range of observed values of the variable.”¹²⁹ Attribution of extremes tends to be more challenging than attribution of means for several reasons: (1) the local nature and short duration of any extremes makes them more difficult to model given the coarse resolution of climate models, (2) the relative rarity of extreme events at a given location makes it more difficult to detect and attribute a climate change “signal” amid the large “noise” of internal variability, and (3) the causal chains for extremes can be quite complicated (e.g., highly nonlinear).¹³⁰ There are also some modeling challenges relevant to extreme-event attribution. For example, models may be too Gaussian in their extreme events (i.e., they don’t produce enough of them).¹³¹ Scientists

130. Sebastian Sippel et al., *Warm Winter, Wet Spring, and an Extreme Response in Ecosystem Functioning on the Iberian Peninsula*, in BAMS 2016, *supra* note 101, at S80, <https://doi.org/10.1175/BAMS-D-17-0135.1> (citing Dorothea Frank et al., *Effects of Climate Extremes on the Terrestrial Carbon Cycle: Concepts, Processes and Potential Future Impacts*, 21 *Glob. Climate Change Biology* 2861 (2015), <https://doi.org/10.1111/gcb.12916>, and John A. Arnone III et al., *Prolonged Suppression of Ecosystem Carbon Dioxide Uptake After an Anomalously Warm Year*, 455 *Nature* 383 (2008), <https://doi.org/10.1038/nature07296>).

131. Bo Christiansen, *The Role of the Selection Problem and Non-Gaussianity in Attribution of Single Events to Climate Change*, 28 *J. Climate* 9873 (2015), <https://doi.org/10.1175/JCLI-D-15-0318.1>. “Gaussian” refers to having the shape of a normal curve or normal distribution, and extreme events may not adhere to a Gaussian distribution. A normal distribution is characterized by a relatively large frequency of values near the mean, with a relatively small frequency of values far from the mean.

have devised statistical approaches to avoid the problems and limitations associated with climate models, but these approaches rely on simplifying assumptions.¹³² Despite these complicating factors, extreme-event studies can generate reliable results for many extreme events, though confidence in attribution findings depends on the type of extreme and the location.

The results of extreme-event studies are sensitive to how the research question is framed, and what methodological approaches and datasets are used. Some studies focus on individual events; others deal with a class of events over a time frame (e.g., the 2020 North Atlantic hurricane season).¹³³ One critical framing question is how to define the event parameters for the purposes of the study. These parameters include the physical threshold for the extreme event (e.g., a certain temperature threshold for a heat wave) as well as the time frame and spatial scale for the study. There are often multiple metrics that could be used for any given event—for example, a heat wave could be defined based on absolute maximum temperature, average maximum temperature over a duration of time, or a combination of temperature and humidity. These framing decisions can affect the results of the study. For example, if researchers were to use the maximum temperature during a heat wave as the temperature threshold, and then focus their analysis on the location that reached the highest temperature during the event, the heat wave may appear more exceptional (or “extreme”) than if the temperature and spatial scale were selected in a more generic way. This is an example of how event framing could introduce selection bias into an attribution study. This is not an insurmountable obstacle—for example, efforts are underway to standardize how extreme events are defined and selected for analysis, and this would have the added benefit of facilitating more systematic comparison between extreme-event studies.¹³⁴

As discussed earlier in this reference guide, there are also different approaches to attribution.¹³⁵ Some studies use a probabilistic or risk-based approach, examining whether and to what extent climate change increased the probability (or risk) of an extreme event. Other studies use a storyline or mechanistic approach, examining how a well-understood aspect of climate change may have affected

132. NASEM (2016), *supra* note 91; Christiansen, *supra* note 131.

133. See, e.g., Kevin A. Reed et al., *Attribution of 2020 Hurricane Season Extreme Rainfall to Human-Induced Climate Change*, 13 *Nature Commc'ns* 1 (2022), <https://doi.org/10.1038/s41467-022-29379-1>.

134. NASEM (2016), *supra* note 91.

135. Although many extreme-event attribution studies clearly fall within one of these two categories, there are also some other approaches in the literature. As one example, Mann et al. suggested a modification to traditional frequentist statistical inference approach, that builds in prior physical understanding and updates based on experience. Michael E. Mann et al., *Assessing Climate Change Impacts on Extreme Weather Events: The Case for an Alternative (Bayesian) Approach*, 144 *Climatic Change* 131 (2017), <https://doi.org/10.1007/s10584-017-2048-3>.

the magnitude and/or other characteristics of an extreme event. Both approaches have benefits and drawbacks.

In probabilistic studies, researchers evaluate the likelihood of a narrowly defined climatological extreme (e.g., a temperature of 95°F) occurring with and without human influence on the climate system. This is typically accomplished by using climate models to run two types of simulations: one that represents the world as it is and another that represents a hypothetical world without anthropogenic climate forcing. Researchers will then evaluate the probability of the extreme occurring in both simulations. The results are often expressed in terms of the relative risk of the extreme occurring with and without human influence on climate, which may be expressed using a risk ratio, which is the ratio of the probability of an event occurring with and without climate change,¹³⁶ or fraction of attributable risk (FAR). In mathematical terms:¹³⁷

$$\text{FAR} = 1 - P_0/P_1$$

P_1 equals the probability of a climatic event (such as a heat wave) occurring in the presence of anthropogenic forcing of the climate system, and P_0 equals the probability of the event occurring if the anthropogenic forcing were not present. If FAR equals zero, it means that anthropogenic climate change had no effect on the probability of the event occurring; if FAR equals one, it means that the event could not have happened in the absence of anthropogenic climate change; if FAR equals 0.5, it means that anthropogenic climate change doubled the probability of the event occurring. In multi-event studies, a FAR of 0.5 can be interpreted as meaning that half of the events would not have happened in a world without anthropogenic climate change.¹³⁸

This approach was pioneered by Myles Allen in a 2003 study in which he introduced the concept of FAR as a potential basis for liability for climate damages.¹³⁹ Many other studies have since replicated Allen's approach, estimating the FAR for a range of extreme events including heat waves, droughts, and floods. This methodology derives from common approaches used in epidemiological

136. Multiple risk ratios may also be used to express probabilities of occurrence at varying levels of climate change or global warming. See, e.g., V.V. Kharin et al., *Risks from Climate Extremes Change Differently from 1.5°C to 2.0° Depending on Rarity*, 6 *Earth's Future* 704 (2018), <https://doi.org/10.1002/2018EF000813>.

137. IPCC, *Climate Change 2007*, *supra* note 48; Myles Allen, *Liability for Climate Change*, 421 *Nature* 891 (2003), <https://doi.org/10.1038/421891a>.

138. While the term FAR is typically used in extreme-event attribution, probabilistic analysis is prevalent across all forms of attribution, and the concept of attributable risk can in principle be applied to both mean changes in climate and a variety of climate impacts. See, e.g., Thomas Knutson et al., *CMIP5 Model-Based Assessment of Anthropogenic Influence on Record Global Warmth During 2016*, in *BAMS 2016*, *supra* note 101, at S11.

139. Allen, *supra* note 137.

studies and other risk-focused research. The advantages of this approach are that it is relatively well established, understood, and accepted by the scientific community,¹⁴⁰ and it provides quantitative (probabilistic) findings similar to those that are often dealt with by policy makers, planners, and courts. Drawbacks include: (1) overreliance on climate models, which as noted earlier may not be able to simulate some types of extremes with fidelity in a baseline climate, and could have blind spots with respect to how climate change may be modifying key processes influencing the extreme event, and (2) susceptibility to Type II errors (i.e., false negatives), where the signal-to-noise ratio for an event is small because of large internal variability of the atmosphere, which is often the case for dynamically driven events such as extreme precipitation and storms.¹⁴¹ Thus the probabilistic approach, like all approaches, is an imperfect measure of the precise degree to which anthropogenic influence has increased the likelihood of an event.

The mechanistic or storyline approach, introduced by Trenberth et al. (2015),¹⁴² focuses on how anthropogenic forcing may have modified the characteristics of a given event, like a regional heat wave. This involves reconstructing the causal chain of events that resulted in the extreme event, typically focusing on a few central causal factors to establish attribution.¹⁴³ Mechanistic studies tend to focus on the relationship between the observed event and well-understood components of climate change, such as warming temperatures and thermodynamics. Because of this, mechanistic studies can generate higher confidence statements with regard to those specific components. The results of this analysis may be quantitative or qualitative—for example, “warming of the upper ocean and atmosphere enabled more rainfall during event Y than otherwise would have occurred” or “caused a 30% increase in rainfall over what would have occurred.”

As with the probabilistic approach, there are advantages and drawbacks to the mechanistic approach. The chief advantages are that the mechanistic approach provides additional insights on how climate change is affecting physical characteristics of extreme events, and it allows for higher confidence attribution regarding the influence of certain aspects of climate change on certain types of events. But there are also criticisms of this approach, as articulated by Otto (2016).¹⁴⁴ First, mechanistic studies may not have the same broad relevance as probabilistic studies because they focus on how climate change has influenced

the specific characteristics of a particular event (whereas the findings from probabilistic studies are more easily applied to a class of events—e.g., all heat waves with temperatures above a certain threshold in a region). Second, it is an oversimplification to assume that some aspects of the climate system (and climate change) are well understood and others are not—rather, there is a gradient of understanding across the various components of the climate system, and that understanding is constantly evolving with new research.¹⁴⁵ Neglecting certain aspects of or processes within the climate system can render these studies incomplete.¹⁴⁶

While there is some debate about the relative merits of these two approaches, the reality is that they are complementary—they each provide different insights on the effect of anthropogenic climate change on extreme events, and one approach can be used to fill gaps where the other is unsuitable. For example, the probabilistic/risk-based approach may be more justifiable for analyzing all events above or below a certain threshold, for a class of events that are relatively well simulated by climate models (e.g., temperature extremes), whereas the storyline approach may be more appropriate for complex, iconic, multivariate events.¹⁴⁷

Status of research

In early IPCC assessments, scientists recognized that climate change would affect the frequency, intensity, spatial extent, duration and timing of weather and climate extremes, but there was low confidence in the attribution of specific extreme events to human influence on climate.¹⁴⁸ Since then, scientific

145. For example, Michael E. Mann notes that dynamical changes with warming are starting to come into focus: more specifically, a growing body of work based on observations and simple models supports the idea that the latitudinal pattern of mean temperature changes (including Arctic amplification) may facilitate changes in atmospheric dynamics that increase wave resonance and “stuck” weather, which enhances the magnitude and duration of extremes. It should be noted that global climate models generally do not reproduce this pattern of wave resonance and “stuck” weather with warming. Michael E. Mann et al., *Influence of Anthropogenic Climate Change on Planetary Wave Resonance and Extreme Weather Events*, 7 *Sci. Reps.* 45242 (2017), <https://doi.org/10.1038/srep45242>.

146. More specifically, focusing on thermodynamics—but not dynamics—within the climate system can result in an incomplete analysis, in part because of the failure to capture interactions between thermodynamics and dynamics. Otto shows how the dynamics and thermodynamics counteracted each other in 2013 German floods. See Otto et al., *supra* note 144, at 815. Similarly, a study in Western Australia found dynamics/circulation changes that favor less rain, but thermodynamic (specifically sea surface temperature) changes that favor increase in rain. Thomas L. Delworth & Fanrong Zeng, *Regional Rainfall Decline in Australia Attributed to Anthropogenic Greenhouse Gases and Ozone Levels*, 7 *Nature Geoscience* 583 (2014), <https://doi.org/10.1038/ngeo2201>.

confidence in extreme-event attribution has advanced significantly as a result of “better physical understanding of processes, an increasing proportion of the scientific literature combining different lines of evidence, and improved accessibility to different types of climate models (*high confidence*).”¹⁴⁹ IPCC AR6 noted that the evidence of observed changes in extremes such as heat waves, heavy precipitation, droughts, and tropical cyclones, and their attribution to climate change, had strengthened since AR5.¹⁵⁰ According to IPCC AR6, it is “now an established fact that human-induced greenhouse gas emissions have led to an increased frequency and/or intensity of some weather and climate extremes,” particularly temperature extremes.¹⁵¹

The following paragraphs provide a summary of recent attribution findings for different classes of extreme events, drawing primarily on IPCC AR6 and findings from the U.S. Fifth National Climate Assessment (NCA5).

Extreme heat: An increase in the magnitude, frequency, and duration of extreme heat events is a direct and foreseeable consequence of a warming climate.¹⁵² NCA5 concluded, with *very high confidence*, that the frequency and intensity of extreme heat events are increasing in most continental regions of the world, consistent with expected physical responses to a warming climate.¹⁵³ IPCC AR6 similarly found that it is “*virtually certain* that hot extremes (including heatwaves) have become more frequent and more intense across most land regions since the 1950s,” and there is “*high confidence* that human-induced climate change is the main driver of these changes.”¹⁵⁴ Moreover, “[s]ome recent hot extremes observed over the past decade would have been *extremely unlikely* to occur without human influence on the climate system.”¹⁵⁵ Importantly, climate change is not only contributing to extreme heat events over land—according to IPCC AR6, marine heat waves have “approximately doubled in frequency since the 1980s (*high confidence*) and human influence has *very likely* contributed to most of them since at least 2006.”¹⁵⁶ The USGCRP and IPCC findings are consistent with a growing number of studies on extreme heat and climate change, many of which have demonstrated a very strong anthropogenic signal in such events.¹⁵⁷

Droughts and aridity: Although warmer temperatures are one relatively well-understood factor that can contribute to droughts, it is more challenging to isolate the effect of anthropogenic climate change on dryness and drought conditions. Droughts are highly complex meteorological events with many different factors affecting their likelihood, severity, duration, and other characteristics, and there is significant natural variability in precipitation, which makes it difficult to identify the anthropogenic signal through the noise of variability.¹⁵⁸ However, researchers have identified evidence of an anthropogenic signal in the heat-related aspects of drought (e.g., increased evapotranspiration) and have been able to estimate the extent to which warmer temperatures have intensified drought conditions.¹⁵⁹ Based on this research, IPCC AR6 expressed *medium confidence* that human-induced climate change had contributed to ecological and agricultural droughts in some regions due to increased land evapotranspiration.¹⁶⁰ IPCC AR6 did not find clear evidence that anthropogenic climate change was causing an increase in meteorological or hydrological droughts in most regions

158. There are several different types of droughts recognized in the literature, including: (1) meteorological droughts, which are defined by the degree and duration of dryness or rainfall deficit (in comparison to a normal or average amount); (2) hydrological droughts, which are defined by the impact of dryness and rainfall deficits on water supplies such as lakes, rivers, streams, reservoirs, and aquifers; (3) agricultural droughts, which are defined by the effect of dryness and rainfall deficits on agricultural systems; and (4) ecological droughts, which are defined by the effect of dryness and rainfall deficits on ecosystems. Attribution for hydrological droughts is particularly challenging because of the complexity of these events, limited data about historical trends, and the fact that human water consumption and management decisions are leading mechanisms behind such droughts (potentially making it harder to detect a climate change signal). See IPCC AR6 WGI, *supra* note 6, at 1576–78.

160. IPCC AR6 WGI, *supra* note 6, at 8.

of the world; however, it did express *medium confidence* that precipitation deficits had increased in several regions across all continents.¹⁶¹

Extreme precipitation: The IPCC and NCAs have both found clear evidence that heavy rainfall events are increasing around the world and in the United States, and this is generally consistent with expected physical responses to a warming climate.¹⁶² IPCC AR6 specifically found that the “frequency and intensity of heavy precipitation events have increased since the 1950s over most land areas for which observational data are sufficient for trend analysis (*high confidence*), and human-induced climate change is *likely* the main driver.”¹⁶³ This is another area where there have been significant advances in detection and attribution research: whereas IPCC AR5 only expressed *medium confidence* in the attribution of extreme precipitation events, IPCC AR6 found that there was “new and *robust evidence* of human influence on extreme precipitation.”¹⁶⁴

The IPCC’s assessment relates to an overall increase in extreme precipitation at a global scale, but there are important regional and seasonal variations in rainfall. The dynamic nature of extreme precipitation events and the large internal variability in precipitation can make it more difficult to attribute specific events to climate change. The storyline approach to attribution was developed in part to improve attribution for difficult-to-model events like extreme precipitation. Researchers used this approach to examine the effect of anthropogenic climate change on the 2013 floods in Boulder, Colorado, and found that anthropogenic drivers increased the magnitude of the rainfall for that week by approximately 30%.¹⁶⁵ The scientists also conducted a probabilistic analysis of potential impacts on flooding and found that this 30% increase in rainfall approximately doubled the likelihood of flood-inducing rainfall occurring during that event. In contrast, researchers using the probabilistic approach to attribution of the Boulder floods found no evidence that anthropogenic climate change had increased the probability of the event occurring.¹⁶⁶ This underscores the sensitivity of results to methodological choices made in extreme-event attribution.

Tropical and extratropical cyclones: Physical understanding suggests that tropical cyclones will become more severe in a warmer climate.¹⁶⁷ Cyclones derive energy from sea surface temperature, and warmer sea surface temperatures, all other things being equal, will increase the intensity of storms (in terms of wind speed, precipitation, and storm surge).¹⁶⁸ A warmer ocean also produces more evaporation, and a warmer atmosphere holds more moisture, thus contributing to heavier rainfall and flooding. IPCC AR6 expressed *high confidence* that anthropogenic climate change had contributed to increases in heavy precipitation associated with tropical cyclones¹⁶⁹ and that it was *likely* that the global portion of major (Category 3–5) tropical occurrences had increased over the past four decades.¹⁷⁰ There is more uncertainty about the effect of a warming climate on extratropical cyclone activity.¹⁷¹ Few attribution studies have found a discernible anthropogenic influence on extratropical cyclones because of factors such as large interannual-to-decadal variability in such cyclones,¹⁷² and thus the IPCC has expressed *low confidence* in the detection and attribution of changes in extratropical cyclones.¹⁷³ However, since research was compiled for IPCC AR6, there have been some studies finding that anthropogenic forcings likely have contributed to more severe extratropical cyclones.¹⁷⁴

Compound extremes: Compound extreme events are those that occur because of the interaction of multiple climate-related extremes. While multiple typologies of compound extremes have been identified, including sequences of events, and simultaneous events in multiple regions,¹⁷⁵ we focus here on the most studied category: multivariate (multivariable) extreme events at a single time and location. Examples include fire weather conditions (a combination of hot, dry, and windy conditions), compound flooding (e.g., flooding caused by a

167. See IPCC AR6 WGI, *supra* note 6, at 70 (“The proportion of tropical cyclones that are intense is expected to increase (*high confidence*), but the total global number of tropical cyclones is expected to decrease or remain unchanged (*medium confidence*).”). Some of the other factors that can influence tropical cyclones include aerosols and dust, wind shear, temperatures in the upper atmosphere, and wave disturbances.

combination of storm surge and heavy rainfall, or rapid snowmelt and heavy rainfall), and concurrent heat waves and droughts.¹⁷⁶ Scientific understanding of anthropogenic influence on such events largely depends on understanding of the various component events. IPCC AR6 found that human influence has *likely* increased the probability of various compound extreme events since the 1950s.¹⁷⁷ There is *high confidence* that anthropogenic climate change has increased the frequency of concurrent heat waves and droughts on a global scale and *medium confidence* that it has increased the frequency of fire weather and compound flooding in some regions.¹⁷⁸ There is also *high confidence* that regions and connected sectors will experience multiple regional extreme events at the same time,¹⁷⁹ placing greater stress on both human and natural systems.¹⁸⁰

Impact Detection and Attribution

Many of the processes and phenomena described in the sections above could be characterized as “impacts” of climate change (e.g., sea-level rise, more severe extreme events). However, for the purposes of this reference guide, we use the term “impact attribution” to describe research on the effects of climate change on humans and ecosystems. This is consistent with the approach taken in recent IPCC assessments, specifically the division between Working Group I (WGI), which synthesizes research on the physical science basis for anthropogenic climate change, and Working Group II (WGII), which synthesizes research on the impacts of climate change.¹⁸¹

179. IPCC AR6 WGI, *supra* note 6, at 135.

180. See section titled “Impact Detection and Attribution.”

181. See IPCC, Climate Change 2022: Impacts, Adaptation, and Vulnerability, Working Group II Contribution to the Sixth Assessment Report of the IPCC 2912 (Hans Otto Pörtner, et al. eds., 2022), <https://perma.cc/VL7D-TMET> [hereinafter IPCC AR6 WGII] (the term “impacts” refers to the effects of climate change on “natural and human systems” including effects on “lives, livelihoods, health and well-being, ecosystems and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure”).

Impact attribution deals with the consequences and outcomes that are most relevant in legal discourse and litigation—specifically, the question of who will be harmed by climate change and to what extent.¹⁸² Impact attribution deals with consequences that are further along the causal chain, and this adds a layer of complexity to the attribution analysis. Nonetheless, there are many impacts that have been attributed to anthropogenic climate forcing with a high level of confidence and certainty.

Methods and parameters

As with other areas of detection and attribution, researchers use physical understanding, observational data, statistical analysis, and climate models to detect and attribute impacts to anthropogenic climate forcing. However, as discussed earlier in this reference guide, there are some unique challenges associated with impact attribution.¹⁸³ In particular, impact attribution researchers must account for a larger number of exogenous variables and processes (i.e., those not related to the climate system) that influence the impact being studied. For example, in order to attribute monetary damages or human casualties from an extreme event to anthropogenic climate change, researchers must account for other factors that contributed to those damages. Data on these exogenous variables and processes may be limited, thus contributing to uncertainty about the relative roles of climate change and other drivers in explaining an observed impact. Furthermore, in most cases there is not a linear cause-and-effect relationship between changes in the climate system and specific impacts on humans and ecosystems. Each additional degree of warming may cause far more damage than the previous degree of warming, and climate change impacts on human and ecosystems may feed back on the climate in complex ways (for example, irrigation of crops in response to extreme temperature may itself impact temperature). Some of the challenges associated with extreme-event attribution also apply to impact attribution (potentially to an even greater extent)—for example, the spatial and temporal scale of an impact may be too fine to capture with existing climate or sectoral impact models.

Nonetheless, researchers can draw fairly robust conclusions about the general causal connection between climate change and many types of impacts, and in some cases, it is possible to quantify the contribution of anthropogenic forcing to specific damages, harms, and economic and noneconomic losses.¹⁸⁴ The use of fixed-effect regression methods to infer causation in large datasets, initially for

182. See Burger et al., *supra* note 77, at 111.

183. See section titled “Challenges Associated with Downscaling and Exogenous Variables” above.

184. IPCC AR6 WGII, *supra* note 181, at 8.

microeconomic applications, has been particularly noteworthy.¹⁸⁵ For example, researchers have developed techniques for estimating the proportion of monetary damages incurred during an extreme event that is attributable to climate change¹⁸⁶ and the public health impacts attributable to climate change.¹⁸⁷ Qualitative analyses can also provide valuable insights, including explanations of the processes and mechanisms by which climate change is affecting a particular system or outcome.¹⁸⁸ Qualitative analyses can be used where there are exogenous and confounding variables that would impede precise quantification of impacts associated with climate change.

Status of research

In recent assessments, the IPCC has found increasingly robust evidence of substantial and wide-ranging impacts of climate change across all climate zones and continents. In particular, observed increases in the frequency and intensity of climate and weather extremes have caused “widespread, pervasive impacts to ecosystems, people, settlements, and infrastructure” (*high confidence*).¹⁸⁹ Slow-onset processes, such as increases in atmospheric and ocean temperatures, ocean acidification, sea-level rise, and regional decreases in average precipitation have also affected human and natural systems across the world (*high confidence*).¹⁹⁰ Some of the impacts that have been attributed to anthropogenic climate forcing include increases in heat-related human mortality (*medium confidence*), coral bleaching and mortality (*high confidence*), increased drought-related tree mortality (*high confidence*), increases in areas burned by wildfires (*medium to high confidence*, depending on the region), and increases in storm-related losses and damages due to sea-level rise and increases in heavy precipitation (*medium confidence*).¹⁹¹ These impacts are disproportionately affecting “the most vulnerable people and

185. See, e.g., Christopher W. Callahan & Justin S. Mankin, *National Attribution of Historical Climate Damages*, 172 *Climatic Change* 1 (2022), <https://doi.org/10.1007/s10584-022-03387-y>. 190. *Id.*

191. *Id.*

systems” across different regions, and some natural and human systems have been “pushed beyond their ability to adapt” (*high confidence*).¹⁹²

Ecosystems, species, and ecological indicators: There is robust evidence that climate change is adversely affecting ecosystems and species in every region of the world, and the extent and magnitude of these impacts are larger than estimated in previous assessments. IPCC AR6 found, with *high confidence*, that climate change has caused “substantial damage, and increasingly irreversible losses, in terrestrial, freshwater and coastal and open marine ecosystems.”¹⁹³ Some ecosystems are already “reaching or surpassing hard adaptation limits,” including warm-water coral reefs, some coastal wetlands, some rainforests, and some polar and mountain ecosystems (*high confidence*).¹⁹⁴ Climate change is also leading to changes in the geographic distribution of some species and the spread of insect pests and invasive species. Climate-change-fueled ecosystem deterioration is having “adverse socioeconomic consequences” on the communities and sectors that depend on these ecosystems (*high confidence*).¹⁹⁵ For example, impacts on marine ecosystems affect fisheries’ health and productivity, and phenological changes associated with climate change, such as longer growing seasons, affect agriculture and food-production systems.

Physical impacts of extreme weather: Many attribution studies straddle the line between extreme-event and impact attribution, examining the effect of anthropogenic forcing on climatological extremes (e.g., heavy precipitation) and corresponding physical hazards (e.g., floods). In some cases, the effect of climate change on physical hazards is quite clear. For example, IPCC AR6 expressed *high confidence* that sea-level rise has contributed to increased coastal flooding in low-lying areas.¹⁹⁶ However, there is less certainty regarding how climate change is affecting inland flooding conditions, owing to the many different factors (both climatological and nonclimatological) that influence river hydrology and flood conditions. Research has also demonstrated a robust link between increased “wildfire weather” caused by climate change and more severe wildfires (e.g., increases in fuel aridity and acres burned) as a result of the strong effect of hotter, drier conditions on wildfire behavior.¹⁹⁷

Food and water security: Climate change has impaired food and water security in many regions of the world as a result of both slow-onset phenomena and extreme events.¹⁹⁸ Some of the slow-onset phenomena with the largest

impacts on food and water security include increasing temperatures, desertification, decreasing precipitation, land and forest degradation, and loss of biodiversity and ecosystem function. Extreme events such as acute droughts, floods, storms, and heat waves can also cause acute food and water stress (e.g., when drinking water systems are contaminated during storms). The effect of climate change on food and water security is evident across most regions of the world, particularly with respect to fisheries' yield and aquaculture production.¹⁹⁹

Public health and well-being: Attribution of public health outcomes from climate change can be challenging owing to data requirements and the complexity of isolating causal factors that contribute to health outcomes. As noted by Ebi et al. (2017), robust detection and attribution of health impacts require reliable long-term datasets, in-depth knowledge of the many drivers and confounding factors that affect public health outcomes, and refinement of analytic techniques to better capture the effect of anthropogenic forcing on health outcomes.²⁰⁰ Two key challenges are the fact that high-quality, long-term public health data are not available for many parts of the world and that there are many confounding factors that influence public health outcomes in any given region. Despite these limitations, the overall body of attribution research demonstrates a clear causal nexus between climate change and health outcomes.²⁰¹ IPCC AR6 expressed *very high confidence* in research showing that climate change is adversely affecting

199. *Id.* at 46, Fig. TS.3 (“Observed Global and Regional Impacts on Ecosystems and Human Systems Attributed to Climate Change”).

200. Kristie L. Ebi et al., *Detecting and Attributing Health Burdens to Climate Change*, 125 *Env't Health Persp.* 085004–1 (2017), <https://doi.org/10.1289/EHP1509>.

201. “[A]dvances are possible in the absence of complete data and statistical certainty: there is a place for well-informed judgments, based on understanding of underlying processes and matching of patterns of health, climate, and other determinants of human well-being.” *Id.* at 085004–7. To illustrate this point, the researchers discuss several contexts in which it is possible to show that a “proportion of the current burden of climate-sensitive health outcomes can be attributed to climate change”: (1) heat waves, (2) the emergence of tick vectors of Lyme disease in Canada, and (3) the emergence of *Vibrio* (bacteria) in northern Europe. For heat waves, the researchers described several approaches for estimating the number of heat wave deaths attributable to anthropogenic climate change. These included two variants on multistep attribution that would combine either the risk-based or storyline approach to extreme-event attribution with an assessment of how changes in exposure to heat waves affect mortality, as well as a single-step attribution approach, which would combine observations of the changes in the incidence and severity of heat waves with the exposure analysis. For *Vibrio*, the researchers found that it was possible to attribute increases in the incidence of *Vibrio* to incremental increases in sea surface temperatures, which could then be attributed to climate change. For tick vectors and Lyme disease, the researchers found that there was indirect evidence that higher temperatures were one of the forces leading to the expansion of these vectors, but that more detailed analyses of longer-term surveillance data were needed to actually quantify the relationship between climate change and tick vectors. One key takeaway from the authors of that study was that there are many different approaches to health impact attribution, including qualitative approaches. *See, generally, id.*

the physical and mental health of people around the world.²⁰² For example, extreme heat events are resulting in human mortality and morbidity across all regions (*very high confidence*),²⁰³ and studies on individual heat events have demonstrated that anthropogenic climate forcing can have a major effect on associated mortality and other health indicators.²⁰⁴ There are many other pathways through which climate change affects physical health. For example, climate change contributes to an increase in the prevalence of food-borne, water-borne, and vector-borne diseases that cause death and illness (*very high confidence to high confidence*).²⁰⁵ Climate change also exacerbates air pollution—for example, an increase in wildfire weather translates to increased wildfire smoke. Heat waves also contribute to air pollution, particularly in urban regions. The effects of climate change on air quality have been connected to increases in cardiovascular and respiratory disease.²⁰⁶

Cities, settlements, and infrastructure: The effects of climate change on human settlements and infrastructure are already apparent. IPCC AR6 found that sea-level rise, hydrological changes, permafrost thaw, and extreme events such as heat waves, droughts, wildfires, and floods are already causing disruptions of key infrastructure and services such as energy supply and transmission, communications, food and water supply (see above), and transportation systems (*high confidence*).²⁰⁷ In addition, cities and settlements are experiencing effects that have “extended from direct, climate-driven impacts to compound, cascading and systematic impacts (*high confidence*).” The nature and magnitude of these impacts vary considerably depending on the region, level of exposure to climate impacts, and vulnerability of affected populations and physical infrastructure. Coastal settlements and infrastructure are particularly vulnerable to compounding climate change impacts because of their exposure to sea-level rise, more intense storms and storm surge, and the associated risks of flooding, inundation, saltwater

207. *Id.* at 53.

intrusion, and land subsidence.²⁰⁸ Many of these communities also depend on coastal and marine ecosystems for food security, livelihoods, and socioeconomic development—and they are thus uniquely affected by ecosystem alterations brought about by ocean warming, ocean acidification, and other aspects of climate change.²⁰⁹

Socioeconomic development and humanitarian impacts: All of the impacts described above have important implications for socioeconomic development, although attributing socioeconomic impacts to anthropogenic climate change can be tricky because of the fact that there are so many nonclimate factors that also influence development trajectories. Nonetheless, attribution studies have identified clear connections between both mean and extreme changes in the global climate system and adverse economic consequences across many regions and sectors, particularly in “climate-exposed” sectors and regions that experience high exposure and vulnerability to climate change impacts (*medium to high confidence*, depending on the sector and region).²¹⁰ Economic impacts are not uniform; some areas are disproportionately affected by adverse impacts,²¹¹ and some positive economic effects have been identified—for example, in “regions that have benefitted from lower energy demand as well as comparative advantages in agricultural markets and tourism” (*high confidence*).²¹² In addition, climate change is contributing to humanitarian disasters and human displacement, particularly in areas of high vulnerability to climate impacts (*high confidence*).²¹³ Extreme events are increasingly driving displacement across all regions of the world (*high confidence*), with disproportionate effects on Small Island Developing States

208. *Id.* (“Coastal cities are disproportionately affected by interacting, cascading and climate-compounding climate- and ocean-driven impacts, in part because of the exposure of multiple assets, economic activities and large populations concentrated in narrow coastal zones (*high confidence*)”).

209. See section titled “Socioeconomic development and humanitarian impacts.”

210. See IPCC AR6 WGII, *supra* note 181, at 11 (“Overall adverse economic impacts attributable to climate change, including slow-onset and extreme weather events, have been increasingly identified (*medium confidence*). . . . Economic damages from climate change have been detected in climate-exposed sectors, with regional effects to agriculture, forestry, fishery, energy, and tourism (*high confidence*), and through outdoor labour productivity (*high confidence*). Some extreme weather events, such as tropical cyclones, have reduced economic growth in the short-term (*high confidence*)”). See also *id.* at 54 (“The effects of climate change impacts have been observed across economic sectors, although the magnitude of the damage varies by sector and by region (*high confidence*). Recent extreme weather and climate-induced events have been associated with large costs through damaged property, infrastructure and supply chain disruptions, although development patterns have driven much of these increases (*high confidence*). Adverse impacts on economic growth have been identified from extreme weather events (*high confidence*) with large effects in developing countries (*high confidence*).”).

211. See, e.g., IPCC AR6 WGII, *supra* note 181, at 54 (discussing disproportionate adverse impacts on Small Island Developing States).

212. *Id.* at 11.

213. *Id.*

(*high confidence*).²¹⁴ Impacts on food and water security, discussed above, are also adversely affecting humanitarian outcomes and socioeconomic development.

Source Attribution

The field of source attribution encompasses research aimed at identifying and attributing climate change to specific sources. A source could be a particular actor (e.g., a country or a company), a sector, or an activity. In climate litigation, this research is used to answer questions such as: (1) whether and to what extent a particular entity has contributed to emissions and climate change impacts, (2) whether a source category generates a sufficient quantity of emissions such that a regulatory threshold is triggered, and (3) whether a government agency has adequately disclosed emissions and climate impacts from its projects and activities. As noted above, source attribution has been, and remains, a distinct discipline from what is commonly labeled “detection and attribution” in the climate science community. However, these research streams have begun to converge in recent years, and there is now a growing body of research aimed at linking specific entities (e.g., countries and private actors) to observed changes, such as sea-level rise and extreme events.²¹⁵

Methods and Parameters

The IPCC does not have a working group that serves as a direct analog for source attribution research like other issues discussed in this reference guide. IPCC Working Group III (WGIII) does synthesize some research on GHG emissions sources (e.g., estimates of regional and sectoral GHG contributions); however, the WGIII reports do not include data on the specific contributions of particular entities to global emissions, as may be required to support a legal finding of responsibility for or obligation to address climate change. Thus, source attribution data in climate litigation are often derived from sources other than IPCC reports.

214. *Id.*

Otto et al., *Assigning Historical Responsibilities for Extreme Weather Events*, 7 *Nature Climate Change* 757 (2017), <https://doi.org/10.1038/nclimate3419>; B. Ekwurzel et al., *The Rise in Global Atmospheric CO₂, Surface Temperature, and Sea Level from Emissions Traced to Major Carbon Producers*, 144 *Climatic Change* 579 (2017), <https://doi.org/10.1007/s10584-017-1978-0>.

The data used in source attribution come from direct measurements of emissions, which can be performed in situ or remotely from satellites, as well as documentary evidence of emissions contained in corporate reports, government inventories, and other sources.²¹⁶ Where direct emissions data are lacking, scientists can use indirect methods, such as models, to estimate emissions from sources and activities. Indirect methods are particularly important for estimating emissions from land use changes and nonpoint sources such as agricultural operations.

Establishing causation in the source attribution context involves quantifying the emissions contribution of the source and ascertaining the proportional contribution of those emissions to: (1) concentrations of greenhouse gases and other forcings and (2) how those changes in concentrations ultimately impact, for example, sea-level rise, extreme weather events, and the resultant impacts on ecosystems and/or communities. As noted above, there are some recent studies linking specific sources to global climate change and extreme events. However, most of the existing research on source attribution focuses on quantifying emissions from sources and determining the proportional contribution to increases in atmospheric greenhouse gases.

There are several factors that must be considered when making this calculation. First, climate change is not a product of a single pollutant or polluting activity, and different GHGs and other forcing agents have different effects on climate in terms of magnitude, duration, location, and type of effect. Second, there are some gaps in knowledge pertaining to total emissions of certain forcing agents, including historical emissions, as well as a good deal of uncertainty about the extent and timing of historical land use changes and their impact on atmospheric concentrations of greenhouse gases.²¹⁷ Some of these land use changes, like deforestation, also impact climate in other ways—for example, by altering the amount of sunlight converted to heat at the surface.²¹⁸

Nonetheless, scientists have endeavored to calculate the relative contributions of emissions and land use change, and, within the category of emissions, of

216. Because such reports are prepared by humans, sometimes pursuant to a political or social agenda, they may contain biases or errors of a different type than those found in raw data or instrumental records.

217. For additional context on the state of knowledge on different GHG emission sources and their relative contribution to global climate change, see NASEM, *Greenhouse Gas Emissions Information For Decision Making: A Framework Going Forward* (2022), <https://doi.org/10.17226/26641>.

218. For example, land use decisions that change the amount of sunlight absorbed at the surface can have an important or negligible effect on climate, depending on factors such as the latitude at which the deforestation occurs and the reflective properties of the surface underneath the previously forested area. Another complicating factor is that climate change itself directly impacts the magnitude of sources and sinks for greenhouse gases (e.g., a warmer ocean is less able to take up carbon dioxide, and changes in vegetation with climate change could switch some natural systems from net sources to net sinks, and vice versa).

different pollutants. In climate change attribution studies, scientists can bolster emissions data with actual measurements of atmospheric greenhouse gases (such as those taken at Mauna Loa in Hawaii) to determine the overall effect of human activity on climate, with the aforementioned caveats. Climate models can also be used both to evaluate the proportional contribution to atmospheric forcing agents and to ascertain the effect of that contribution on other aspects of climate change.

Finally, it is important to recognize that source attribution involves questions that cut across different social and scientific disciplines. Certainly, there is a physical science component to source attribution, as the ultimate goal is to ascertain the physical contribution of the source to anthropogenic climate change. But there are also social and normative questions that come into play when attributing emissions (or sequestration) to a particular source, particularly when trying to assign “responsibility” for emissions. Consider the many different ways that emissions can be “divvied up” across different lines—by stage of economic development, global region, country, sector, company, consumer, etc. Even within these categories, there are different ways of assigning emissions responsibility. For example, when assessing national responsibility for climate change, one can look at emissions that are generated within the country (territorial emissions), emissions embodied in products consumed within the country (consumption-based emissions), or emissions from fossil fuels produced within the country (production-based emissions). Similarly, when assessing corporate responsibility for climate change, there are important questions about the relative responsibility of upstream entities (e.g., fossil fuel producers) and downstream entities (e.g., manufacturers and end users of carbon-intensive products and consumers of fossil fuels) in addition to the entities that directly generate emissions.²¹⁹

Granted, it is entirely possible to avoid such normative questions when publishing information about source attribution. For example, a study could simply provide a breakdown of emissions across different countries using different accounting approaches (territorial, consumption-based, and production-based) without reaching any conclusions about the responsibility of different actors or source categories. But in practice, when attribution science is used in the courtroom, the question of responsibility may be of paramount importance.

International climate negotiations have historically focused on using national responsibility as the basis for allocating emission reduction burdens. This focus is evident in the United Nations Framework Convention on Climate Change (UNFCCC), which places the responsibility for reporting on and reducing

219. These types of considerations also factor into assessments of how to allocate the global carbon budget among different actors. See section titled “Impact Detection and Attribution” above.

emissions on national governments;²²⁰ the “Brazilian Proposal,” which emerged from UNFCCC negotiations in the mid-1990s and holds that greenhouse gas emission reduction targets should be set according to each country’s historical contribution to climate change;²²¹ and the Paris Agreement, which relies on nationally determined contributions (NDCs) as the primary basis for mitigating emissions.²²² The UNFCCC reporting framework has historically focused on territorial emissions (i.e., emissions generated within the country) as the metric for gauging national responsibility. However, in recent years there has been a strong push in both international and domestic forums to account for consumption-based emissions (i.e., emissions embodied in products consumed within the country) and extraction-based emissions (i.e., emissions from fossil fuels produced within the country) in addition to territorial emissions when assessing national obligations.²²³

While most national emissions inventories currently focus on territorial emissions, researchers have found that it would be relatively easy for countries to produce extraction-based and consumption-based inventories utilizing readily available data.²²⁴ In other words, pursuing these alternative accounting methodologies would not be significantly more expensive or technically challenging than the territorial approach. These alternative accounting methodologies also provide valuable insights that are not captured in the territorial approach—for

Power, *The Impact of Powder River Basin Coal Exports on Global Greenhouse Gas Emissions*, Energy Found. (2013), <https://perma.cc/RV4A-SCH3>.

example, the consumption-based approach accounts for “leakage” of GHG emissions to other countries via trade and helps countries understand the importance of developing policies aimed at reducing consumption of carbon-intensive products. Ultimately, though they may carry different legal weight, all three methodologies are useful in addressing the question of who is “responsible” for climate change.

In addition, researchers have compiled detailed historical inventories of emissions attributable to some corporate actors and industries. Corporate emissions inventories and disclosures also serve as a source of data for assessing corporate contributions to climate change.

Status of Research

National contributions

Since the 1990s, countries, including the United States, have been preparing national GHG inventories pursuant to guidelines articulated by the UNFCCC. These inventories encompass emissions from energy, industrial processes and product use, agriculture, land use practices, and waste. Emission estimates are based on territorial emissions. The inventories are publicly available and frequently used as a data source by researchers who analyze emission trends. They provide somewhat comprehensive coverage of recent emissions from countries, but they do not provide a complete picture of historical emissions before the 1990s and early 2000s (for some countries). There are also accounting inconsistencies in the inventories owing to the issuance of different standards and reporting requirements for countries with different capacities.²²⁵

Governmental agencies, scientific organizations, and researchers have helped to fill these gaps through further research on national and sectoral emissions. Two key sources of data for this research are (1) atmospheric emission measurements, and (2) information about production and activities that contribute to GHG emissions. As noted by the National Academies, “[t]he most accurate and precise estimates are available for emission-producing activities that have explicit economic value (e.g., energy production),” and “[n]ational CO₂ emissions from fossil fuel burning are typically well characterized by economic data on fossil fuel trade and production.”²²⁶ In comparison, there is a good deal of uncertainty about CO₂ emissions estimates from land use and land use change,

225. For a more detailed discussion of limitations in UNFCCC emission inventories, see NASEM, *supra* note 217.

226. *Id.* at 50.

as well as emissions of non-CO₂ GHGs from both industry and land use.²²⁷ For example, recent research indicates that methane emissions from fossil fuel infrastructure are 50% larger than inventory estimates, and there is additional uncertainty regarding methane emissions from wetlands, reservoirs, agriculture, waste, and other sources.²²⁸ Nitrous oxide (N₂O) emissions, primarily from agriculture, are another important source of anthropogenic climate forcing, and measurements of atmospheric N₂O suggest that these emissions are underestimated globally.²²⁹

There are different accounting approaches for estimating national emissions. For example, researchers have developed national estimates of consumption- and extraction-based emissions in addition to territorial emissions.²³⁰ With respect to cumulative contributions, there is more uncertainty about the attribution of consumption-based emissions to individual countries as the result of limited data about historical emissions embodied in trade. Work has also been done to quantify emissions at different scales and to evaluate emissions by different metrics (e.g., per capita emissions within a country).²³¹ Overall, there is a large body of emissions data that litigants and other actors can draw on—especially for U.S. CO₂ emissions, which are well documented by both government agencies and independent researchers.²³²

There is also a growing body of research aimed at linking national emissions contributions to specific aspects of climate change. These studies use many of the same general techniques and climate models that are used when studying the aggregate effects of anthropogenic climate forcings; however, because these studies deal with a smaller quantity of emissions (national rather than global emissions), it can be more difficult to ascertain the impact of those emissions with precision and certainty. Accordingly, attribution studies for individual countries

227. *Id.* As a point of reference, the uncertainty for global fossil fuel CO₂ emissions is thought to be less than ±8%, whereas the uncertainty for land use CO₂ emissions is estimated at roughly ±75%. At the national level, these uncertainty estimates vary depending on the quality of data systems.

232. See, e.g., Hannah Ritchie et al., *United States: CO₂ Country Profile*, OurWorldinData (2020), <https://perma.cc/7WRT-XKSV> (cumulative emissions are important owing to the long atmospheric lifetime of CO₂); Hannah Ritchie, *Where in the World Do People Emit the Most CO₂?*, OurWorldinData (2019), <https://perma.cc/282X-UNUL>.

(or other individual sources) may result in a relatively broad range of possible values (i.e., a large confidence interval) as compared with attribution studies that deal with climate change in the aggregate. It is also important that such studies include a robust discussion of uncertainty.

Many national attribution studies deal with contributions to global mean surface temperature (GMST) increases, as there is robust physical understanding of the relationship between anthropogenic forcings and GMST.²³³ For example, Skeie et al. (2017) used a climate model to link the territorial emissions between 1850 and 2012 from multiple countries to GMST change, taking into account historical emissions and focusing on the largest emitters.²³⁴ In a similar study, Jones et al. (2023) calculated changes in GMST attributable to national CO₂, methane (CH₄), and nitrous oxide (N₂O) emissions from 1850 to 2021.²³⁵

Researchers are also examining the causal relationship between national emissions and a range of other impacts, including regional/country-specific impacts, and changes in extreme events. Otto et al. (2017) was the first study to apply the nation-based emissions framework to individual extreme-event attribution, focusing on a heat wave in Argentina.²³⁶ The researchers used two

233. See Nathan P. Gillett et al., *Constraining the Ratio of Global Warming to Cumulative CO₂ Emissions Using CMIP5 Simulations*, 26 J. Climate 6844 (2013), <https://doi.org/10.1175/JCLI-D-12-00476.1>; Pierre Friedlingstein & Susan Solomon, *Contributions of Past and Present Human Generations to Committed Warming Caused by Carbon Dioxide*, 102 PNAS 10832 (2005), <https://doi.org/10.1073/pnas.0504755102>; Ting Wei et al., *Developed and Developing World Responsibilities for Historical Climate Change and CO₂ Mitigation*, 109 PNAS 12911 (2012), <https://doi.org/10.1073/pnas.1203282109>; Julia Pongratz & Ken Caldeira, *Attribution of Atmospheric CO₂ and Temperature Increases to Regions: Importance of Preindustrial Land Use Change*, 7 Env't Rsch. Letters 034001 (2012), <https://doi.org/10.1088/1748-9326/7/3/034001>; Sophie C. Lewis et al., *Assessing Contributions of Major Emitters' Paris-Era Decisions to Future Temperature Extremes*, 46 Geophysical Rsch. Letters 3936 (2019), <https://doi.org/10.1029/2018GL081608>; Niklas Höhne et al., *Contributions of Individual Countries' Emissions to Climate Change and Their Uncertainty*, 106 Climatic Change 359 (2011), <https://doi.org/10.1007/s10584-010-9930-6>; Bo Fu et al., *The Contributions of Individual Countries and Regions to the Global Radiative Forcing*, 118 PNAS e2018211118 (2021), <https://doi.org/10.1073/pnas.2018211118>.

234. Ragnhild B. Skeie et al., *Perspective Has a Strong Effect on the Calculation of Historical Contributions to Global Warming*, 12 Env't Rsch. Letters 024022 (2017), <https://doi.org/10.1088/1748-9326/aa5b0a>. Skeie et al. noted that these findings were very sensitive to the parameters of the study, including technical decisions such as the time frame for the analysis, as well as more normative decisions about the basis for attributing emissions (e.g., place of extraction vs. place of burning vs. place of final consumption) and about whether to look at per capita or total emissions. They also emphasized that, in nonlinear systems, the proportional contribution to emissions will differ from the proportional contribution to impacts. *Id.*

235. Matthew W. Jones et al., *National Contributions to Climate Change Due to Historical Emissions of Carbon Dioxide, Methane, and Nitrous Oxide Since 1850*, 10 Sci. Data 155 (2023), <https://doi.org/10.1038/s41597-023-02041-1>. Note that Jones et al. and Skeie et al., *supra* note 234, use different time frames for the emissions analysis (1850–2012 and 1850–2021), which is one factor contributing to the different findings in these studies.

236. Otto et al., *supra* note 215.

different statistical methodologies²³⁷ to assess historical responsibility.²³⁸ This research provides useful initial insights on possible measures of national responsibility, but the large uncertainty ranges reported in the study illustrate the difficulty of attributing specific extreme events or climate impacts to specific emitters with a high level of precision.

Corporate contributions

Much of the research on corporate contributions to climate change has focused on corporations involved in fossil fuel production, energy, and other emissions-intensive industries. In the foundational Carbon Majors study, Heede (2014) developed estimates of historical emissions for ninety producers of oil, gas, coal, and cement based on their production records.²³⁹ Corporate emissions estimates can also be obtained through voluntary disclosures through initiatives like the Climate Disclosure Project, as well as legally mandated disclosures, which are becoming increasingly common.²⁴⁰ The IPCC and government agencies also compile emissions data for specific sectors (energy, transport, buildings, industry, forestry, agriculture, and waste). Sectoral data are potentially relevant when assessing government legal obligations related to the regulation of GHG emissions, or for comparing corporate emissions to industry norms.

Researchers have also begun conducting attribution studies aimed at linking corporate emissions to specific climate impacts (as with national emissions), for example, using findings from the Carbon Majors study to assess the impacts of emission contributions to global temperature change, sea-level rise,²⁴¹ and ocean acidification.²⁴² As noted in the discussion above, such studies rely on

237. As explained by the authors, the first methodology, the distribution method, “fits a distribution to the raw model data for both ensembles and estimates the percentage change in the distribution characteristics for individual regions by applying the [national] contributions to GMST.” The second methodology, the gradient method, “differs in that the return time curve is used directly to calculate the gradient of the curve at the threshold of the event in both ensembles, and scale between the two gradients according to the [percentage contributions].” *Id.*

238. The study also examined EU responsibility, but we focus on U.S. findings for the purposes of this reference guide. *Id.*

well-established attribution techniques and climate models, but there tends to be more uncertainty (often expressed as a broader confidence interval) when attributing impacts to specific emitters and sources.

Projections of Future Climate Change

Climate change projections provide insights on the magnitude and scope of changes and impacts that could occur under different emission trajectories and warming scenarios. It is generally understood that the effects of climate change will become increasingly severe and pervasive as GHGs continue to accumulate in the atmosphere. However, the relationship among emissions, changes in the global climate system, and corresponding impacts is not always linear—for example, there are potential tipping points, feedback cycles, and cascading impacts that could result in acceleration of certain trends such as sea-level rise. Scientists have developed sophisticated methods for predicting future changes and impacts based on anthropogenic forcing and levels of atmospheric warming. Importantly, these projections are not intended to convey the world *as it will be* but rather the world *as it could be* depending on future human activities.

Methods and Parameters

Like attribution research, projections of climate change are based on physical understanding, climate datasets, statistical methods, and modeling tools. In addition, the findings from detection and attribution research, discussed above, provide the foundation for predicting future trends, insofar as they characterize the changes that are already underway as a result of anthropogenic climate forcing. Climate change projections are typically used in climate litigation to establish the foreseeability of future climate harms and to assess legal obligations to control GHG emissions and/or adapt to the effects of climate change.

The projections in IPCC assessments and many other studies rely heavily on the CMIP model ensemble to simulate how changes in climate forcers, such as GHGs, may affect the global climate system. IPCC AR6 relies on CMIP Phase 6 (CMIP6), which has better representations of physical processes as well as higher resolution compared to climate models used in previous IPCC assessments.²⁴³ The climate projections in IPCC AR6 are based on five illustrative scenarios that reflect potential changes in GHG emissions and land uses as well as natural climate forcers. They include near-term (2021–2040), mid-term (2041–2060), and long-term (2081–2100) projections.

243. IPCC AR6 WGI, *supra* note 6, at 12.

There is considerable confidence in the ability of global climate models to provide credible quantitative estimates of future climate change at large geographic scales.²⁴⁴ Confidence in global projections is higher for some climate variables (e.g., global mean temperature) than for others (e.g., precipitation). To evaluate the credibility and robustness of model projections, scientists will assess how well the model is able to simulate observed climate conditions. For example, the CMIP6 multimodel ensemble underwent a diagnostic evaluation that revealed that it captured most aspects of observed climate change well.²⁴⁵ One key improvement in global climate models is that they are now better at simulating natural climate variability, which can play a significant role in shaping future climate conditions.

Global climate models deal with large-scale weather patterns; they do not have the spatial resolution to simulate the effects of anthropogenic climate change at a regional or local scale. Scientists can use regional models to simulate the interactions between changes in large-scale weather patterns and regional or local conditions. Regional climate models have much finer spatial resolution (e.g., 1–50 km grid spacing, as opposed to 100–300 km grid spacing in a global model).²⁴⁶ There is generally more uncertainty and less confidence in projections at the regional scale because of the challenges with regional climate analysis and downscaling described above. In particular, internal variability tends to play a larger role in shaping regional climate conditions, and this complicates the identification of forced climate signals at the regional level. There are methods for reducing uncertainty in regional projections—for example, by combining and comparing results from different regional models, or by using initial-condition ensembles, where the same model is run repeatedly under identical forcing but with small variations in initial conditions (which helps researchers quantify uncertainty owing to internal variability).²⁴⁷

Even where models are unable to provide robust quantitative projections of future climate conditions, it may be possible to qualitatively predict trends with a fairly high level of confidence. Such qualitative projections can be used to assess climate risk and to define legal obligations related to climate change mitigation and adaptation. However, there are some variables for which it may be difficult to even reach qualitative conclusions about the direction of future trends. For example, it is unclear whether average precipitation will increase or decrease in some regions as a result of anthropogenic climate change.²⁴⁸

247. IPCC AR6 WGI, *supra* note 6, at 562.

248. At the global scale, models project that there will be greater contrast in mean precipitation between dry and wet regions (i.e., dry areas will become drier; wet areas will become wetter) but with large regional variations and low confidence in projections. *Id.* at 1109. Some regions, such

As noted above, climate projections must be issued in reference to future emissions (or anthropogenic forcings) and/or warming scenarios. These future emissions, which will depend primarily on future human decisions, thus include an additional type of uncertainty relative to attribution research. In its latest assessment, the IPCC used the following emission scenarios based on Shared Socio-economic Pathways (SSPs) to frame its analysis: (1) a “very low” emissions scenario, where GHG emissions decline sharply, reaching net zero around 2050, followed by net negative emissions (SSP1–1.9); (2) a “low” emissions scenario, where emissions decline quickly (but not as fast as the very low scenario), reaching net zero emissions after 2050, followed by net negative emissions (SSP1–2.6); (3) an “intermediate” emissions scenario, where CO₂ emissions remain at current levels until mid-century and then decline to net zero by 2100 (SSP2–4.5); (4) a “high” scenario where emissions continue to increase through the century (SSP3–7.0); and (5) a “very high” scenario with larger emission increases, followed by a slight decline in emissions toward the end of the century (SSP5–8.5).²⁴⁹ These five scenarios correspond with different temperature increases (see Figure 2), and they have been used as the basis for climate modeling in CMIP6 ensembles.

Status of Research

Using the emissions scenarios described above, IPCC AR6 projected future changes in global surface temperature²⁵⁰ and other aspects of the climate system, including (1) mean sea level, (2) ocean acidification and deoxygenation, (3) intensity and variability of the global hydrological cycle, (4) the extent and volume of all cryosphere resources such as sea ice and glaciers, and (5) climatological extremes.²⁵¹ It also projected changes in climate hazards and impacts under future emissions scenarios, such as changes in heat-related mortality and morbidity; food-borne, water-borne, and vector-borne diseases; flooding in coastal and low-lying areas; biodiversity loss; impacts on food and water security; and mental health impacts.²⁵² IPCC AR6 concluded that the loss and damage caused by anthropogenic climate change will be severe even if we limit global warming to 1.5°C or “well below” 2.0°C (the Paris Agreement targets for averting dangerous anthropogenic climate change, which are often used to formulate

as the western United States, are projected to have increased precipitation in some models and decreased precipitation in other models. *Id.* at 1110 (Fig. 8.14). However, this is not the case for most regions. There are other regions for which there is more pervasive uncertainty about the trajectory of future impacts (e.g., ice storms and tornadoes).

scenarios for climate projections and shape emissions reduction efforts).²⁵³ Many of the projected changes in the climate system will be “irreversible on centennial to millennial timescales,” particularly changes in the ocean, ice sheets, and global sea level.²⁵⁴

Notably, for any given future warming level, many climate-related risks are higher than those assessed in AR5, and the severity of projected long-term impacts is often significantly higher than currently observed impacts like those described above (*high confidence*).²⁵⁵ The effects of climate change will also interact with nonclimatic risks, creating “compound and cascading risks that are more complex and difficult to manage” (*high confidence*).²⁵⁶ The relationship between impacts and global warming is often not linear, and small temperature increases can result in dramatically more severe impacts. IPCC AR6 also found that the planet is already very close to surpassing many critical thresholds within the climate system, and some of these thresholds will likely be surpassed if global warming exceeds 1.5°C.²⁵⁷ More recent studies on tipping points that were published after evidence was compiled for IPCC AR6 indicate that we are close to surpassing certain thresholds, and may have already surpassed some, particularly those associated with cryosphere impacts (e.g., the melting of ice sheets).²⁵⁸

Adaptation measures can play a significant role in mitigating certain risks, such as the risks associated with extreme precipitation and flooding. However, adaptation may not be as effective at mitigating other harmful impacts, such as those on biodiversity and ecosystems. Moreover, the effect of climate change on vulnerable populations and ecosystems often reduces their adaptive capacity, thus creating a compounding problem where adaptation becomes increasingly challenging and costly as climate change becomes more severe. Additionally, most adaptations involve tradeoffs, and there is a risk of maladaptation and inequitable adaptation.

How Climate Science Factors into Litigation

The United States has seen considerable growth in the field of climate litigation, that is, cases that involve legal claims related to climate change mitigation,

adaptation, compensation, and disclosures.²⁵⁹ This section provides an overview of the types of climate cases that are being filed in U.S. courts, particularly federal courts, and describes how different areas of climate science may factor into judicial assessments of causation, foreseeability, and legal obligations and authorities. It also discusses some considerations that are relevant when evaluating the admissibility, probative value, and weight of scientific evidence and expert testimony on matters related to climate change.

Overview of Climate Litigation

Many different types of climate-related claims have been filed in federal and state courts over the past several decades. Most of the federal cases involve questions about government obligations or authorities with respect to climate change mitigation, adaptation, and disclosures, as detailed below. These are typically administrative law claims, where judges may encounter questions about climate science when assessing (1) the scope of scientific evidence that must be considered by the agency before it decides on a course of action and (2) whether the agency has made a decision based on that evidence that meets the applicable legal standard.²⁶⁰ There are some exceptions, including constitutional claims against governments²⁶¹ and statutory and tort law claims against corporate defendants.²⁶² But the majority of federal claims involve government defendants and tend to fall in one of the following broad categories.

259. Mitigation refers to actions to reduce greenhouse gas emissions and other anthropogenic drivers of climate change. Adaptation refers to actions to prepare for and respond to the effects of climate change on human and natural systems. Compensation refers to payments or other resources given to people who have experienced damages as a result of anthropogenic climate change. Disclosures refer to the analysis and disclosure of information related to climate change (particularly climate-change-related risks) in government and corporate documents, such as environmental impact statements and financial reports.

260. *See, e.g.*, 5 U.S.C. § 706(2)(A) (directing courts to hold unlawful and set aside agency action, findings, and conclusions that are “arbitrary, capricious, an abuse of discretion, or otherwise not in accordance with law”); 5 U.S.C. § 706(2)(E) (directing courts to set aside a formal rulemaking or adjudication if it is not supported by “substantial evidence”). *See also* *Motor Vehicles Mfrs. Ass’n v. State Farm Mut. Auto. Ins. Co.*, 463 U.S. 29, 43 (1983) (when applying the arbitrary and capricious standard, courts evaluate whether the agency “examine[d] the relevant data and articulate[d] a satisfactory explanation for its action, including a rational connection between the facts found and the choice made”).

261. *See infra* note 273.

262. For example, federal cases have been filed against corporate actors seeking to establish liability for climate-change-related damages. *See, e.g.*, *Native Village of Kivalina v. ExxonMobil Corp.*, 696 F.3d 849 (9th Cir. 2012); *Complaint, Municipalities of Puerto Rico v. ExxonMobil Corp.*, No. 3:22-cv-01550 (D.P.R. Nov. 22, 2022). However, most corporate liability cases in the United States involve state law claims. *See, e.g.*, *City of Oakland v. BP PLC*, No. 22-16810, 2023

First, there are legal disputes about the scope of government obligations or authorities to regulate GHG emissions (i.e., mitigation). This category includes administrative lawsuits seeking regulatory action for GHG emissions pursuant to the Clean Air Act or other federal and state statutes, as well as lawsuits where agencies are defending GHG regulations against industry and/or state challenges.²⁶³ It also includes constitutional claims alleging that the government has violated fundamental rights through inadequate control of GHG emissions (these are sometimes called “atmospheric trust” cases, as the public trust doctrine is typically invoked alongside substantive due process).²⁶⁴ Constitutional claims have also been filed in opposition to government actions aimed at controlling GHG emissions and activities that contribute to GHG emissions (e.g., government restrictions on fossil fuel infrastructure).²⁶⁵

Second, many of the federal lawsuits filed against government agencies involve questions about procedural obligations to analyze and disclose climate-change-related considerations in administrative decision-making. These typically take the form of Administrative Procedure Act and National Environmental Policy Act (NEPA) claims alleging that federal agencies have not adequately accounted for climate-change-related considerations in administrative documentation prior to undertaking final agency action.²⁶⁶ Cases in this category may focus on agency obligations to account for GHG emissions and associated impacts attributable to federal actions, such as fossil fuel leases, natural gas pipeline approvals,

WL 8179286 (9th Cir. Nov. 27, 2023) (affirming remand to state court); *City & Cnty. of Honolulu v. Sunoco LP*, 39 F.4th 1101 (9th Cir. 2022), *cert. denied*, 143 S. Ct. 1795 (2023) (affirming remand to state court). Corporate actors may also be sued for the “failure to adapt” to climate change (e.g., the failure to prepare a coastal facility that stores hazardous substances for the effects of sea-level rise and more severe storms), or the “failure to disclose” known climate risks (e.g., in federal securities filings). *See, e.g.*, *Complaint, Conservation Law Found. v. Shell Oil Prods. US*, No. 1:17-cv-00396 (D.R.I. Aug. 28, 2017); *Complaint, Conservation Law Found. v. ExxonMobil Corp.*, No. 1:16-cv-11950 (D. Mass. Sept. 29, 2016).

263. *See, e.g.*, *Massachusetts v. EPA*, 549 U.S. 497 (2007); *Coal. for Responsible Regul. v. EPA*, 684 F.3d 102 (D.C. Cir. 2012), *aff’d in part, rev’d in part on other grounds by Util. Air. Regul. Grp. v. EPA*, 573 U.S. 302 (2014).

264. *See, e.g.*, *Juliana v. United States*, No. 6:15-cv-01517, 2023 WL 9023339 (D. Or. Dec. 29, 2023); *Animal Legal Defense Fund v. United States*, No. 19–35708, 2022 WL 5241274 (9th Cir. Feb. 9, 2022); *Komor v. United States*, No. 22–15851, 2023 WL 4313136 (9th Cir. July 3, 2023). State courts have also confronted constitutional and public trust claims about government obligations with regard to GHG emissions. *See, e.g.*, *Held v. Montana*, No. CDV-2020-307, 2023 WL 5229257 (Mont. Dist. Ct. Aug. 14, 2023).

265. *See, e.g.*, *Montana v. City of Portland*, No. 3:23-cv-00219, 2023 WL 8452447 (D. Or. Oct. 12, 2023); *Levin Richmond Terminal Corp. v. City of Richmond*, 482 F. Supp. 3d 944 (N.D. Cal. 2020).

266. *See, e.g.*, *Diné Citizens Against Ruining Our Env’t v. Haaland*, 59 F.4th 1016 (10th Cir. 2023); *Ctr. for Biological Diversity v. Nat’l Highway Traffic Safety Admin.*, 538 F.3d 1172, 1189 (9th Cir. 2008).

and forest management decisions.²⁶⁷ They may also focus on agency obligations to account for the effects of climate change on the action and its affected environment—for example, parties to a lawsuit may argue that an agency is obliged to account for observed and predicted hydrological changes in its assessment of a water management project.²⁶⁸

Third, there are cases that deal with government obligations or authorities to prepare for and respond to the effects of climate change on physical infrastructure, natural resources, or other matters under agency jurisdiction (i.e., adaptation). For example, there have been over 100 Endangered Species Act (ESA) cases that involve climate-change-related claims.²⁶⁹ These include cases where plaintiffs are trying to compel the federal government to conduct assessments of climate-change-related risks and/or issue protections for climate-change-imperiled species, as well as cases where the government is defending ESA protections for climate-change-imperiled species against legal challenges.²⁷⁰ Government agencies may also be sued regarding the treatment of climate change and climate science in decisions about land management plans, quotas for the sustainable use of resources, and government approvals for infrastructure and facilities that may be affected by climate change.²⁷¹ Finally, there are some examples of lawsuits aimed at blocking government adaptation measures (e.g., on the grounds that such measures constitute a regulatory taking or are in violation of federal law).²⁷²

267. See, e.g., *Diné Citizens*, 59 F.4th at 1016; 350 *Montana v. Haaland*, 50 F.4th 1254 (9th Cir. 2022); *Sierra Club v. Fed. Energy Regul. Comm'n*, 867 F.3d 1357 (D.C. Cir. 2017); *Ctr. for Biological Diversity v. U.S. Forest Serv.*, No. CV 22-114-M-DWM, 687 F. Supp. 3d 1053 (D. Mont. 2023); *High Country Conservation Advocs. v. U.S. Forest Serv.*, 333 F. Supp. 3d 1107 (D. Colo. 2018). Some cases specifically challenge the failure to employ a “social cost of carbon” metric to estimate the significance of GHG emissions. See, e.g., *Ctr. for Biological Diversity v. Fed. Energy Regul. Comm'n*, 67 F.4th 1176 (D.C. Cir. 2023); *Utah Physicians for a Healthy Env't v. U.S. Bureau of Land Mgmt.*, 528 F. 271. See, e.g., *Maine Lobsterman's Ass'n, Inc. v. Nat'l Marine Fisheries Serv.*, 70 F.4th 582 (D.C. Cir. 2023); *New York v. Raimondo*, 594 F. Supp. 3d 588 (S.D.N.Y. 2022); *Sound Action v. U.S. Army Corps of Eng'rs*, No. C18-0733JLR, 2019 WL 446614 (W.D. Wash. Feb. 5, 2019); *Ctr. for Biological Diversity v. Nat'l Marine Fisheries Serv.*, 977 F. Supp. 2d 55 (D.P.R. 2013), *as amended* (Oct. 23, 2013), *adhered to on reconsideration*, 191 F. Supp. 3d 157 (D.P.R. 2016).

272. See, e.g., *Complaint, Casa Mira Homeowners Ass'n v. Cal. Coastal Comm'n*, No. 19-civ-04677 (Cal. Super. Ct. Dec. 13, 2019); *Complaint, Jurisich Oysters, LLC v. U.S. Army Corps of Eng'rs*, No. 2:24-cv-00106 (E.D. La. Jan. 11, 2024).

These three categories encompass most but not all of the federal climate claims that have been filed to date. Some examples of lawsuits falling outside of these categories include: (1) legal challenges to federal and state regulations requiring disclosure of GHG emissions and climate-related risks from private companies;²⁷³ (2) legal challenges to the federal government’s use of “social cost of carbon” metrics in regulatory programs and other agency actions;²⁷⁴ (3) legal challenges to regulatory approvals of clean energy projects;²⁷⁵ (4) lawsuits seeking to establish liability on the part of corporations for climate-change-related damages;²⁷⁶ and (5) lawsuits seeking to establish obligations on the part of corporate actors to prepare for and respond to the effects of climate change on facilities, operations, or resources under their control.²⁷⁷

Legal Applications of Climate Science

There are several ways in which climate science may factor into the resolution of climate lawsuits. First, climate science may be used to evaluate claims of causation and harm, e.g., whether the GHG emissions at issue in a case cause or contribute to public endangerment or injury to a specific plaintiff. Second, climate science may be used to evaluate whether climate-related risks or harms were or are foreseeable. Finally, climate science may be used to determine the scope of a defendant’s legal obligations and authorities with regard to GHG mitigation, climate change adaptation, climate-related disclosures, and other matters.

Causation and Harm

Disputes about causation and harm arise in different types of climate lawsuits. For example, in cases where plaintiffs are seeking to compel government regulation of GHG emissions from a sector or activity, the parties may dispute the nature and/or magnitude of harm that can be attributed to those emissions, and whether the harm is substantial enough to trigger a regulatory obligation on the part of the government defendant.²⁷⁸ Causation may also be an issue in cases

273. See, e.g., *Iowa v. Sec. & Exch. Comm’n*, No. 24–1522 and consolidated cases (8th Cir. Mar. 12, 2024); *Chamber of Commerce v. California*, No. 2:24-cv-00801 (C.D. Cal. Jan. 30, 2024).

274. See *Missouri v. Biden*, 52 F.4th 362 (8th Cir. 2022), *cert. denied*, 144 S. Ct. 278 (2023).

275. See, e.g., *Seafreeze Shoreside, Inc. v. U.S. Dep’t of the Interior*, No. 1:22-CV-11091-IT, 2023 WL 6691015 (D. Mass. Oct. 12, 2023).

276. See *supra* note 262.

277. *Id.*

278. See, e.g., *Juliana v. United States*, 339 F. Supp. 3d 1062, 1096 (D. Or. 2018), *rev’d and remanded*, 947 F.3d 1159 (9th Cir. 2020). In the foregoing case, a group of youth plaintiffs claimed

where government agencies are defending GHG regulations against legal challenges, insofar as it may be necessary to demonstrate that those emissions cause some form of environmental or public harm in order to justify the regulatory action.²⁷⁹ Finally, the issue of causation and harm tends to be a major element of the standing analysis in cases where the plaintiff is alleging that they have experienced an injury as a result of the defendant's actions or inaction with regard to GHG emissions and climate change.²⁸⁰

As discussed in the sections of this reference guide titled “Foundational Components of Climate Science” and “Climate Change Detection, Attribution, and Projections,” there is scientific agreement that human GHG emissions are the dominant cause of global climate change. Thus, causation disputes in recent climate cases typically deal with one or both ends of the causation chain linking emissions to impacts (i.e., questions of source attribution and impact attribution). The source attribution questions pertain to the defendant's contribution to climate change—for example, what are the emissions attributable to the defendant's conduct, and do those emissions surpass a threshold of materiality or substantiality as may be necessary to establish legal causation? The impact attribution questions pertain to the nature of the alleged harm—for example, has the plaintiff experienced a specific and concrete injury that is attributable to climate change?²⁸¹ These two sets of questions combine into the overarching question of whether the defendant is responsible for the climate-change-related harms that are at issue in the case.

The contours of this analysis will differ depending on the nature of the claim and the status of the litigants. One important consideration is whether the case requires a showing of particularized injury as opposed to generalized

that the federal government had violated their constitutional rights by permitting, authorizing, and subsidizing fossil fuel extraction and consumption that contributed to climate change. They sought both declaratory and injunctive relief requiring the federal government to reduce emissions from fossil fuels. The district court held that plaintiffs had Article III standing because they had alleged sufficiently personalized and concrete injuries that were fairly traceable to the GHG emissions resulting from U.S. fossil fuel production and use. The Ninth Circuit reversed, holding that plaintiffs had failed to satisfy the redressability prong of standing because the injunctive relief they sought was outside the power of an Article III court.

279. See, e.g., *Coalition for Responsible Regulation v. EPA*, 684 F.3d 102 (D.C. Cir. 2012).

280. See, e.g., *Massachusetts v. EPA*, 549 U.S. 497 (2007); *Wash. Env't Council v. Bellon*, 732 F.3d 1131 (9th Cir. 2013), *reh'g en banc denied*, 741 F.3d 1075 (9th Cir. 2014); *Comer v. Murphy Oil USA*, 585 F.3d 855 (5th Cir. 2009), *rev'd and remanded in part, on other grounds*, 585 F.3d 855 (5th Cir. 2009); *Amigos Bravos v. U.S. Bureau of Land Mgmt.*, 816 F. Supp. 2d 1118, 1136 (D.N.M. 2011); *Juliana*, 339 F. Supp. 3d at 1062.

281. These questions of source attribution may implicate questions about climate change and extreme-event attribution. For example, if a plaintiff alleges injury based on exposure to an extreme event, the court would need to refer to extreme-event attribution research to evaluate the relationship between global climate change and the extreme event (what is the attributable risk?), as well as impact attribution data to evaluate the relationship between the plaintiff's injury and the event.

harm. A showing of particularized injury is required for standing. Specifically, for Article III standing, plaintiffs must demonstrate that: (1) they have experienced an injury-in-fact that is concrete and particularized, and actual or imminent, not conjectural or hypothetical; (2) the injury-in-fact is fairly traceable to the defendants' allegedly unlawful actions; and (3) the injury could be redressed by a favorable court decision.²⁸² Plaintiffs who are suing on the basis of climate-change-related injuries may attempt to establish these elements by presenting evidence that they are experiencing a unique injury as a result of climate change and that the defendant has made a substantial enough contribution to global climate change such that the injury can be fairly traced to the defendant's conduct.²⁸³

The Supreme Court's 5–4 decision in *Massachusetts v. EPA* is illustrative.²⁸⁴ The state of Massachusetts and other petitioners had filed a lawsuit challenging EPA's denial of a petition to regulate GHG emissions from motor vehicles under the Clean Air Act. One of EPA's stated rationales for declining the petition was that "a causal link between greenhouse gases and the increase in global surface air temperatures was not unequivocally established."²⁸⁵ EPA also argued that the petitioners lacked standing because they could not demonstrate a particularized injury that could be fairly traced to its decision to not regulate GHG emissions from motor vehicles. However, the Supreme Court disagreed, finding that:

The harms associated with climate change are serious and well recognized. The Government's own objective assessment of the relevant science and a strong consensus among qualified experts indicate that global warming threatens, *inter alia*, a precipitate rise in sea levels, severe and irreversible changes to natural ecosystems, a significant reduction in winter snowpack with direct and important economic consequences, and increases in the spread of disease and the ferocity of weather events. That these changes are widely shared does not minimize Massachusetts' interest in the outcome of this litigation.²⁸⁶

282. *Lujan v. Defs. of Wildlife*, 504 U.S. 555 (1992). In addition to these constitutional requirements, there is also a prudential requirement that the complaint be in the zone of interests of the applicable statute in order for the plaintiff to have standing. *Bennett v. Spear*, 520 U.S. 154 (1997).

283. The second and third elements of standing (causation and redressability) are closely related, sometimes referred to as "two sides of the same coin." See *FDA v. All. for Hippocratic Med.*, 602 U.S. 367, 380–81 (2024); *Ctr. for Biological Diversity v. EPA*, 90 F. Supp. 3d 1177, 1190 (W.D. Wash. 2015); *Gonzales v. Gorsuch*, 688 F.2d 1263, 1267 (9th Cir. 1982); *Duke Power Co. v. Carolina Env't Study Grp.*, 438 U.S. 59, 74 (1978). Thus, if plaintiffs establish that their injury can be "fairly traced" to the defendant's conduct, then there is a reasonable prospect that a court order that compels a change in that conduct will at least partially mitigate the injury. However, if the court does not have the authority to issue a remedy, then it may find that plaintiffs lack standing based on this third element. See section titled "Legal Obligations and Authorities" below.

284. *Massachusetts v. EPA*, 549 U.S. 497 (2007).

285. *Id.* at 497.

286. *Id.* at 499.

The Court also went on to find that Massachusetts had suffered a particularized and cognizable injury based on documentary evidence and expert testimony describing climate-related impacts such as the loss of state-owned property to rising sea levels; the added costs to deal with emergency response measures caused by more frequent intense storm surge flooding events; damage to state-owned historic, archaeological, and natural resources; and damage to state-owned facilities and infrastructure along the coast.²⁸⁷ The Court held that this injury could be fairly traced to EPA's decision not to regulate based on IPCC reports, which demonstrated a clear causal nexus between GHG emissions and climate change impacts as a general matter, and emissions data showing that the unregulated source category (U.S. motor vehicles) generated approximately 1.7 billion metric tons of CO₂ in 1999 (more than 6% of worldwide emissions). The Court noted that this was a "meaningful contribution" to global emissions by any metric.²⁸⁸ With regard to redressability, the Court acknowledged that Clean Air Act regulation would not fully mitigate the problem, but the prospect of partial redress was all that was required for Article III standing.²⁸⁹

Turning to the merits of the lawsuit, the Court held that GHG emissions qualified as "air pollutants" within the meaning of the Clean Air Act and that EPA had an obligation to regulate those emissions unless it "determine[d] that greenhouse gases do not contribute to climate change" or otherwise provided "some reasonable explanation as to why it cannot or will not exercise its discretion to determine whether they do."²⁹⁰ Although the Court remanded to EPA to make its own determination on these issues, the Court's own decision contained ample information indicating that those GHG emissions did endanger public health and welfare (e.g., the Court's assertion that the "harms associated with climate change are serious and well recognized" and the Court's finding that GHG emissions from motor vehicles qualified as a meaningful contribution to global climate change). EPA issued an affirmative endangerment finding for GHG emissions from this source category shortly after the Court issued this judgment, which was subsequently challenged and upheld in *Coalition for Responsible Regulation v. EPA*, discussed below.²⁹¹

287. The Court noted that Massachusetts had a "special position and interest" in the case, in part because "it actually owns a great deal of the territory alleged to be affected" by climate change, and in part because of its status as a sovereign state. *Id.* at 520–23. The Court referred to data in the petitioners' affidavits showing that "global sea levels rose between 10 and 20 centimeters over the 20th century as a result of global warming and have already begun to swallow Massachusetts' coastal land" and that "[r]emediation costs alone . . . could reach hundreds of millions of dollars." *Id.* at 521–23.

288. *Id.* at 525.

289. *Id.* at 525–26.

290. *Id.* at 501 ("EPA can avoid promulgating regulations only if it determines that greenhouse gases do not contribute to climate change or if it provides some reasonable explanation as to why it cannot or will not exercise its discretion to determine whether they do.").

291. Shortly before publication of this Manual, EPA issued a proposed rule to rescind the endangerment finding and associated regulations for GHG emissions from motor vehicles. See Reconsideration of 2009 Endangerment Finding and Greenhouse Gas Vehicle Standards, 90 Fed.

Courts may confront questions about whether the GHG emissions at issue in a case are substantial enough to cause legally cognizable harm when adjudicating both standing and the merits of cases (i.e., do the emissions represent a “meaningful” or “material” contribution to climate-change-related harms?).²⁹² The threshold of legal relevance, significance, or materiality will depend on the nature of the claim and the applicable legal standard.²⁹³ Attribution research and predictive research can provide technical insights to help answer this question, including insights on the scope and magnitude of impacts that could be attributed to those emissions, but this is ultimately a legal determination.

Questions about whether specific harms can be attributable to global climate change may also arise as part of the standing or the merits analysis. The evidence required to demonstrate such causation depends on the type of injury and, for standing purposes, the scope of the plaintiff’s affected interests. Attribution data tend to be more robust for impacts at a broader spatial and temporal scale, and for certain types of impacts (e.g., heat-related impacts). A plaintiff like the state of Massachusetts will experience many climate impacts at a relatively broad spatial scale, making it easier to demonstrate that at least some of those injuries can be attributed to climate change with reasonable confidence. This is also true for many cities and communities—the breadth of local interests affected by climate change can be quite large, and some communities are directly exposed to trends and events that have been attributed to climate change with high confidence.²⁹⁴ It

Reg. 36288 (proposed Aug. 1, 2025) (to be codified at 40 C.F.R. pts. 85, 86, 600, 1036, 1037, 1039). EPA also issued a proposed rule to rescind the “cause or contribute” findings and associated regulations for GHG emissions from fossil fuel-fired power plants. See Repeal of Greenhouse Gas Emissions Standards for Fossil Fuel-Fired Electric Generating Units, 90 Fed. Reg. 25752 (proposed June 17, 2025) (to be codified at 40 C.F.R. pt. 60). EPA initiated both rulemaking processes pursuant to Exec. Order No. 14154, 90 Fed. Reg. 8353 (Jan. 20, 2025).

292. Some courts have cast doubt on whether the GHG impacts of smaller regulatory decisions and agency actions are sufficiently large to establish standing for specific plaintiffs. See, e.g., *Wash. Env’t Council v. Bellon*, 732 F.3d 1131, 1135 (9th Cir. 2013) (emissions from Washington power plants amounting to 6% of state’s total GHG emissions not a “meaningful contribution” to climate change), *reh’g en banc denied*, 741 F.3d 1075 (9th Cir. 2014); *Amigos Bravos v. U.S. Bureau of Land Mgmt.*, 816 F. Supp. 2d 1118, 1136 (D.N.M. 2011) (254,730 metric tons of GHGs per year that might result from the approval of 92 oil and gas leases were not a “meaningful contribution” to global climate change).

293. For example, to support tort claims, plaintiffs may need to demonstrate that defendants made a “substantial contribution” to their injury (although the precise standard depends on the jurisdiction). Under the Clean Air Act, EPA has a legal obligation to regulate air pollution that will “cause or contribute” to the endangerment of public health and welfare. Under NEPA, the federal government has a legal obligation to conduct a comprehensive analysis of “significant” environmental impacts. These vague textual standards have been fleshed out, to some extent, through litigation—but as with standing, there are no firm quantitative thresholds for such standards, and these are ultimately subjective, case-specific determinations.

294. For example, many communities are already experiencing frequent floods and inundation as a result of sea-level rise. William Sweet et al., *Sea Level Rise and Nuisance Flood Frequency*

is potentially more difficult to downscale impact attribution claims to the level of individual injury, but this depends on the specific injury at issue.²⁹⁵

There are some cases where litigants do not need to demonstrate particularized harm as a result of climate change, but it is necessary for a plaintiff or defendant to establish a link between climate change and more generalized harm. This may be the case when a government agency is defending GHG regulations or other climate policies in court.²⁹⁶ For example, in *Coalition for Responsible Regulation v. EPA*, the D.C. Circuit Court of Appeals was tasked with evaluating the legality of a Clean Air Act endangerment finding in which EPA had determined that GHG emissions from motor vehicles “cause, or contribute to, air pollution which may reasonably be anticipated to endanger public health or welfare.”²⁹⁷ One critical question was whether EPA could rely on IPCC, USGCRP, and NRC reports to establish a causal link between motor vehicle GHG emissions and public endangerment. The court held that EPA’s reliance on these external studies was entirely proper and that the endangerment finding was supported by a “substantial” body of evidence amassed through decades of scientific research on climate change.²⁹⁸

The court specifically confronted arguments that there was “too much uncertainty” about the science underpinning climate change, and that EPA had improperly “delegated” its judgment to the IPCC, USGCRP, and NRC by relying on those assessments of climate science.²⁹⁹ The court disagreed on both

Changes Around the United States, NOAA Tech. Rep., NOS CO-OPS 073 (2014), <https://perma.cc/F4SM-BERS>; Kristina A. Dahl et al., *Effective Inundation of Continental United States Communities with 21st Century Sea Level Rise*, 5 *Elementa: Sci. of the Anthropocene* 1 (2017), <https://doi.org/10.1525/elementa.234>. Many communities have also been adversely affected by extreme events that were likely exacerbated by climate change, such as Hurricane Harvey. See Wehner & Samson, *supra* note 87.

295. The court in *Juliana v. United States*, 339 F. Supp. 3d 1062, 1096 (D. Or. 2018), *rev’d and remanded*, 947 F.3d 1159 (9th Cir. 2020), provides an example of how attribution research can factor into standing disputes as well as the merits of cases involving government obligations and individual rights. For a detailed discussion of that case, see Burger et al., *supra* note 77, at 164–66. See also Jessica Wentz, *Climate Science and Litigation*, in *Research Handbook on Climate Change Litigation* (Francesco Sindico et al. eds., 2024).

296. Another example would be NEPA lawsuits where plaintiffs are seeking to compel federal agencies to account for GHG impacts from federal actions. Although plaintiffs must establish standing in such cases, the causation requirements are relaxed for procedural claims under NEPA, and plaintiffs can also establish standing on the basis of injuries flowing from other deficiencies in the NEPA documentation. See, e.g., *WildEarth Guardians v. Jewell*, 738 F.3d 298 (D.C. Cir. 2013); *WildEarth Guardians v. Bureau of Land Mgmt.*, 8 F. Supp. 3d 17 (D.D.C. 2014). See also Jessica Wentz, *Environmental Impact Assessment*, in *Global Climate Change and U.S. Law* (Michael B. Gerrard et al. eds., 3d ed. 2023); Wentz, *supra* note 295; *Massachusetts v. EPA*, 549 U.S. 497, 498 (2007) (holding that standing requirements are relaxed where plaintiffs are seeking to enforce procedural rights created by Congress); *TransUnion LLC v. Ramirez*, 594 U.S. 413, 414 (2021) (holding that, even in the context of a statutory violation, the asserted injury must have a “close historical or common-law analogue”).

297. *Coal. for Responsible Regul. v. EPA*, 684 F.3d 102 (D.C. Cir. 2012); Clean Air Act § 202(a)(1), codified as amended at 42 U.S.C. 7521(a)(1).

298. *Coal. for Responsible Regul.*, 684 F.3d at 120.

299. *Id.* at 119–21.

counts. In upholding EPA’s reliance on the external studies, it noted that these “peer-reviewed assessments synthesized thousands of individual studies on various aspects of greenhouse gases and climate change” and that EPA was “not required to re-prove the existence of the atom every time it approaches a scientific question.”³⁰⁰ The court also rejected petitioners’ argument that EPA could not rely on IPCC assessments because some of the studies referenced therein were not peer reviewed—it noted that the IPCC assessment relied on approximately 18,000 studies that *were* peer reviewed, and petitioners had not “uncovered a ‘pattern’ of flawed science” in the assessments that undermined the endangerment finding.³⁰¹ On the more general issue of whether there was too much uncertainty about climate change impacts to justify the endangerment finding, the court found that EPA had supported its determination through three key lines of evidence: (1) “basic physical understanding” of the greenhouse effect, (2) observational evidence of past climate change, and (3) models predicting how the climate will respond to GHG concentrations in the future.³⁰²

Foreseeability

There are many different types of climate cases that implicate questions about the foreseeability of climate change impacts. Such questions tend to be prominent in cases involving adaptation and disclosure-related claims, where the core factual dispute may center on whether certain risks or impacts are “reasonably foreseeable” or “speculative,” as this is relevant to determining whether a defendant is required or authorized to take some action or make a disclosure in response to climate change. For example, disputes about the foreseeability of impacts are common in NEPA and ESA litigation. Questions about foreseeability may also arise in the context of causation inquiries—for example, where plaintiffs seek to establish standing based on an “imminent” injury, or when a government agency defends regulatory action based on the risk of future harm.

Both attribution research and predictive research can be used to evaluate the foreseeability of climate change impacts. Attribution research provides insights on the trends and impacts that are already occurring as a result of anthropogenic climate change, thus allowing a court to determine whether specific trends and impacts are hypothetical or speculative. Predictive research provides insights on the future trajectory of those trends and impacts under different emissions and warming scenarios. Courts can refer to scientific assessments of confidence and likelihood when evaluating whether specific trends and impacts are foreseeable as opposed to speculative or hypothetical.

300. *Id.* at 120.

301. *Id.* at 125.

302. *Id.* at 120–21.

Some of the most detailed scientific disputes involving the foreseeability of climate impacts have arisen in the context of ESA litigation.³⁰³ Many of the ESA cases address how federal agencies should deal with scientific uncertainty when evaluating the foreseeability and likelihood of specific trends and impacts that may pose a threat to a species (e.g., warmer ocean temperatures, the loss of Arctic sea ice, declines in food sources). Although courts are generally deferential to agency conclusions about climate change and scientific uncertainty,³⁰⁴ courts have also held that an agency cannot simply ignore climate-change-related threats on the basis of uncertainty or imprecision—the agency must formulate a rationale finding about the probability of threats, taking into account the “best scientific evidence,” including available climate research.³⁰⁵

There are also cases where parties may dispute the foreseeability of GHG emissions. Such disputes may arise, for example, in the context of NEPA litigation where plaintiffs are seeking disclosure of emissions from federal actions, and in the context of lawsuits involving corporate climate disclosures. In this context, courts can refer to source attribution data to determine whether emissions are reasonably foreseeable and should be addressed in NEPA documentation or other planning and disclosure documents.

Legal Obligations and Authorities

Climate science can also inform judicial determinations about the scope of a defendant’s legal obligations and/or authorities with regard to climate change mitigation, disclosure, and adaptation. Where climate science factors into such determinations, it is typically in relation to the analysis of causation and foreseeability, as discussed above.³⁰⁶ For example, whether a government agency is authorized or required to regulate GHG emissions from a particular source category may depend

303. See Daniel Kim et al., *Judicial Review of Scientific Uncertainty in Climate Change Lawsuits: Deferential and Nondeferential Evaluation of Agency Factual and Policy Determinations*, 46 *Harvard Env’t L. Rev.* 367 (2022), <https://perma.cc/YQ5E-BZY6>; Jessica Wentz, *Climate Change Attribution Science and the Endangered Species Act*, 39 *Yale J. Regul.* 1043 (2022), <https://perma.cc/YW2Y-QB4C>. Some significant scientific disputes have also arisen in the context of other wildlife protection statutes, such as the Marine Mammal Protection Act (MMPA). See, e.g., *Ctr. for Biological Diversity v. Kempthorne*, 588 F.3d 701 (9th Cir. 2009).

304. See, e.g., *Nat. Res. Def. Council, Inc. v. Coit*, 597 F. Supp. 3d 73 (D.D.C. 2022); *Ctr. for Biological Diversity v. Lubchenco*, 758 F. Supp. 2d 945 (N.D. Cal. 2010). See also *Kempthorne*, 588 F.3d 701 (upholding federal government’s conclusions about climate-change-related threats to species in the context of an MMPA claim).

305. See, e.g., *Ctr. for Biological Diversity v. Zinke*, 900 F.3d 1053 (9th Cir. 2018); *Greater Yellowstone Coal. Inc. v. Servheen*, 665 F.3d 1015 (9th Cir. 2011); *Def. of Wildlife v. Jewell*, 176 F. Supp. 3d 975 (D. Mont. 2016). See also Wentz, *supra* note 303; Kim, *supra* note 303.

306. This analysis would encompass questions related to whether emissions represent a material or substantial contribution to global climate change.

on whether there is sufficient record evidence that those emissions are contributing to public endangerment.³⁰⁷ Alternatively, whether a federal agency has an obligation to disclose GHG emissions and climate-change-related impacts under NEPA depends on whether those impacts are reasonably foreseeable, caused by the action under review, and sufficiently large such that they represent a material contribution to climate change.³⁰⁸ Federal agencies may also have NEPA obligations to disclose climate change impacts that are not caused by the action under review, specifically insofar as those impacts may affect baseline environmental conditions and influence the environmental outcomes of the project.³⁰⁹

The analysis of foreseeability also plays a prominent role in judicial assessments of legal obligations to assess, prepare for, and respond to the effects of climate change. For example, whether the federal government is required or authorized to issue protections for species under the ESA depends, in part, on whether there is a foreseeable risk of harm to those species. In ESA cases, courts have consistently held that climate science qualifies as the “best available science” that must be considered when agencies are making decisions about listing determinations, critical habitat designations, and other decisions involving the management and protection of endangered and threatened species.³¹⁰ Courts have also upheld the federal government’s use of climate science to support ESA protections for species that are at risk of extinction because of climate change, specifically rejecting arguments that projections of future climate change are “too speculative” to support the government’s assessment of risk.³¹¹

307. See, e.g., *Coal. for Responsible Regul. v. EPA*, 684 F.3d 102, 122 (D.C. Cir. 2012).

308. See, e.g., *Food & Water Watch v. Fed. Energy Regul. Comm’n*, 28 F.4th 277 (D.C. Cir. 2022); *Montana v. Haaland*, 50 F.4th 1254 (9th Cir. 2022); *Ctr. for Biological Diversity v. Bernhardt*, 982 F.3d 723 (9th Cir. 2020); *Sierra Club v. Fed. Energy Regul. Comm’n*, 867 F.3d 1357 (D.C. Cir. 2017); *Ctr. for Biological Diversity v. Nat’l Highway Traffic Safety Admin.*, 538 F.3d 1172 (9th Cir. 2008). For examples of cases where courts did not require disclosures for actions with smaller GHG impacts, see *Hapner v. Tidwell*, 621 F.3d 1239 (9th Cir. 2010); *Senville v. Peters*, 327 F. Supp. 2d 335 (D. Vt. 2004). Glossary of Terms

The following terms and definitions were adapted from various sources, including the Intergovernmental Panel on Climate Change (IPCC), the World Meteorological Organization (WMO), the U.S. Global Change Research Program (USGCRP), and the U.S. Environmental Protection Agency (EPA).

adaptation. The process of adjustment to actual or anticipated climate change and its effects.

anthropogenic climate change. A change in climate that can be attributed directly or indirectly to human activity.

anthropogenic emissions. Emissions of greenhouse gases (GHGs), precursors to GHGs, and aerosols caused by human activities. These activities include the burning of fossil fuels, deforestation, land use and land-use changes, livestock production, fertilization, waste management, and industrial processes.

atmosphere. The gaseous envelope surrounding the Earth that comprises five layers (troposphere, stratosphere, mesosphere, thermosphere, and exosphere). The atmosphere contains various gases, including water vapor and GHGs. The atmosphere is one component of the global climate system.

attribution. The process of evaluating the relative contributions of multiple causal factors to a change or event.

biogeochemical cycle. The biological, geological, and chemical cycling of elements such as carbon between different global systems (including living and nonliving systems). The carbon cycle is an example of a biogeochemical cycle.

biosphere. The part of the earth system comprising all ecosystems and living organisms, including within the atmosphere, on land (terrestrial biosphere), or in oceans (marine biosphere).

carbon budget. The amount of cumulative net global anthropogenic emissions that would result in limiting global warming to a given level within a given probability, taking into account the effect of other anthropogenic climate forcers. The carbon budget may be calculated in reference to carbon dioxide (CO₂) emissions exclusively, or in reference to combined emissions of CO₂, methane (CH₄), nitrous oxide (N₂O), and other gases.

carbon dioxide (CO₂). A heat-trapping gas. It occurs naturally but is also a by-product of burning fossil fuels and biomass, land-use change, and industrial processes. It is the principal anthropogenic GHG that affects the Earth's radiative balance. It is the reference gas against which the potency of other GHGs is measured and therefore has a global warming potential (GWP) of 1.

carbon sink. A type of carbon pool (natural or human, in soil, ocean, and plants) that stores or takes up more carbon than it releases into the atmosphere.

climate. The climate can be defined, alternatively, as the state of the climate system, or the average weather conditions over a period of time ranging from months to thousands or millions of years. The World Meteorological Organization (WMO) uses a standard period of thirty years to characterize climate conditions. See also climate system.

climate change. A change in the state of the climate (or global climate system) that can be identified by changes in the mean and/or variability of properties and that persists for an extended period, typically decades or longer. The climate system changes in time under the influence of its own internal dynamics and because of external forcings, such as volcanic eruptions, solar variations, orbital forcing, and anthropogenic forcings.

climate forcer. Any substance or process that affects the flow of energy coming into or out of the global climate system, thus affecting the amount of heat retained within the system. Anthropogenic climate forcers include GHGs, aerosols, and changes in land use that make land reflect more or less solar energy. There are also natural climate forcers, such as solar radiation and the particulate matter from volcanic eruptions. See also radiative forcing.

climate forcing. The net effect of various climate forcers on the flow of energy coming into or out of the global climate system.

climate model. A qualitative or quantitative representation of the climate system based on the physical, chemical, and biological properties of its components, as well as their interactions and feedback processes. Climate models are used as research tools to study and simulate the effect of anthropogenic forcings on the climate system.

climate projection. A simulated response of the climate system to a scenario of future emissions or concentrations of greenhouse gases, aerosols, and changes in land use, generally derived using climate models.

climate system. The global system that determines climate conditions, consisting of five major components (the atmosphere, the hydrosphere, the cryosphere, the lithosphere, and the biosphere) and the interactions among them.

confidence interval. A range of values calculated from the results of a study within which the true value is likely to fall. The range of this interval depends on the confidence level—e.g., if the confidence level is 95%, then there is a 95% probability that the true value of a parameter will fall within the range of values provided in the confidence interval. The size of a confidence interval provides insight on the level of precision and range of uncertainty in study results.

confidence level. The probability that a particular value falls within a specified confidence interval.

cryosphere. The frozen components of the earth system, including sea ice, lake ice, river ice, snow cover, glaciers, ice sheets, ice caps, ice shelves, and frozen ground (permafrost). The cryosphere is part of the global climate system.

detection. The process of demonstrating that the climate system (or a system affected by the climate system) has changed in some defined statistical sense. As per IPCC definitions, an identified change is detected in observations if its likelihood of occurrence because of internal variability alone is determined to be small, for example $<10\%$.

fraction of attributable risk. In climate change research, the fraction of attributable risk (FAR) is the ratio of a particular outcome occurring with and without human influence on climate. Mathematically speaking, $FAR = 1 - P0/P1$ (where $P1$ equals the probability of the outcome occurring in the presence of anthropogenic forcing of the climate system, and $P0$ equals the probability of the event occurring if the anthropogenic forcing were not present).

global warming potential (GWP). A measurement of the radiative forcing from a unit of a given substance, accumulated over a chosen time horizon, relative to that of CO_2 .

greenhouse gas (GHG). A gas that absorbs incoming solar radiation (i.e., heat) in the atmosphere, preventing it from escaping into space. GHGs in the Earth's atmosphere include water vapor, carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), ozone, chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulfur hexafluoride (SF_6), and nitrogen trifluoride (NF_3).

hydrosphere. The components of the earth system including liquid surface and subterranean water, such as oceans, seas, rivers, freshwater lakes, underground water, and wetlands. The hydrosphere is part of the global climate system.

lithosphere. The rocky outer portion of the Earth, composed of the crust and upper part of the mantle. The lithosphere is part of the climate system, as it absorbs and reflects solar energy, radiates heat, stores carbon, and interacts with regional climate conditions.

methane (CH_4). A greenhouse gas; methane is the main constituent of natural gas, and key anthropogenic sources of methane include oil and gas systems, landfills, agricultural and livestock activities, coal mining, fossil fuel combustion, wastewater treatment, industrial processes, and land use changes. Methane is more than twenty-five times as potent as CO_2 , but it has a shorter atmospheric lifetime and is eventually converted into CO_2 in the atmosphere. Methane is the second largest contributor to anthropogenic climate forcing, after CO_2 .

model ensembles. Can refer to both (1) the full set of models, for example climate models developed by different modeling centers, used by the IPCC and other bodies for risk assessment, and (2) the averaging of results across multiple such models. The averaging of multiple models is generally considered more reliable than the use of a single model, although presenting the results separately from all the models is often considered superior to showing only the average across models, since the former gives a sense of the range of possible outcomes and important uncertainties.

natural variability. Naturally occurring variations in the mean state and other statistical measures of the climate.

nitrous oxide (N₂O). A greenhouse gas produced by agriculture, fuel combustion, industrial processes, and waste management systems, as well as natural systems. Nitrous oxide is approximately 300 times more potent than CO₂ but it is shorter lived in the atmosphere. Nitrous oxide also contributes to ozone depletion. It is the third largest contributor to anthropogenic climate forcing, after CO₂ and methane.

radiative forcing. The change in energy flux within the Earth's atmosphere caused by natural or anthropogenic climate forcers (e.g., increasing atmospheric concentrations of CO₂). Positive radiative forcing occurs when the Earth receives more incoming energy from sunlight than it radiates into space, and this net gain of energy causes warming.

relative risk. In climate studies, the relative risk is the ratio of probabilities for an event or impact occurring with and without anthropogenic influence on the climate system (or at varying levels of anthropogenic influence on the climate system).

tipping point. A critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly.

Appendix: Overview of Scientific Organizations and Government Agencies Involved in the Production, Synthesis, and Dissemination of Climate Science

World Meteorological Organization (WMO)

The WMO is a United Nations (UN) agency responsible for coordinating and advancing climatological and meteorological research around the world.³¹² One key goal of the WMO is to promote the “free and unrestricted” exchange of data, information, and research between the 193 countries and territories that are signatories to the WMO convention.³¹³ The WMO is governed by the World Meteorological Congress, which is composed of member states.

Although the WMO is a political organization, it is recognized as an authoritative source of climatological and meteorological data. It provides standardized data products for climate research, most notably the “Climatological Standard Normals,” which provide information on typical climate conditions averaged over thirty-year periods for thousands of locations across the world.³¹⁴ The WMO also publishes an annual *State of the Global Climate Report* that summarizes the latest observations and findings for various “global climate indicators” including greenhouse gases, global temperature, ocean heat content, sea level, marine heat waves, the cryosphere, and precipitation.³¹⁵ The report also discusses natural phenomena that are important drivers of year-to-year variability in weather patterns, such as the El Niño Southern Oscillation, and explains how these have influenced recent weather observations.

Intergovernmental Panel on Climate Change (IPCC)

The IPCC is widely considered to be the leading scientific body for the assessment and synthesis of research on climate change. It was established in 1988 by the United Nations Environment Programme (UNEP) and the WMO as an

312. The WMO originated from the International Meteorological Organization (IMO), which was a nongovernmental organization founded in the late 1800s in order to promote the exchange of meteorological research. The WMO was subsequently established as a direct successor of the IMO through an agreement of UN member states in 1950.

313. WMO, *Overview*, <https://perma.cc/SC9L-CTSL>.

314. See WMO, *WMO Climatological Normals*, <https://perma.cc/65TT-69XV>.

315. See, e.g., WMO, *Provisional State of the Global Climate*, <https://perma.cc/X8J7-KVX7>.

intergovernmental body of the UN. Its primary mandate is to provide governmental bodies and the public with regular assessments of the scientific basis for climate change, its impacts and future risks, and options for mitigation and adaptation.³¹⁶ It is governed by 195 member states.³¹⁷ There are also nearly 200 observer organizations that participate in IPCC activities—for example, by nominating scientists to serve as report authors, and by reviewing draft reports.³¹⁸

The IPCC publishes periodic assessments of the state of the scientific knowledge on anthropogenic climate change. The IPCC does not conduct its own research; rather, it conducts systematic reviews of relevant scientific publications and then synthesizes key findings from the literature in its assessments. It does so with the assistance of thousands of scientists with diverse expertise across the field of climate research.³¹⁹ There are three IPCC working groups involved in the assessment process: Working Group I synthesizes research on the physical-science basis for anthropogenic climate change, including research on the changes that are already underway as well as projections of future climate change; Working Group II synthesizes research on the physical, social, and economic impacts of climate change; and Working Group III synthesizes research on potential pathways for mitigating and adapting to climate change. The experts involved in these working groups are selected by IPCC member governments, observer organizations, and the IPCC Bureau.

The IPCC conducts a comprehensive assessment of climate science every six to seven years. During this process, each working group prepares a full “assessment report” that contains a detailed technical discussion of its respective topic.³²⁰ Each draft report undergoes an initial review by a team of scientific and technical experts and then a second review by governments and experts. A

316. See IPCC, History of the IPCC, <https://perma.cc/W5K7-PT4B>.

317. Representatives of IPCC member governments meet one or more times a year in plenary sessions. The member states elect a Bureau of Scientists to guide technical activities for each assessment cycle. They also review and approve draft assessments. IPCC, Structure of the IPCC, <https://perma.cc/7LZ2-F9CP>.

318. Any nonprofit body or agency with relevant expertise may apply to become an IPCC observer organization. The current list of observer organizations includes UN bodies and organizations, intergovernmental organizations, government agencies, universities, scientific research organizations, environmental NGOs, and industry NGOs. Representatives of observer organizations may attend sessions of the IPCC and the plenary sessions of the IPCC working groups. They are also invited to encourage experts to review draft IPCC reports. See IPCC, *Structure*, *supra* note 317; IPCC, Observer Organizations, <https://perma.cc/697T-GKC7>.

319. The scientists involved in the assessments are selected through a nomination process. Prior to initiating an assessment, the IPCC issues a call to governments and IPCC observer organizations for nominations; the authors are then selected by the Bureau of Scientists on the basis of their expertise. The IPCC seeks to build author teams that reflect a range of scientific, technical, and socioeconomic expertise. See IPCC, Factsheet: How Does the IPCC Select Its Authors?, <https://perma.cc/45V6-W8TB>.

320. For a complete explanation of the process governing IPCC assessments, see IPCC, Procedures, <https://perma.cc/C39M-TW6H>.

selection of scientists within each working group then produces a Summary for Policymakers (SPM), which is intended to help policy makers and nonscientists understand key findings from each report. The IPCC member states conduct a detailed review of each SPM, in consultation with scientists, and they must approve the SPM line-by-line. The IPCC member states also approve the full reports, but that approval process is less detailed and government inputs are more limited (as compared with the SPMs). At the end of the assessment process, the IPCC also prepares a Synthesis Report that combines findings from all three working groups. The Synthesis Report goes through the same type of review process as other reports, with an SPM subject to detailed review by member states.

The IPCC also publishes methodology reports, technical papers, and other special reports in response to requests for scientific and technical information from the United Nations Framework Convention on Climate Change (UNFCCC), governments, and international organizations. For example, in 2018, the IPCC issued a special report evaluating the impacts of climate change if anthropogenic emissions caused global warming at or in excess of 1.5°C.³²¹

Although the IPCC is generally considered to be a global authority on climate science, it has been critiqued on the grounds that it is a political institution subject to the governance of member states. Concerns have also been raised about the inclusion of experts with potential bias in the assessment process (e.g., representatives from renewable energy industry associations or, conversely, from fossil fuel industry associations).³²² While no organization is perfect, an argument can be made that the structure of the IPCC actually contributes to institutional legitimacy and helps mitigate individual bias on the part of report authors and government representatives.³²³ The assessments are prepared with the help of a large number of contributors, including the report authors (which include physical scientists as well as researchers with other expertise), governmental representatives, and observer organization representatives, and they reflect the consensus on the part of both scientific experts and governments. The assessments have also received criticism from both sides of the climate change debate (some arguing that they overestimate the severity of anthropogenic climate change, others arguing that they underestimate the severity).³²⁴ This suggests that there is not a pervasive industry or environmental bias within the IPCC.

Other Major Scientific Organizations

There are several U.S.-based organizations that play a key role in the dissemination of climate research. These include the American Meteorological Society (AMS), the American Geophysical Union (AGU), and the National Academies of Sciences, Engineering, and Medicine (National Academies or NASEM). The scientific community views all three as credible sources of climate science.

The National Academies were established by the federal government in 1863, with a specific mandate of providing scientific assessments to help support government decision-making. Although the National Academies' mandate is to assist the federal government, they are fully independent from the government.³²⁵ Like the IPCC, the National Academies do not conduct independent research; rather they assess and synthesize existing research in order to provide objective scientific advice. They periodically publish reports on scientific matters of national significance. They have published numerous reports on the topic of climate change, including *Climate Change: Evidence and Causes*³²⁶ and *Attribution of Extreme Weather Events in the Context of Climate Change*.³²⁷ The National Academies also maintain peer-reviewed scientific journals, most notably the *Proceedings of the National Academies of Sciences* (PNAS), and they are involved in reviewing the *National Climate Assessments* prepared by the federal government (discussed below). For many years, the National Research Council (NRC) was the operating arm of the National Academies (e.g., the NRC published many scientific reports); but the NRC has since been reorganized into seven program units with different thematic focuses.³²⁸

The AMS is a professional membership organization involved in the dissemination of atmospheric, oceanic, and hydrologic sciences. It was founded in 1919 with the mission of advancing scientific research in these fields, and since then it has grown to a membership of nearly 12,000 scientific professionals.³²⁹ The AMS maintains a number of publications that disseminate new research in climate science and related fields. These include the *Bulletin of the American Meteorological Society* (BAMS), the *Journal of the Atmospheric Sciences*, the *Journal of Applied Meteorology and Climatology*, *Earth Interactions*, and the *Journal of Climate*, among others. These are all peer-reviewed publications with excellent standing in the scientific community. Each year, AMS also publishes a *State of the Climate* report as a supplement to BAMS as well as a special edition of BAMS on *Explaining Extreme Events from a Climate Perspective*.³³⁰ This is an annual review of

330. BAMS, Explaining Extreme Events from a Climate Perspective, <https://perma.cc/ZG2C-LRZS>.

peer-reviewed research assessing how anthropogenic climate change has affected the magnitude, likelihood, and other characteristics of extreme events such as floods and heat waves.

The AGU is a professional membership organization involved in the dissemination of atmospheric, ocean, hydrologic, space, and planetary research. It was established in 1919 by the NRC and it operated as an affiliate of the National Academies until it was independently incorporated in 1972.³³¹ It now has more than half a million members from around the world. Like AMS, AGU maintains various peer-reviewed publications that disseminate new research in climate science and related fields. These include the *Journals of Geophysical Research*, the *Journal of Advances in Modeling Earth Systems*, *Earth and Space Science*, and *Geophysical Research Letters*. As with AMS publications, the AGU journals have excellent standing in the scientific community.

Government Agencies

The U.S. federal government also plays a major role in both the production and dissemination of climate research.³³² The federal programs and agencies that have been most heavily involved in the production of climate science outputs include the U.S. Global Change Research Program (USGCRP), the National Oceanic and Atmospheric Administration (NOAA), the National Aeronautics and Space Administration (NASA), the U.S. Geological Survey (USGS), and the Environmental Protection Agency (EPA).

The USGCRP has been the leading federal entity involved in the coordination and dissemination of research on climate change. The program began as a presidential initiative in 1989 and was subsequently codified by Congress in 1990 as “a comprehensive and integrated United States research program which will assist the Nation and the world to understand, assess, predict, and respond to human-induced and natural processes of global change.”³³³ Per this Congressional directive, the USGCRP has coordinated federal research on climate change and has periodically published *National Climate Assessments* (NCAs), which

331. AGU, Learn About AGU, <https://perma.cc/RFY9-6WZ3>.

332. Many states also have government agencies involved in the production and dissemination of climate research. But for the purposes of this reference guide, we focus on scientific outputs from federal agencies, as federal judges are more likely to engage with these outputs.

333. Global Change Research Act of 1990, Pub. L. 101–606, title I, § 101, 104 Stat. 3096 (codified at 15 U.S.C. § 2931). Presidential Administrations and Congress have taken various positions on the program. Kathryn G. Kynett, Cong. Rsch. Serv., R48478, U.S. Global Change Research Program (USGCRP): Overview and Considerations for Congress (2025). In April 2025, several federal contracts supporting USGCRP were reportedly canceled and federal staff previously involved in the program were reportedly dismissed. At the time of writing, the USGCRP website appears to no longer be available. *See id.*

summarize the latest science on anthropogenic climate change, including research on how climate change is affecting and may affect the United States now and in the future.³³⁴ These reports have been a useful supplement to IPCC assessments insofar as they focus on the U.S. context. The *Fifth National Climate Assessment* (NCA5) was published in 2023.

A number of other federal agencies, including NOAA, NASA, USGS, and EPA, are directly involved in climate research and the production of climate data products.³³⁵ NOAA plays a particularly important role in federal climate research and dissemination—it maintains records of climate indicators (e.g., national precipitation and temperature records) and publishes monthly reports summarizing the latest climate data for the United States and the globe.³³⁶ NASA also produces and maintains climate data products—these include satellite data as well as outputs from NASA weather and climate models.³³⁷ The USGS carries out geophysical research on climate change and its impacts as part of its Ecosystems Land Change Science Program,³³⁸ and it also maintains national and regional Climate Adaptation Science Centers, which are collaborative scientific partnerships aimed at building knowledge to help resource managers and communities prepare for and respond to the effects of climate change.³³⁹ EPA primarily conducts research on the environmental and public health effects of climate

334. Among other responsibilities, the USGCRP is required by Congress to develop an assessment of global change at least every four years, which means that the deadline to submit the Sixth National Climate Assessment to Congress is 2027. See 15 U.S.C. § 2931. A court enforced this deadline in the past, in *Center for Biological Diversity v. Brennan*, 571 F. Supp. 2d 1105 (N.D. Cal. 2007).

335. This is not an exhaustive list of all federal entities involved in climate research. So many agencies are involved in climate research because climate change research involves many areas of science and has such far-reaching implications for the U.S. government, citizens, and natural resources. Other departments and agencies, including but not limited to the Department of Energy (DOE), the Department of Interior (DOI), the Department of Defense (DOD), the Department of Agriculture (USDA), and agencies and services within these departments, also conduct climate-related research relevant to their respective mandates. Recently, the DOE established a Climate Working Group, consisting of five scientists assembled by the DOE Secretary. The DOE released a report written by this group, which was still in draft form at the time of this writing, in tandem with EPA's proposed rule repealing the 2009 endangerment finding. See U.S. Dep't of Energy, Climate Working Group, A Critical Review of Impacts of Greenhouse Gas Emissions on the U.S. Climate (July 23, 2025), <https://perma.cc/KHF8-TTQR>; Dep't of Energy, Climate, <https://perma.cc/647D-7224> (last visited Oct. 8, 2025) (providing a report evaluating the impact of greenhouse gasses on U.S. climate and inviting the public to comment). See also *supra* note 290 and accompanying text for a related discussion of the endangerment finding.

336. NOAA, National Centers for Environmental Information: Products by Category, <https://perma.cc/S9U9-V7W6>.

change—for example, examining how climate change will affect air quality and ecosystems.³⁴⁰

Nongovernmental Organizations

In addition to the international and U.S.-based organizations described above, there are many nongovernmental and academic organizations involved in the production and dissemination of climate research and data products. Some examples include the World Weather Attribution project, a collaboration of climate scientists that provides rapid assessments on the role of anthropogenic climate change in extreme weather events;³⁴¹ the Climate Impact Lab, a coalition of scientists, economists, and other analysts that conduct research on the impacts and costs of climate change;³⁴² and Climate Signals, an initiative that provides written synthesis of and data visualization products for climate attribution research.³⁴³

Many of these entities provide high-quality research products. However, these organizations do not have the same scientific standing as the major scientific organizations discussed above, and their research products do not always undergo formal peer review. There are various ways in which to evaluate the credibility of these research products. The credentials of the individuals producing the products are very important—the World Weather Attribution project, for example, consists of scientific researchers at top universities who have extensive experience in the climate and atmospheric sciences. Funding sources may also provide insights on credibility—for example, if a group is funded by fossil fuel interests or other industry actors that have a financial stake in preventing the regulation of fossil fuels, this could raise red flags about the credibility of any research findings. Finally, research products can also be evaluated for consistency with climate assessments from authoritative institutions like the IPCC.

Appendix

Biographical Information of Committee and Staff

Co-Chairs

Nancy D. Freudenthal is a U.S. District Judge for the U.S. District Court for the District of Wyoming. Freudenthal was born and raised in Cody, WY, and earned both a bachelor's degree and a juris doctorate from the University of Wyoming. She worked for former Wyoming governors Ed Herschler and Mike Sullivan, and then was appointed to the State Board of Equalization. She entered private practice in 1995 with the law firm of Davis & Cannon. In 2010, following a presidential appointment and Senate confirmation, Judge Freudenthal became the first woman appointed to the federal court in Wyoming and the seventh federal district judge in the state's history.

Fred H. Gage, Ph.D., is the Adler Professor in the Laboratory of Genetics at the Salk Institute for Biological Studies and an adjunct professor at the University of California, San Diego. He served as president of the Salk Institute from 2018 to 2023. He received his Ph.D. from Johns Hopkins University. Gage's work concentrates on the adult central nervous system and unexpected plasticity and adaptability to environmental stimulation that remains throughout the life of all mammals. In addition, he studies human neurological and psychiatric disease in vitro using human stem cells. His lab also studies the genomic mosaicism that exists in the brain as a result of mobile elements that are active during neurogenesis. Gage is a fellow of the American Association for the Advancement of Science, a member of the National Academy of Sciences, the National Academy of Medicine, and the American Philosophical Society, a foreign member of the European Molecular Biology Organization, and a member of the American Academy of Arts and Sciences. He served as president of the Society for Neuroscience in 2002, and of the International Society for Stem Cell Research in 2012.

Members

Russ Biagio Altman is the Kenneth Fong Professor of Bioengineering, Genetics, Medicine, Biomedical Data Science, and (by courtesy) Computer Science at Stanford University, senior fellow at the Stanford Institute for HAI (Human-Centered

Artificial Intelligence), and past chairman of the Bioengineering Department at Stanford University. Altman's research applies computing (informatics, data science, and artificial intelligence) to problems relevant to medicine. He is interested in methods for understanding drug action, efficacy, and adverse effects while integrating molecular, cellular, organism, and population data. His lab has a special focus on how human genetic variation impacts drug response, or pharmacogenomics. He is the founding principal investigator of the Pharmacogenomics Knowledgebase (PharmGKB.org). Altman helps lead an FDA-supported Center of Excellence in Regulatory Science & Innovation and is an associate director of the Stanford Institute for HAI. Altman holds an A.B. from Harvard College, an M.D. from Stanford Medical School, and a Ph.D. in Medical Information Sciences from Stanford. He received the U.S. Presidential Early Career Award for Scientists and Engineers and a National Science Foundation CAREER Award. He is a fellow of the American College of Physicians (ACP), the American College of Medical Informatics (ACMI), the American Institute of Medical and Biological Engineering (AIMBE), and the American Association for the Advancement of Science (AAAS). He is a member of the National Academy of Medicine. He is a past-president, founding board member, and a fellow of the International Society for Computational Biology (ISCB), and a past-president of the American Society for Clinical Pharmacology & Therapeutics (ASCPT). He has chaired the Science Board advising the FDA commissioner, served on the NIH Director's Advisory Committee, and co-chaired the Institute of Medicine's Drug Forum. He is an organizer of the annual Pacific Symposium on Biocomputing, and a founder of Personalis. Altman is board certified in Internal Medicine and in Clinical Informatics. He directed the Stanford Biomedical Informatics training program from 2000–2018 and currently directs the undergraduate major in Biomedical Computation. Altman received the Stanford Medical School graduate teaching awards in 2000 and 2020 and its mentorship award in 2014. He received the Stanford Alumni Association Kornberg–Berg Lifetime Achievement Award in 2023. He is the founding editor of the *Annual Reviews of Biomedical Data Science*, and hosts a podcast titled *The Future of Everything*.

David G. Campbell is a Senior U.S. District Judge for the District of Arizona, having served on the court since 2003. Campbell currently chairs the U.S. Courts' Committee on International Judicial Relations. He previously chaired the U.S. Committee on Rules of Practice and Procedure, which oversees the work of the five Advisory Committees on the Federal Rules of Civil, Criminal, Bankruptcy, and Appellate Procedure and the Federal Rules of Evidence. He also chaired the Advisory Committee on the Federal Rules of Civil Procedure from 2011 to 2015 and served as a member of the committee from 2005 to 2011. Campbell is a member of the American Law Institute and a fellow of the American Bar Foundation. He has travelled to Botswana, Namibia, South Africa, Turkey, Gambia, Slovakia, South Korea, Bulgaria, the Philippines, and other countries on judicial case

Appendix: Biographical Information of Committee and Staff

management and rule-of-law projects and has taught civil procedure and constitutional law at the Arizona State and Brigham Young University Law Schools. Following his graduation from the University of Utah Law School, he served as a law clerk for Justice William H. Rehnquist of the U.S. Supreme Court and Judge J. Clifford Wallace of the U.S. Court of Appeals for the Ninth Circuit. Campbell worked as a commercial litigator with the Phoenix, Arizona, law firm of Osborn Maledon before becoming a judge.

Alicia L. Carriquiry is a Distinguished Professor of Liberal Arts and Sciences and the President's Professor of Statistics at Iowa State University. She researches applications of statistics in human nutrition, bioinformatics, forensic sciences, and traffic safety. Carriquiry has published more than 160 peer-reviewed articles in corresponding academic journals.

Carriquiry is the lead investigator for the Center for Statistics and Applications in Forensic Evidence (CSAFE) program, providing scientific oversight and research expertise. Along with Drs. Hal S. Stern and Michael Daniels, she was among the first to question the probative value of bullet lead analysis. A 2000 report to the Federal Bureau of Investigation that suggested the probability of a coincidental match might not be negligible led to the establishment of a National Academies of Sciences, Engineering, and Medicine (National Academies) committee to explore the issue. Carriquiry subsequently served as a member of the National Academies' Committee on Assessing the Feasibility, Accuracy, and Technical Capability of a National Ballistics Database. Overall, Carriquiry has chaired or participated in over 15 National Academies boards, panels and committees and is currently a statistics editor for the *Proceedings of the National Academy of Sciences*. Carriquiry has spoken at many national and international conferences in statistics, forensic science, and nutrition and has been invited to deliver multiple named lectures and seminars. She has served on several subcommittees in the National Institute for Standards and Technology (NIST) Organization of Scientific Area Committees for Forensic Science (OSAC) and is a member of the U.S. Technical Advisory Group to the International Organization for Standardization (ISO) Committee on Forensic Science. Carriquiry was elected to the National Academy of Medicine in 2016 and to the American Academy of Forensic Sciences in 2023. She is a fellow of the American Association for the Advancement of Science, the American Statistical Association, the Institute of Mathematical Statistics, the International Society for Bayesian Analysis, and the International Statistical Institute. She was recently elected fellow of the Hagler Institute for Advanced Studies at Texas A&M University. Carriquiry received an M.S. in animal science from the University of Illinois, and an M.S. and a Ph.D. in statistics and animal genetics from Iowa State University.

Lynn R. Goldman, a pediatrician and an epidemiologist, is the Michael and Lori Milken Dean and Professor of Environmental and Occupational Health at the

Milken Institute School of Public Health at the George Washington University. She was previously a professor of environmental health sciences at the Johns Hopkins Bloomberg School of Public Health; an assistant administrator for toxic substances at the U.S. Environmental Protection Agency, where she directed the Office of Chemical Safety and Prevention; and the chief of the Division of Environmental and Occupational Disease Control at the California Department of Public Health. Goldman completed a B.S. and M.S. from the University of California, Berkeley, an M.D. from the University of California, San Francisco (UCSF); an M.P.H. from the Johns Hopkins Bloomberg School of Public Health; and pediatric residency at the UCSF Benioff Children's Hospital in Oakland.

Goldman is a member of the National Academy of Medicine (NAM). She serves as a trustee of the Environmental Defense Fund; a member of the National Academy of Sciences, Engineering and Medicine's Environmental Health Matters Initiative; a member of the American Academy of Pediatrics Council on Environmental Health Executive Committee; cochair of the Association of Schools and Programs of Public Health Climate Change and Health Task Force; and a member of the National Academies of Sciences, Engineering, and Medicine's Committee on Managed Retreat in the U.S. Gulf Coast Region.

Brian W. Kernighan is the William O. Baker '39 Professor in Computer Science at Princeton University. He received his B.A.Sc. in engineering physics at the University of Toronto in 1964 and his Ph.D. in electrical engineering from Princeton in 1969. Kernighan was a member of technical staff and department head in the Computing Science Research Center at Bell Laboratories from 1969 until 2000 and was named a Bell Labs fellow in 1990. He joined the Princeton Department of Computer Science in 2000. Kernighan is a co-creator of several programming languages, including AWK and AMPL, and of a number of tools for document preparation. He holds five patents, and is a co-founder of AMPL Optimization Inc. Kernighan's research areas include programming languages, tools, and interfaces that make computers easier to use, often for non-specialist users. He is the co-author of a number of widely used computer science books, including *The C Programming Language* (with Dennis Ritchie) and *The Unix Programming Environment* (with Rob Pike). He has also written books on technology for non-technical audiences: *Understanding the Digital World*; *Millions, Billions, Zillions: Defending Yourself in a World of Too Many Numbers*; and *Unix: A History and a Memoir*. Kernighan is a member of the National Academy of Engineering and the American Association of Arts and Sciences.

Pramod P. Khargonekar, Ph.D., is Vice Chancellor for Research and Distinguished Professor of Electrical Engineering and Computer Science at the University of California, Irvine. His research and teaching interests are centered on confluence of machine learning and control; advanced manufacturing; energy

Appendix: Biographical Information of Committee and Staff

system decarbonization; climate change mitigation, adaptation, and resilience; and societal impacts of technology. Previously, after serving briefly as Deputy Director of Technology at the Advanced Research Projects Agency – Energy in 2012–13, Khargonekar served, until June 2016, as the head of the Directorate of Engineering at the National Science Foundation. From 2001 to 2009, he was Dean of the College of Engineering at the University of Florida and was the Eckis Professor of Electrical and Computer Engineering at the university until 2016. Khargonekar was chair of the Department of Electrical Engineering and Computer Science at the University of Michigan from 1997 to 2001, where he also held the position of Claude E. Shannon Professor of Engineering Science. At the University of Michigan, he received the Claude Shannon Chair and Arthur F. Thurnau Professorship. Khargonekar has been recognized as a Web of Science Highly Cited Researcher. He is a recipient of the IEEE (Institute of Electrical and Electronics Engineers) Control Systems Award, IEEE Control Systems Society Bode Lecture Prize, National Science Foundation Presidential Young Investigator Award, the American Automatic Control Council’s Donald Eckman Award, the Japan Society for Promotion of Science fellowship, World Automation Congress Honor, the IEEE W. R. G. Baker Prize Award, the IEEE CSS George Axelby Best Paper Award, the Hugo Schuck American Control Conference (ACC) Best Paper Award, and distinguished alumnus and distinguished service awards from the Indian Institute of Technology, Bombay. Khargonekar is an inaugural member of the Hall of Fame, Department of Electrical and Computer Engineering, University of Florida, and a fellow of IEEE, the International Federation of Automatic Control (IFAC), and the American Association for the Advancement of Science.

Goodwin Liu is an Associate Justice of the California Supreme Court. He was nominated by Governor Jerry Brown and sworn into office in 2011 and retained by the electorate in 2014 and 2022. Before joining the state’s highest court, Liu was Professor of Law and Associate Dean at the University of California, Berkeley School of Law. His areas of expertise span constitutional law, education law and policy, and diversity in the legal profession. Liu is an elected member and chair of the board of the American Academy of Arts & Sciences. He is also an elected member of the American Law Institute and American Philosophical Society, in addition to having served of the board of numerous service organizations and academic institutions. The son of Taiwanese immigrants, Liu grew up in Sacramento and earned a bachelor’s degree in biology from Stanford University, master’s degrees in philosophy and physiology from Oxford University on a Rhodes Scholarship, and J.D. from Yale Law School. He clerked for Judge David S. Tatel on the U.S. Court of Appeals for the D.C. Circuit and for Justice Ruth Bader Ginsburg on the U.S. Supreme Court. His accomplished career also includes practicing at O’Melveny & Myers, serving in the U.S. Department of Education, and helping launch the AmeriCorps national service program.

Shobita Parthasarathy is Professor of Public Policy and Women's and Gender Studies, and co-founder and director of the Science, Technology, and Public Policy Program at the University of Michigan. Her research examines the political economy of innovation and innovation policy focusing on equity and justice, and the politics of knowledge and expertise in public policy making and law. She often takes a cross-national or international perspective in her research, and has published widely on genetics and biotechnology, intellectual property, innovation policy, inclusive innovation, and artificial intelligence/machine learning in the United States, United Kingdom, Europe, and India. Parthasarathy is the author of numerous scholarly articles and two books: *Building Genetic Medicine: Breast Cancer, Technology, and the Comparative Politics of Health Care* (MIT Press, 2007) and *Patent Politics: Life Forms, Markets, and the Public Interest in the United States and Europe* (University of Chicago Press, 2017). The former influenced the 2013 U.S. Supreme Court case that determined human genes were not patentable; the latter won the 2018 Robert K. Merton Award from the American Sociological Association. She writes frequently for public audiences including in *The New York Times*, *Boston Review*, *Slate*, *Issues in Science and Technology*, *Scientific American*, and *Nature* and co-hosts The Received Wisdom podcast on issues at the intersection of science, technology, policy, and society. Parthasarathy regularly advises policy makers around the world. She is the recipient of fellowships from the Woodrow Wilson International Center for Scholars, American Council of Learned Societies, American Bar Foundation, the Max Planck Institute for Innovation and Competition, and the Wellcome Trust. She holds master's and Ph.D. degrees in science and technology studies from Cornell University, and an undergraduate degree in biology from the University of Chicago.

U.S. District Judge **Patti B. Saris** is a graduate of Radcliffe College '73 and Harvard Law School '76. She clerked for the Massachusetts Supreme Judicial Court and, when Senator Edward M. Kennedy became chairman of the Senate Judiciary Committee, she worked as his staff counsel. She later became an assistant U.S. attorney and eventually served as chief of the Civil Division. In 1986, Saris became a U.S. magistrate judge. In 1989, she was appointed as an Associate Justice of the Massachusetts Superior Court. In 1994, she was appointed to the U.S. District Court for the District of Massachusetts by President Clinton, and she served as chief judge from 2013 to 2019. She served as Chair of the U.S. Sentencing Commission from January 2011 until January 2017. Saris has been active on various judicial committees, including the Budget Committee, and the Defender Services Committee (2002–2005), which she chaired in 2005. Saris currently teaches as a lecturer at Harvard Law School. Saris has received awards for judicial excellence from the Boston Bar Association, the Federal Bar Association, the Patent Bar Association, and the Massachusetts Bar Association. She is a recipient of the Harvard Medal and has received an award for her work in reducing federal sentences for drug offenders.

Appendix: Biographical Information of Committee and Staff

Thomas D. Schroeder is a U.S. District Judge for the Middle District of North Carolina, having taken his oath of office on January 8, 2008. He served as chief judge from 2017 to 2023. Schroeder attended the University of Cincinnati College-Conservatory of Music and received a B.S. in Business Administration from Kansas University in 1981. He received his J.D. from Notre Dame Law School in 1984 and served as editor-in-chief of the Notre Dame Law Review. Following law school, he served as law clerk for the Honorable George E. MacKinnon of the U.S. Court of Appeals for the District of Columbia Circuit. He then practiced law for more than 22 years with Womble Carlyle Sandridge & Rice, PLLC (now Womble Bond Dickinson [US] LLP), where he handled litigation and trials involving a variety of business and product liability matters, many in the capacity as national counsel and frequently involving expert scientific evidence. Schroeder is an elected member of the American Law Institute. He has served as a vice president of the North Carolina Bar Association (2014–15) and co-chair of its bench/bar liaison committee. From 2017 to 2023, he served on the Federal Rules of Evidence Advisory Committee of the Judicial Conference of the United States and chaired the subcommittee that resulted in the 2023 amendments to Rule 702. He has periodically co-taught a class in pretrial litigation as a senior lecturer at Duke University School of Law and is a member of the boards of directors of the Notre Dame Law Association (president, 2021–23) and the Chief Justice Joseph Branch Inn of Court (president, 2016–18).

David S. Tatel served on the U.S. Court of Appeals for the District of Columbia Circuit from 1994 to 2024, succeeding future U.S. Supreme Court Justice Ruth Bader Ginsburg. After graduating from the University of Michigan and the University of Chicago Law School, he served as the founding director of the Chicago Lawyers' Committee for Civil Rights Under Law and then director of the National Lawyers' Committee. He headed the Office for Civil Rights of the U.S. Department of Health, Education, and Welfare during the Carter administration and then founded and led the education practice at Hogan Lovells, where he is now senior counsel. Tatel, along with Dr. David Baltimore, co-chaired the National Academies of Sciences, Engineering, and Medicine's Committee on Science, Technology, and Law from 2016 to 2023. He also chaired the boards of The Spencer Foundation and The Carnegie Foundation for the Advancement of Teaching. Tatel is a member of the American Philosophical Society and the American Academy of Arts & Sciences. He is the author of *Vision: A Memoir of Blindness and Justice* (Little Brown, 2024).

Staff

Anne-Marie Mazza, Ph.D., is the founding director of the National Academies of Sciences, Engineering, and Medicine's Committee on Science, Technology,

and Law. She has served as the study director on more than 20 National Academies reports on topics ranging from science and national security to governance of academic research and emerging technologies to voting technologies to science and the courts. Mazza was the senior staff director for three international summits on human genome editing and has served as senior director of the Committee on Science, Engineering, Medicine, and Public Policy; the National Science, Technology, and Security Roundtable; and the Christine Mirzayan Science and Technology Policy Fellowship Program. She has also served as a senior advisor to the president of the National Academy of Sciences and the president of the National Academy of Medicine. Mazza served in the White House as executive director of the President's Council of Advisors on Science and Technology (2021–2022) and as a senior policy analyst in the White House Office of Science and Technology Policy (1999–2000). She is a fellow of the American Association for the Advancement of Science. She holds a Ph.D., M.A., and B.A. from The George Washington University.

Elizabeth C. Wiggins, J.D., Ph.D., has been on the research staff of the Federal Judicial Center since 1989 and the director of the Center's Research Division since 2020. Among her areas of study are research methods for the study of legal systems, civil case management, bankruptcy law and procedure, judicial workload measurement, court performance standards and assessment, judicial performance feedback, workplace environment surveys, courtroom technology and digital evidence, and access to justice and self-represented litigants. She has helped numerous international judiciaries undertake empirical work to assess the quality of justice and court administration they deliver. She is a fellow of the American Bar Foundation and of the American College of Bankruptcy. She holds a B.S. in psychology and administration of justice from the University of North Carolina at Chapel Hill, a Ph.D. in social and quantitative psychology from Johns Hopkins University, a J.D. from the University of Maryland Francis King Carey School of Law, and an LL.M. from Vermont Law School. Prior to joining the Center, she was on the faculty at Barnard College of Columbia University and a post-doctoral fellow in quantitative psychology at the Ohio State University.

Joe S. Cecil, J.D., Ph.D., is a senior fellow at the Civil Justice Research Initiative at the University of California, Berkeley School of Law. In 2021, Cecil retired from the Research Division at the Federal Judicial Center. While at the Center, Cecil focused on the role of scientific evidence in federal courts, conducting empirical research projects on expert testimony and admissibility of scientific evidence in civil and criminal litigation and the role of court-appointed experts. He developed the first edition of the *Reference Manual on Scientific Evidence* and has worked with teams of scholars to develop subsequent editions. Cecil was a member of the National Academies of Sciences, Engineering, and Medicine's Committee on Science, Technology, and Law, and has served on several National

Appendix: Biographical Information of Committee and Staff

Academies' committees, including study committees that issued consensus reports on eyewitness identification and forensic science. He received his J.D. and a Ph.D. in psychology from Northwestern University.

Steven Kendall, Ph.D., is a senior program officer for the Committee on Science, Technology, and Law at the National Academies of Sciences, Engineering, and Medicine. He has contributed to numerous National Academies' reports, including *Facial Recognition Technology: Current Capabilities, Future Prospects, and Governance* (2024); *Reflecting Sunlight: Recommendations for Solar Geoen지니어링 Research and Research Governance* (2021); *The Emerging Field of Human Neural Organoids, Transplants, and Chimeras: Science, Ethics, and Governance* (2021); *Securing the Vote: Protecting American Democracy* (2018); *Optimizing the Nation's Investment in Academic Research* (2016); *Identifying the Culprit: Assessing Eyewitness Identification* (2014); *Strengthening Forensic Science in the United States: A Path Forward* (2009); and the third edition of the *Reference Manual on Scientific Evidence* (2011). Dr. Kendall has been a staff officer for the National Academies' National Science, Technology, and Security Roundtable since its inception in 2020. Prior to joining the National Academies in 2007, he worked at the Smithsonian American Art Museum and The Huntington in San Marino, California. He received an M.A. in Victorian art and architecture at the University of London and completed a Ph.D. in the Department of the History of Art and Architecture at the University of California, Santa Barbara.

Jason A. Cantone, J.D., Ph.D. is a senior research associate at the Federal Judicial Center. His Center research addresses scientific evidence, civil rules and litigation, federal and state courts, alternative dispute resolution, and court administration/case management. He has also worked with foreign judiciaries on such topics as the rule of law, judicial education, legal psychology, program evaluation, and mediation. Before joining the Center in 2011, he was a U.S. Air Force civilian at U.S. Strategic Command at Offutt Air Force Base in Nebraska. Outside of his Center role, he is an adjunct professor, represented the American Psychology-Law Society on the American Psychological Association (APA) Council of Representatives from 2017 to 2023, and currently serves on the APA Committee for the Advancement of General and Applied Psychology. Dr. Cantone is an APA Fellow and received an APA Presidential Citation for his work related to the criminal justice system. His non-Center research focuses on psychology and legal decision-making and has been published in numerous social science journals and law reviews. He recently published his first co-edited book through Cambridge University Press: *The Cambridge Handbook of Psychology and Legal Decision-Making* (2024).

Meghan A. Dunn, Ph.D., is a senior research associate at the Federal Judicial Center. Her Center research includes survey construction, shared administrative

services, workplace conduct, and the use of courtroom technology and social media by jurors and attorneys. She has co-authored peer reviewed manuscripts on the use of computer animation and juror decision-making and co-authored a social psychology workbook. As part of her work with the Center, she assisted with previous editions of the *Reference Manual on Scientific Evidence*. Dr. Dunn holds a B.A. in history and psychology from Williams College, and an M.S. and Ph.D. in social psychology from Yale University.

Renee Daly was a senior program assistant with the National Academies of Sciences, Engineering, and Medicine's Committee on Science, Technology, and Law (CSTL). Before coming to CSTL, Daly worked with the Board on Animal Health Sciences, Conservation, and Research (formerly known as the Institute for Laboratory Animal Research) in the National Academies' Division of Earth and Life Studies. She received a master's degree in biotechnology from Johns Hopkins University and a bachelor's degree in biomedical science from Virginia Tech.

Dominic LoBuglio was a senior program assistant in the U.S. Science and Innovation Policy Theme at the National Academies of Sciences, Engineering, and Medicine until February 2023. In addition to his work for the policy theme, LoBuglio provided administrative support for the National Academies of Sciences, Engineering, and Medicine's Committee on Science, Technology, and Law. Prior to joining the National Academies in 2019, LoBuglio developed outreach and science education programs within the fundraising department of the Natural History Museum of Los Angeles County. Previously, he also worked in the science and technology division at the Los Angeles office of the Japan External Trade Organization, a section of the Japanese government's Ministry of Economy, Trade, and Industry. LoBuglio holds a B.A. in Japanese language and culture from the University of California, Santa Barbara.
